Many angiosperm plants, including basal dicots, eudicots, and monocots, emit (E,E)-4,8,12-trimethyltrideca-1,3,7,11-tetraene, which is derived from geranyllinalool, in response to biotic challenge. An Arabidopsis (Arabidopsis thaliana) geranyllinalool synthase (GLS) belonging to the e/f clade of the terpene synthase (TPS) family and two Fabaceae GLSs that belong to the TPS-g clade have been reported, making it unclear which is the main route to geranyllinalool in plants. We characterized a tomato (Solanum lycopersicum) TPS-e/f gene, TPS46, encoding GLS (SIGLS) and its homolog (NaGLS) from Nicotiana attenuata. The $K_m$ value of SIGLS for geranylgeranyl diphosphate was 18.7 μM, with a turnover rate value of 6.85 s⁻¹. In leaves and flowers of N. attenuata, which constitutively synthesize 17-hydroxygeranyllinalool glycosides, NaGLS is expressed constitutively, but the gene can be induced in leaves with methyl jasmonate. In tomato, SIGLS is not expressed in any tissue under normal growth but is induced in leaves by alamethicin and methyl jasmonate treatments. SIGLS, NaGLS, AtGLSs, and several other GLSs characterized only in vitro come from four different eudicot families and constitute a separate branch of the TPS-e/f clade that diverged from kaurene synthases, also in the TPS-e/f clade, before the gymnosperm-angiosperm split. The early divergence of this branch and the GLS activity of genes in this branch in diverse eudicot families suggest that GLS activity encoded by these genes predates the angiosperm-gymnosperm split. However, although a TPS sequence belonging to this GLS lineage was recently reported from a basal dicot, no representative sequences have yet been found in monocot or nonangiospermous plants.

Geranyllinalool is an acyclic diterpene alcohol with a wide distribution in the plant kingdom; it has been identified as component of essential oils of distantly related plant species such as Jasmin grandiflorum, Michelia champica, and Homamelis virginiana (Sandeep, 2009). Geranyllinalool is the precursor of 4,8,12-trimethyltrideca-1,3,7,11-tetraene (TMTT), a volatile C₁₆-homoterpenic alcohol emitted from the foliage of many angiosperm species including Arabidopsis (Arabidopsis thaliana), tomato (Solanum lycopersicum), maize (Zea mays), fava bean (Vicia faba), lima bean (Phaseolus lunatus), alfalfa (Medicago sativa), and Eucalyptus spp. (Van Poecke et al., 2001; Ament et al., 2004; Williams et al., 2005; Hopke et al., 1994; Leitner et al., 2010; Webster et al., 2010). In addition, various hydroxygeranyllinalool glycosides have been isolated from many Solanaceous species such as Capsicum annum, Lycium chinense, and at least 26 Nicotiana species (Yahara et al., 1993; Iorizzo et al., 2001; Snook et al., 1997).

The biosynthetic pathway leading to geranyllinalool, as for all other terpenoids, begins with the condensation of isopentenyl diphosphate and its allylic isomer, dimethylallyl diphosphate. Sequential condensation of one isopentenyl diphosphate molecule with three dimethylallyl diphosphate molecules produces geranylgeranyl diphosphate (GGPP), the C-20 intermediate of the diterpenoid pathway. Next, a terpene synthase (TPS) catalyzes a two-step reaction in which carbocation formation of the C20 precursor is followed by an allylic rearrangement that results in the production of the tertiary alcohol geranyllinalool (Herde et al., 2008).

Although geranyllinalool and its derivatives, TMTT and geranyllinalool glycosides, have been reported in a wide variety of plant species, a geranyllinalool synthase (GLS) involved in TMTT biosynthesis was only recently identified in Arabidopsis (Herde et al., 2008). AtTPS04 belongs to the TPS-e/f subfamily along with the previously identified Clarkia spp. linalool synthases (Chen et al., 2011). More recently, two TPSs from Vitis...
and Phaseolus lunata, also members of the TPS-e/f subfamily, were found to exhibit GLS activity in vitro (Martin et al., 2010; Zerbe et al., 2013). However, no in planta information has been presented for these, nor any evidence showing their involvement in TMTT biosynthesis.

The common characteristic of the TPS-e/f GLSs so far identified is that they lack a predicted plastidial transit peptide, and direct evidence for nonplastidial localization was obtained in Arabidopsis by observing the AtTPS04-GUS fusion protein in the cytosol and endoplasmic reticulum (Herde et al., 2008). On the other hand, two TPS-g subfamily proteins from the closely related Fabaceae species Medicago truncatula and Phaseolus lunata (MtTPS03 and PitTPS2, respectively) were shown to be plastidic and to catalyze the formation of geranyllinalool in vitro when GGPP was provided as a substrate and also when expressed in a heterologous plant species (Arimura et al., 2008; Brillada et al., 2013). However, the same enzymes also produced linalool and nerolidol when supplied with geranyl diphosphate (GPP) and farnesyl diphosphate (FPP), respectively (Arimura et al., 2008; Brillada et al., 2013). Given the present paucity of in vivo and in vitro studies of geranyllinalool biosynthesis in plants, it is not clear whether geranyllinalool in plants is typically produced via TPS-g or TPS-e/f type TPSs, or both.

The role of geranyllinalool itself in plant tissues is not well established. Often geranyllinalool coexists in floral or vegetative tissues with its homoterpene derivative TMTT. The contribution of TMTT to the floral scent of insect-pollinated species suggests a putative role in attraction of pollinators (Tholl et al., 2011). On the other hand, in many angiosperm species, including tomato, TMTT is a component of volatile blends released from vegetative tissues upon herbivore attack, sometimes in parallel with its constitutive emission from floral tissues (Hopke et al., 1994; Ament et al., 2004; de Boer et al., 2004; Kant et al., 2004; Williams et al., 2005, Herde et al., 2008). The latter case suggests that TMTT might play a defensive role in both vegetative and floral tissues. TMTT production from insect-infested plants is considered as an indirect defense mechanism because TMTT attracts insect predators of the insect herbivores (Brillada et al., 2013). Interestingly, production of TMTT, and the homoterpene (E)-4,8-dimethyl-1,3,7-nonatriene, from herbivore-attacked lima bean plants has been found to correlate with enhanced expression of defense genes in neighboring nonaffected control plants (Arimura et al., 2000). In these cases, homoterpenes are believed to act as stress-responsive signals that enable intraspecies plant-to-plant communication.

A plant defense role has also been suggested for 17-hydroxygeranyllinalool diterpene glycosides (HGL-DTGs) present in leaves and flowers of Nicotiana species, with higher concentrations measured in buds (Heiling et al., 2010; Jassbi et al., 2010). Several studies have found negative correlation between total leaf HGL-DTG content and the mass of the larvae that feed on them (Jassbi et al., 2008; Dinh et al., 2013). Eleven HGL-DTGs that differ in sugar moieties and number of malonyl esters have been isolated from Nicotiana attenuata. The sugar groups of these compounds are Glc and rhamnose and are conjugated to the hydroxygeranyllinalool skeleton via bonds at C3 and C17 hydroxylated carbons. Additional sugars may be added to these sugars on their hydroxyl groups at C2, C4, and C6, and malonyl esters are typically formed at the C6 hydroxyl group of the glucose. The concentrations of these HGL-DTGs are higher in young and reproductive tissues. While their total levels appear to be constant, the concentration of individual compounds change upon herbivore attack, with a proportionally greater increase in malonylated compounds. Unlike many other defense-related specialized metabolites, the N. attenuata HGL-DTGs are not found on the leaf surface or the trichomes, but, instead, they accumulate inside the leaves (Heiling et al., 2010).

Here, we show that in the Solanaceae species cultivated tomato and N. attenuata, geranyllinalool is synthesized by TPSSs that belong to the TPS-e/f subfamily and that the corresponding genes are related to Arabidopsis TPS04. The tomato and N. attenuata enzymes were biochemically characterized, and the kinetic parameters were determined. We also describe a detailed quantitative expression of these genes in different parts of the plant. In addition, we establish that the expression of the geranyllinalool synthase genes correlates well with the induced emission of TMTT in tomato leaves after alamethicin and methyl jasmonate (MeJA) treatments and with the total concentrations of HGL-DTGs in N. attenuata leaves and floral organs.

RESULTS

Tomato TP546 Encodes GLS

In a previous study, we identified 44 TPS genes in the genome of tomato, of which 29 were shown or predicted to encode functional enzymes (Falara et al., 2011). Although tomato plants were previously shown to make geranyllinalool (Ament et al., 2006), a GLS could not be identified among these 29 genes based on pattern of expression or in vitro enzymatic activity (Falara et al., 2011). However, a search of an updated version of the tomato genome sequence from 2011 (http://solgenomics.net/organism/Solanum_lycopersicum/genome) identified an additional TPS gene on chromosome 3, which we named TP546 (TP545 is a gene found in Solanum habrochaites but not in tomato; Matsuba et al., 2013). TP546 encodes a protein of 818 amino acids that belongs to the TPS-e/f clade and is 39% identical to Arabidopsis GLS, a higher identity level than its level of identity to any other tomato TPS protein (Fig. 1; Supplemental Fig. S1). The sequence of the N terminus of the tomato TP546 protein (SitTPS46) is similar to that of AtGLS (Fig. 1), suggesting that it too does not have a transit peptide, and no transit peptide is predicted by SignalP. However, SitTPS46 has an internal deletion of
Figure 1. Alignments of TPS-e/f proteins with experimentally demonstrated GLS activity and several additional TPS sequences from *P. inflata*, *N. benthamiana*, *N. attenuata*, and potato with high sequence identity to SlGLS. The deletions in the tomato and tobacco sequences in the γ-domain are outlined. Accession numbers of these proteins are as follows: *At* (*Arabidopsis thaliana*), Q93YV0; *Sl* (*Solanum lycopersicum*), KJ755870; *St* (*Solanum tuberosum*), KJ755872; *Pi* (*Petunia inflata*), KJ755871; *Na* (*Nicotiana attenuata*), KJ755868; *Nb* (*Nicotiana benthamiana*), KJ755869; *Gh* (*Grindelia hirsutula*), AGN70888; *Vv*1 (*Vitis vinifera*1), NP_001268201; and *Vv*2 (*Vitis vinifera*2), NP_001268004. [See online article for color version of this figure.]
42 amino acids relative to AtGLS (Fig. 1). This deletion is at the γ domain (Köksal et al., 2011) in the N-terminal half of the protein (amino acid positions 205–246 in the Arabidopsis TPS04 protein).

It was previously shown that treating detached Arabidopsis leaves with the fungal peptide alamethicin from the fungus Trichoderma viride led to induction of AtGLS and TMTT emission (Herde et al., 2008). To test whether alamethicin also induces TMTT emission in tomato, we placed the petioles of detached tomato leaves in water solution containing alamethicin for 24 h and observed that TMTT was emitted, whereas no TMTT emission was observed in detached leaves that were placed in water only for 24 h or in leaves that were just detached from the stem (Fig. 2). This experiment also confirmed that the major terpene volatiles from the leaf are 2-carene, β-phellandrene, germacrene, β-caryophyllene, and α-humulene, which are known to be produced mostly in the trichomes by TPS20, TPS9, and TPS12 (Schilmiller et al., 2010; Falara et al., 2011). We next measured the levels of transcripts of each of the 30 active tomato TPS genes in leaves treated with alamethicin by reverse transcription (RT)-PCR with pairs of specific primers and compared the results to the levels of the respective transcripts in leaves treated with water only for 24 h or in leaves from which RNA was isolated immediately after detachment. Alamethicin induced the expression of several tomato TPS genes to some degree, although some of them already showed expression in the two control samples (Fig. 3). However, all the TPS genes showing any level of induction by alamethicin, with the exception of TPS46, encode proteins that have been previously characterized, with none of them active with GGPP (Falara et al., 2011). TPS5, TPS7, and TPS8 encode monoterpenes synthases of the TPS-b clade, TPS17 is a sesquiterpene synthase of the TPS-a clade, and TPS20 and TPS21 are, respectively, monoterpenes and diterpene synthases of the TPS-e/f clade, and neither one uses GGPP as a substrate or produces geranyl-linalool (Falara et al., 2011; Matsuba et al., 2013). We also observed the induction of TPS37, a member of the TPS-g clade, but its protein has also been previously characterized and shown to catalyze the formation of linalool from GPP and nerolidol from FPP and to have no activity with GGPP (Falara et al., 2011).
The activity of SlGLS were determined with GGPP and FPP (Table I). Incubation with GPP did not give any product. The kinetic parameters of the production of nerolidol (Fig. 4, B and C). Incubation of SlTPS46 with FPP led to the production of one major terpenoid product and had an identical mass spectrum to the standard (GC)-mass spectrometry (MS). Incubation with GGPP resulted in the production of NaGLS, which we designated as NaGLS (Fig. 1; Supplemental Fig. S1). The NbGLS and NaGLS encode proteins that are 87% identical to each other, and they fall into the TPS-e/f clade, the same clade as SlTPS46, to which they show 66.7% and 67.5% identity, respectively (Figs. 1 and 5). The two Nicotiana spp. GLS proteins do not contain the internal deletion found in SlTPS46 (Fig. 1). The NaGLS protein was produced in E. coli with an N-terminal His-tag, purified (Fig. 4D), and tested for activity with GGPP, FPP, and GPP. GC-MS analysis of the reaction products indicated that NaGLS had activity only with GGPP (Fig. 4, D and E). The $K_m$ value of NaGLS for GGPP was 31.5 ± 4.1 μM, with a $K_{cat}$ of 7.53 ± 0.9 s$^{-1}$ (Table I).

**SIGLS Transcript Levels under Normal Conditions and after Treatments with Alamethicin, MeJA, and MeSA**

Although tomato leaf GLS enzymatic activity was previously shown to be inducible by MeJA treatment (Ament et al., 2006), transcripts of SIGLS were not previously reported in EST databases, suggesting a very low level of expression under our regular growth conditions. Analysis of SIGLS transcript levels in tomato plants grown in the growth room without insect challenge found extremely low levels of such transcripts in all tissues (Fig. 6A). Alamethicin treatment of detached leaves for 48 h showed peak transcript levels after 24 h, corresponding with peak TMTT emission (Fig. 6B). Treatment of intact leaves with MeJA led to a similar pattern of increases in transcript levels and TMTT emission, peaking at 24 h after the start of the treatment (Fig. 6C). No induction of SIGLS transcripts was observed after methyl salicylate (MeSA) treatment (Fig. 6D).

To determine if TMTT emission came primarily from trichomes or the rest of the leaf tissue, we treated detached leaves with alamethicin for 24 h, removed the trichomes or the rest of the leaf tissue, we treated detached leaves with alamethicin for 24 h, and leaves treated with alamethicin solution for 24 h as described in the Figure 2 legend. RT-PCR of actin transcripts was also carried out for control.

Conversely, TPS46 showed clear induction by alamethicin treatment and not by water treatment alone. We therefore synthesized the complete open reading frame of SlTPS46 recoded for optimal expression in *Escherichia coli* and inserted it into the expression vector PEXP5-NT-TOPO to create a fusion protein with an N-terminal His-tag. His-tagged SlTPS46 was purified from *E. coli* cells by affinity purification (Fig. 4A) and used for in vitro enzyme assays with various substrates, after which products were extracted and analyzed by gas chromatography (GC)-mass spectrometry (MS). Incubation with GGPP resulted in the production of one major terpenoid product that comigrated with an authentic geranylgeranilalool standard and had an identical mass spectrum to the standard (Fig. 4, B and C). Incubation of SlTPS46 with FPP led to the production of menthylalool (Fig. 4, B and C). Incubation with GPP did not give any product. The kinetic parameters of SIGLS were determined with GGPP and FPP (Table I). The $K_m$ value for GGPP was 18.7 μM with a turnover rate ($K_{cat}$) of 6.85 s$^{-1}$, and for FPP, the corresponding values were 63.7 μM and 0.43 s$^{-1}$. Overall, SIGLS was 55-fold more efficient with GGPP than with FPP (Table I).

**Nicotiana benthamiana and N. attenuata Have TPS Genes Encoding Proteins with High Similarity to SlTPS46**

We examined the recently released genome sequence of *N. benthamiana* and identified a single gene encoding a protein with high similarity to SlTPS46 (Fig. 1), which we designated as NbGLS. Because a detailed analysis of the presence and concentration of glycosylated geranylgeranilalool derivatives was performed on *N. attenuata* (Heiling et al., 2010), we use the sequence of NbGLS to isolate a full-length complementary DNA (cDNA) of the corresponding gene from this species, which we designated as NbGLS (Fig. 1; Supplemental Fig. S1). The $K_m$ value for GGPP of NbGLS was 18.7 μM, which is consistent with the $K_m$ value for GGPP of SlTPS46 (Table I).
without trichome showed a slightly higher level of induction, consistent with an additive effect of the alamethicin and physical damage elicitors. Isolated trichomes from treated leaves showed about 20-fold increase (Fig. 7A).

Measurements of TMTT emission from treated whole leaves and from treated leaves after their trichomes were removed showed that TMTT emission levels were only slightly lower after the trichomes had been removed (Fig. 7B). Overall, these results indicate that SlGLS is expressed and induced in both trichomes and nontrichome leaf cells and that TMTT is produced in both cell populations. However, because trichome cells in tomato constitute only a small portion of the total mass of the leaf, it must be concluded that the majority of TMTT emission comes from nontrichome leaf cells.

To further explore the response of SlGLS to herbivory attack, intact tomato plants were challenged with two different spider mite lines, *Tetranycus urticae* Santpoort-2, a benchmark defense-inducing line (Kant et al., 2008), which induces TMTT emission in tomato (Ament et al., 2004), and *Tetranycus evansi* Vicosa-1, a benchmark defense-suppressing line, which does not induce TMTT emission in tomato (Sarmento et al., 2011). SlGLS transcript levels were measured at 1, 4, and 7 days post-attack.

**Figure 4.** GC-MS analysis of hexane-extracted products formed from GGPP by recombinant His-tagged SlTPS46 (GLS). A, Affinity purification of the 97-kD His-tagged SlTPS46 on Nickel-agarose column. B, Peak 1 was identified as the only product with GGPP as the substrate, and peak 2 was the only product with FPP as the substrate (minor peaks are not terpenoids). The retention time of peak 1 is identical to that of an authentic geranyllinalool standard, and the retention time of peak 2 is identical to that of an authentic nerolidol standard. An assay with boiled GLS incubated with GGPP served as a negative control. C, Mass spectrum of peak 1 was identical to the mass spectrum of the geranyllinalool standard, and the mass spectrum of peak 2 was identical to the mass spectrum of the nerolidol standard. D, Affinity purification of the 100-kD His-tagged NaGLS on Nickel-agarose column. E, Peak 1 was identified as the only product with GGPP as the substrate (minor peaks are not terpenoids). The retention time of peak 1 is identical to that of an authentic geranyllinalool standard. An assay with boiled GLS incubated with GGPP served as a negative control. F, Mass spectrum of peak 1 was compared with and found identical to the mass spectrum of the geranyllinalool standard. $m/z$, Mass-to-charge ratio.
7 d after mite infestation. SIGLS transcript levels were already substantially and significantly increased after only 1 d with the defense-inducing spider mite line, reaching a 59-fold induction 7 d after the initiation of the infestation. Conversely, defense-suppressing mites had no effect on SIGLS transcript levels after 1 d and only minor effects after 4 and 7 d (Fig. 8A). To investigate whether the higher and lower GLS transcript levels correlated with TMTT production, we also collected the headspace of spider mite-infested and control tomato plants. Infestation with the defense-inducing spider mite line resulted in increased TMTT production, whereas the defense-suppressing mites had no effect on TMTT levels (Fig. 8B).
NaGLS Transcript Levels Are Constitutively High in N. attenuata Flowers and Are Elevated in Leaves by MeJA Treatment

Previous investigations showed that levels of HGL-DTGs are constitutively present in buds and flowers of N. attenuata and, to a lower extent, in leaves found on the stem and that this species does not emit TMTT (Heiling et al., 2010). We examined the transcript levels of NaGLS in different parts of the plant (Fig. 9A) and found that they were highest in reproductive organs, which show the highest levels of HGL-DTGs, and next highest in stem leaves, which have the second-highest levels of HGL-DTGs (Heiling et al., 2010), thus showing a positive correlation, although not exactly proportional, with HGL-DTGs biosynthesis. We also examined the changes in transcript levels upon MeJA and MeSA treatments of rosette and stem leaves. Rosette leaves, which have very low levels of NaGLS transcript under unchallenged conditions, exhibited approximately 100-fold increase after 24 h of treatment with MeJA, whereas stem leaves, which have 30-fold higher levels of NaGLS transcript levels compared with the levels of NaGLS transcripts in rosette leaves in the unchallenged conditions, exhibited just about a 2-fold increase after 24 h of MeJA treatment (Fig. 9B). Treatment with MeSA resulted in no increase in NaGLS transcript levels in both types of leaves (Fig. 9C).
DISCUSSION

**SlTPS46 Encodes GLS**

We previously demonstrated that a total of 44 TPS genes could be found in the version of the tomato genome sequence released in 2010, of which 29 were shown or predicted to encode functional enzymes (Falara et al., 2011). Only three of the tomato TPS enzymes characterized to date were found to be diterpene synthases, including the two TPS enzymes involved in GA biosynthesis, copalyl diphosphate synthase (CPS) and kaurene synthase (KS; Falara et al., 2011), and TPS21, which uses neryl diphosphate to make a cyclic diterpene (Matsuba et al., 2013). However, the presence of the specialized linear diterpene metabolite geranyllinalool (which could be enzymatically converted to TMTT) had been reported in tomato, together with an enzymatic activity that uses GGPP to catalyze the formation of geranyllinalool (Ament et al., 2006). Thus, the identity of the TPS gene encoding GLS was unresolved.

A recently updated tomato genome sequence (http://solgenomics.net/organism/Solanum_lycopersicum/genome) contains a previously unavailable TPS sequence on chromosome 3 that encodes a protein with similarity to Arabidopsis GLS (Figs. 1 and 5). Because alamethicin is a known inducer of Arabidopsis GLS and of TMTT emission and it also induces TMTT emission in tomato (Fig. 2), we used it to determine which of the tomato TPS genes encode GLS. Levels of transcript accumulation of all functional tomato TPS genes, including the newly identified *SlTPS46* (a TPS45 gene is found in *S. habrochaites* but not in tomato), were measured in leaf tissue after 24 h of alamethicin treatment and compared to levels in nontreated leaves (Fig. 3). Some genes showed increase transcript accumulation following alamethicin treatment, but none of these genes, with the exception of *SlTPS46*, encoded proteins that can use GGPP as a substrate (Falara et al., 2011). On the other hand, *SlTPS46*, a gene highly similar to AtTPS04, showed strong induction with alamethicin (Figs. 4 and 7), and the purified recombinant TPS46 exhibited GLS activity when given GGPP as a substrate. Its $K_m$ value for GGPP was 18.7 $\mu$M, and its $K_{cat}$ value was 6.85 s$^{-1}$ (Table I). SIGLS also exhibits some activity with FPP, catalyzing the formation of nerolidol, but its efficiency with GGPP was 55-fold higher than with FPP (Table I). It had no activity with GPP. To the best of our knowledge, no kinetic parameters have been reported for previously identified GLSs. Thus, our data identified *SlTPS46* as encoding GLS; however, in the absence of a mutant line defective in *SlTPS46*, we cannot rule out the possibility that the tomato genome has additional gene(s) encoding GLS activity.

![Figure 7](image-url)
Interestingly, SlGLS has a deletion of 42 amino acids in its $\gamma$ domain in the N terminus. This domain is usually not active in Type I diterpene synthases that use GGPP to directly make a diterpene olefin without a copalyl disphosphate intermediate, although it is often conserved in these enzymes for unknown reasons (Hillwig et al., 2011). A very closely related sequence from potato (*Solanum tuberosum*), a species in the same genus as tomato, also has a similar (but slightly shorter) deletion at this position, but *N. attenuata* GLS and related sequences from *N. benthamiana* and *Petunia inflata* (all in family Solanaceae) do not. The N termini of all of these proteins, including SIGLS, coincide with the N terminus of AtGLS, which was shown to have no transit peptide and to be localized in the cytosol. It is therefore likely that tomato GLS is located in the cytosol.

**SIGLS and NaGLS Have Very Different Expression Characteristics**

Our analyses of the expression of GLS in tomato and *N. attenuata* showed that whereas SIGLS is strictly inducible in response to cues of biotic challenge (Figs. 7–9), NaGLS is constitutively expressed in flowers and, to a lower degree, in leaves (Fig. 9), consistent with previous reports showing the presence of HGL-DTGs in these organs (Heiling et al., 2010). However, some induction in *N. attenuata* leaves was observed upon MeJA treatment, with a higher fold induction in rosette leaves, whose constitutive level of expression was much lower than in the stem leaves. We previously showed that attack by the generalist spider mite *T. urticae* Santpoort-2 on tomato induces jasmonate responses and causes emission of TMTT (Kant et al., 2008), thereby augmenting the plant’s attractiveness to predatory mites, the spider mite’s natural enemy (Ament et al., 2004). Here, we show that during such an interaction between *T. urticae* Santpoort-2 and tomato, the levels of steady-state SIGLS transcripts as well as TMTT emission were greatly increased, suggesting that the increase in TMTT emission is partially determined by pretranslational regulation (Fig. 8, A and B). When the tomato specialist *T. evansi* Viçosa-1 was feeding on the plants, the increase in steadystate level of SIGLS transcripts was approximately 8-fold lower compared with *T. urticae* Santpoort-2 infestation, and no increase in TMTT emission was observed (Fig. 8, A and B), consistent with previous results showing that *T. evansi* Viçosa-1 suppressed jasmonate responses in tomato leaves.
and that their infestation of tomato did not lead to TMTT production (Sarmento et al., 2011). We note that in the experiments measuring TMTT emission (Fig. 8B), one of the control plants emitted some TMTT, but the other two had undetectable levels of TMTT emission. While the outlier control plant raised the average of TMTT emission for the control group, analysis showed that there was no statistically significant difference in emission between the control plants and plants infested with T. evansi Viçosa-1.

Overall, the function of GLS in both species appears to be related to defense. However, the end products, TMTT in tomato and HGL-DTGs in N. attenuata, appear to have different functions. HGL-DTGs are non-volatile compounds that are toxic to the native insect herbivores, including the larvae of the specialist tobacco hornworm (Manduca sexta; Heiling et al., 2010). TMTT, on the other hand, is a volatile that has been shown in tomato and other plant species to be emitted under insect attack and thereby attract insect predators of the herbivorous insects (Kant et al., 2004; Brillada et al., 2013). Thus, while the gene encoding the enzyme GLS appears to have been present in their common ancestor, the South American species tomato and the western North American species N. attenuata evolved the ability to make different end products from geranylinalool, likely the result of selection exerted by local herbivores. Our results underscore the role that contingency and chance play in the evolution of new biochemical pathways.

Cytosolic GLSs Constitute a Deep Branch of the TPS-e/f Clade of the TPS Family

TMTT emission has so far been reported from basal dicot families, eudicots, and monocots but not from any plant species outside the angiosperms (Tholl et al., 2011). To date, all experimentally demonstrated GLS enzymes have been characterized only from eudicot angiosperms, and five of these seven proteins, found in four different families, belong to the TPS-e/f clade, while the others, two closely related sequences from M. truncatula and P. lunatus (both in Fabaceae), belong to the TPS-g clade. The TPS-g clade originated within the angiosperms, and it contains mostly mono- and sesquiterpene synthases (Chen et al., 2011), including SlTPS37, which is inducible by alamethicin (Fig. 3) and encodes a protein that catalyzes the formation in vitro of linalool from GPP and nerolidol from FPP but is inactive with GGPP (Falara et al., 2011). It is therefore likely that the reported M. truncatula and P. lunatus GLSs evolved their ability to make geranylinalool from GGPP only recently and perhaps their main role lies elsewhere, because they are more efficient in catalyzing the formation of nerolidol from FPP and linalool from GPP (Arimura et al., 2008; Brillada et al., 2013).

The GLSs of the TPS-e/f clade, on the other hand, form a deep branch in this clade that diverged from the KS lineage before the split between the gymnosperms...
and the angiosperms. Thus, the KS gene lineage has been shown that 

-kaurene itself is emitted from 

Terpenes and sesquiterpenes, but microbial TPS-like enzymes) that specify the production of mono-

This gene is believed to be ancestral to the entire plant

Characterization of SITPS46 and NaGLS

Full-length cDNA for SITPS46 were obtained by RT-PCR amplification with gene-specific primers (Supplemental Table S1) based on genomic DNA sequences with degenerate primers. The reaction was performed with a DNA reverse transcriptase and RT reaction buffer from the DesignScript (Invitrogen). PCR amplification was performed with the KOD DNA polymerase (Novagen) and the following PCR conditions: 2 min at 95°C and then 20 s at 95°C, 10 s at 58°C, and 30 s at 68°C for 30 cycles. For NaGLS amplification, degenerate primers (Supplemental Table S1) were designed based on the Nicotiana benthamiana genome sequence and used to amplify a 500-bp fragment from cDNA prepared from N. benthamiana leaves. Next, gene-specific primers (Supplemental Table S1) were designed and used for 5' and 3' RACE amplification experiments using the BD SMART RACE cDNA amplification kit according to the manufacturer's instructions. For SITPS46, a full-length cDNA version of the DnAP was synthesized (Genscript) to achieve higher expression levels in Escherichia coli. The open reading frame was amplified using primers T4El/T4Er and inserted into pEFPX-NF/TOPo to be fused to a N-terminal His-tag according to the manufacturer's instructions (Invitrogen). A recombinant version of NaGLS was also synthesized by Genscript for expression in E. coli and spliced into pACYC-Duet-1 (Novagen), fused in frame to an N-terminal His-tag coding region.

SITPS46 and NaGLS Expression in E. coli and Affinity Purification

E. coli BL21-plysS cells (Invitrogen) containing the plasmids pEFPX-NF-TOPo were grown in Luria-Bertani medium containing the appropriate anti-

Materials and Methods

Plant Growth and Treatment Conditions

Seeds of tomato (Solanum lycopersicum) were obtained from the Tomato Genetic Resource Center (http://tgrc.ucdavis.edu). When not specifically indic-

Biotic Stresses

Spider mite Tetramychus urticae Sandport-2 (Cytochrome C oxidase subunit I-sequence KF447575 in GeneBank) was described previously by Kant et al. (2008), where it was referred to as line KMB and has been propagated on detached leaves of Phaseolus vulgaris 'Speedy' in a climate room at 25°C and a 16-h/8-h light regime with 300 μE m⁻² s⁻¹ and 60% relative humidity. Spider mite Tetramychus evansi Viçosa-1 (Cytochrome C oxidase subunit I-sequence KF447575 in GeneBank) was described previously by Sarmento et al. (2011) and has been propagated on detached leaves of tomato 'Castlemart' under the same conditions. Twenty-one-day-old tomato plants were infested with 45 adult female mites as described in Kant et al. (2004). Total RNA was isolated with a phenol-LiCl-based method and treated with Turbo-DNAase (Ambion). Subsequently, 2 μg of the DNA-free samples was used for cDNA synthesis using M-MulV RT (Fermentas) as a template for quantitative PCR (qPCR) using the Platinum SYBR Green qPCR-Mix-UDG Kit (Invitrogen) in the ABI 7900 Real-Time PCR System (Applied Biosystems). The cycling program was set to 45 cycles of 15 s at 95°C and 1 min at 60°C, followed by a melting curve analysis. The normalized expression (NE) data were calculated as follows: \( NE = \frac{1}{PE_{target}} \cdot \frac{1}{PE_{reference}} \cdot \frac{1}{Ct_{target}} \), where PE refers to primer efficiency and Ct refers to cycle threshold. The primer efficiencies were determined by fitting a linear regression line on the cycle threshold values of a standard cDNA dilution series. NE of each target gene was compared per time point independently using a generalized linear model (γ error distribution and logarithmic as link function). The model included spider mite strain as factor, the technical replicate for each reaction. A nested to biological replicate and included as nested factor. Means of each groups were contrasted by Fisher's LSD post hoc test using PASW Statistics 17.0.

The volatiles in the headspace of control and spider mite-infested plants were collected and analyzed according to Ament et al. (2010) with the following modifications: volatiles were trapped on 5-mm-wide glass tubes filled with 100 mg of Porapak Q/100 mesh (Supelco); compounds were separated on a capillary HP-5MS column (5%-Phenyl)-methylpolysiloxane; 30 m × 250 μm × 0.25 μm; Agilent 6890 GC, 6850 N GC, columns, (http://www.chrom.agilent.com) with the temperature of the GC oven set to 40°C for 3 min, after which the temperature was raised to 250°C at 10°C per min and the column flow was 1.2 mL of He per min. Mass spectra of the eluting compounds were collected on an Agilent 7200 Q-TOF MS, with an acquisition rate of 20 spectra s⁻¹. TMTT was identified and quantified on the basis of pure TMTT after normalization to the internal standard (benzyl acetate). Differences in volatile production between treatments and control were tested with a general linear model (log transformed) with replicates as a random factor, followed by LSD posthoc test.

SITPS46 and NaGLS Enzymatic Assays

Elution buffer containing the purified His-tagged SITPS46 or NaGLS protein was exchanged with assay buffer containing 50 mM HEPES, 7.5 mM MgCl₂, 5 mM KCl, 5 mM dithiothreitol, and 10% (v/v) glycerol, pH 7.0, using Ultracel 30K centrifugal filters (Amicon Ultra). The enzyme reactions contained 40 μM of partially purified protein in assay buffer and 60 μM prenyl diphosphate substrates: GPP, FPP, and GGPP (Echelon Biosciences).

GC-MS Analyses

Volatiles were collected by solid phase micro extraction (SPME) or by hexane extraction as described in Falara et al. (2011). Samples were injected into an EC-WAX column (Grace Davison; 30-m length, 0.25-μm film thickness, and 0.32-mm i.d.) on a GC17-A (Shimadzu) coupled to a QP-5000 GC-MS system. Injector temperature was 220°C and working on splitless mode. Interface temperature was 280°C. The temperature program was as follows: 44°C for 3.5 min, 5°C min⁻¹ up to 280°C, 70°C min⁻¹ up to 275°C, and hold for 1 min. Solvent extractions were done with methyl tert-butyl ether containing tetradecane as internal standard. In the case where SPME fiber was used for extraction, the tissue was exposed to the fiber in a 2-ml glass vial for 15 min at 42°C.

Gene Expression Analyses

Expression Analysis of Tomato TPS Genes Performed by RT-PCR

Total RNA was isolated with the RNeasy Kit (Qiagen), treated with the DNA-free kit (Ambion) to remove genomic DNA contamination, and used for first-strand cDNA synthesis using SuperScript II reverse transcriptase and oligo(dT)₁₂–₁₅ primer (Invitrogen) according to the manufacturer’s protocol. PCR amplification was performed with GoTaq Green Master Mix (Promega) using an initial denaturation step for 2 min at 94°C, followed by denaturation for 30 s at 94°C, annealing for 30 s at 68°C, extension for 30 s at 72°C, and a final extension of 5 min for 30 cycles. Tomato TPS gene-specific primers and actin primers used can be found in Falara et al. (2011). Reactions were done with RNA isolated from three identical experiments.

Expression Analysis of SITPS46 and NaGLS Performed by Quantitative RT-PCR

Total RNA extraction and first-strand cDNA synthesis were performed as mentioned above. The resulting cDNA was diluted 10-fold, and 1 μl was used as a template for PCR amplification in a 30-μl reaction using Power SYBR Green PCR master mix (Applied Biosystems) and gene-specific primers (Supplemental Table S1). Reactions were performed with the StepOnePlus Real-Time PCR System (Applied Biosystems) with the following cycles: 95°C for 10 min, followed by 40 cycles of 95°C for 15 s and 60°C for 1 min. A final dissociation step was performed to assess the quality of the amplified product. Relative expression levels of SITPS46 and NaGLS in various organs and in leaf tissues under various treatments were calculated by using the relative quantification method normalized to the expression levels of tomato EF1α (GenBank accession no. X14449). Measurements were done by triplicates on RNA isolated from each of three independent experiments.

Sequence data from this article can be found in the GenBank/EMBL data libraries under accession numbers KJ753586, KJ753589, KJ7535870, KJ7535871, and KJ7535872.

Supplemental Data

The following materials are available in the online version of this article.

Supplemental Figure S1. Sequences of SITPS46 and NaGLS.

Supplemental Figure S2. A phylogenetic tree of GLS protein sequences and biochemically characterized and uncharacterized sequences that fall inside the GLS clade.

Supplemental Table S1. A list of the oligonucleotide primers used in this work.

ACKNOWLEDGMENTS

We thank Dr. Ian T. Baldwin for providing seeds of N. attenuate and Drs. Yuki Matsuoka and Reza Sohrabi for logistics help with some of the experiments.

Received June 1, 2014; accepted July 21, 2014; published July 22, 2014.

Supplemental Figure 2. A phylogenetic tree of GLS protein sequences and biochemically characterized and uncharacterized sequences that fall inside the GLS clade. These sequences come from species in diverse eudicot families and a basal dicot, *Amborella trichopoda*, but none have been found in monocots or non-angiospermous plants. For each sequence, the name of the species it comes from and the accession number of the corresponding protein are provided, as well as the enzymatic function when characterized (GLS: geranylinalool synthase; LIN: linalool synthase). Phylogenetic analysis was conducted using the MAFFT algorithm (Katoh et al., 2013). Kaurene synthase (KS) protein sequences from *S. lycopersicum*, *Oryza sativa*, and *Picea glauca* serve as the outgroup.
