Abstract A search is presented for direct top squark pair production using events with at least two leptons including a same-flavour opposite-sign pair with invariant mass consistent with the $Z$ boson mass, jets tagged as originating from $b$-quarks and missing transverse momentum. The analysis is performed with proton–proton collision data at $\sqrt{s} = 8$ TeV collected with the ATLAS detector at the LHC in 2012 corresponding to an integrated luminosity of 20.3 fb$^{-1}$. No excess beyond the Standard Model expectation is observed. Interpretations of the results are provided in models based on the direct pair production of the heavier top squark state ($\tilde{t}_2$) followed by the decay to the lighter top squark state ($\tilde{t}_1$) via $\tilde{t}_2 \rightarrow Z\tilde{t}_1$, and for $\tilde{t}_1$ pair production in natural gauge-mediated supersymmetry breaking scenarios where the neutralino ($\tilde{\chi}^0_1$) is the next-to-lightest supersymmetric particle and decays producing a $Z$ boson and a gravitino ($\tilde{G}$) via the $\tilde{\chi}^0_1 \rightarrow Z\tilde{G}$ process.

1 Introduction

Supersymmetry (SUSY) [1–9] is an extension of the Standard Model (SM) which predicts new bosonic partners for the existing fermions and fermionic partners for the known bosons. In the framework of a generic $R$-parity conserving minimal supersymmetric extension of the SM (MSSM) [10–14], SUSY particles are produced in pairs and the lightest supersymmetric particle (LSP) is stable, providing a possible dark matter candidate.

In a large variety of models, the LSP is the lightest neutralino ($\tilde{\chi}^0_1$) which is a mixture of the neutral supersymmetric partners of the gauge and Higgs bosons, known as gauginos and higgsinos. Similarly, charginos are a mixture of the charged gauginos and higgsinos, with the lightest denoted by $\tilde{\chi}^\pm_1$. The scalar partners of right-handed and left-handed quarks, $\tilde{q}_R$ and $\tilde{q}_L$, mix to form two mass eigenstates, $\tilde{q}_1$ and $\tilde{q}_2$, with $\tilde{q}_1$ defined to be the lighter of the two. Naturalness arguments [15,16] imply that the supersymmetric partners of the top quark (stops) are light, with mass below 1 TeV.

Searches for direct pair production of the $\tilde{t}_1$ have been performed by the ATLAS [17–22] and CMS [23–26] collaborations. These searches with $t\tilde{t}$ currently have little sensitivity to scenarios where the lightest stop is only slightly heavier than the sum of the masses of the top quark and the LSP, due to the similarities in kinematics with SM top pair production ($t\bar{t}$). In those scenarios, by considering instead the direct pair production of the heavy stop ($\tilde{t}_2$) decaying via $\tilde{t}_2 \rightarrow Z\tilde{t}_1$, stop signals can be discriminated from the $t\bar{t}$ background by requiring a same-flavour opposite-sign (SFOS) lepton pair originating from the $Z$ boson decay. Requiring a third lepton, that in signal events can be produced from the top quark in the $\tilde{t}_1 \rightarrow t\tilde{\chi}^0_1$ decay, can further reject $t\bar{t}$. Sensitivity to direct $\tilde{t}_2$ pair production can be obtained with this three-lepton signature even in models where additional decay modes of the $\tilde{t}_2$, such as $\tilde{t}_2 \rightarrow t\tilde{\chi}^0_1$ or via the lightest Higgs boson ($h$) in $t\tilde{t}_2 \rightarrow h\tilde{t}_1$, are significant.

A similar signature can also occur in $\tilde{t}_1$ pair production in gauge-mediated SUSY breaking (GMSB) models [27–32]. The $\tilde{\chi}^0_1$ from $\tilde{t}_1$ decay is typically the next-to-lightest supersymmetric particle (NLSP) and the supersymmetric partner of the graviton ($\tilde{G}$) is typically the LSP and is very light ($m_{\tilde{G}} < 1$ keV). Assuming a mass scale of the messengers responsible for the supersymmetry breaking of around 10 TeV and little fine tuning [15], the lightest stop is expected to have a mass of less than 400 GeV [33]. The $\tilde{\chi}^0_1$ decays to either a $\gamma$, $Z$, or $h$ boson and a $\tilde{G}$. If the $\tilde{\chi}^0_1$ is higgsino-like, as suggested by naturalness arguments, it dominantly decays either via $\tilde{\chi}^0_1 \rightarrow h\tilde{G}$ or via $\tilde{\chi}^0_1 \rightarrow Z\tilde{G}$, in the latter case giving a $Z$ boson at the end of the stop decay chain.

In this paper a search for stop pair production is reported in final states characterised by the presence of a $Z$ boson with or without additional leptons, plus jets originating from $b$-quarks ($b$-jets) produced in the stop decay chain and significant missing transverse momentum from the undetected...
LSPs. Results are interpreted in simplified models featuring \( \tilde{t}_2 \) production and in the framework of natural GMSB. This paper presents the first result on \( \tilde{t}_2 \) direct pair production and extends the results of a previous ATLAS analysis, carried out using 7 TeV data corresponding to an integrated luminosity of 2.05 fb\(^{-1} \) [34], that excluded stop masses up to 310 GeV for 115 GeV < \( m_{\tilde{\chi}_1^\pm} \) < 230 GeV in natural GMSB scenarios.

2 The ATLAS detector

ATLAS [35] is a general-purpose particle physics experiment at the LHC. The layout of the detector consists of inner tracking devices surrounded by a superconducting solenoid, electromagnetic and hadronic calorimeters and a muon spectrometer with a magnetic field produced by three large superconducting toroids each with eight coils. The inner tracking detector is formed from silicon pixel and microstrip detectors, and a straw tube transition radiation tracker, and provides precision tracking of charged particles for pseudorapidity |\( \eta \)| < 2.5.\(^1 \) The calorimeter system, placed outside the solenoid, covers |\( \eta \)| < 4.9 and is composed of electromagnetic and hadronic sampling calorimeters with either liquid argon or scintillating tiles as the active medium. The muon spectrometer surrounds the calorimeter and consists of a system of precision tracking chambers within |\( \eta \)| < 2.7, and detectors for triggering within |\( \eta \)| < 2.4.

3 Signal and background simulation

Monte Carlo (MC) simulated event samples are used to aid in the estimation of the SM background and to model the SUSY signal. MC samples are processed through a detector simulation [36] based on GEANT4 [37] or a fast simulation using a parameterisation of the performance of the electromagnetic and hadronic calorimeters and GEANT4 for the other parts of the detector [38], and are reconstructed in the same manner as the data. The simulation includes the effect of multiple pp collisions in the same and neighbouring bunch crossings and is weighted to reproduce the observed distribution of the average number of collisions per bunch crossing. All MC samples used in the analysis are produced using the ATLAS underlying event tune 2B [39] unless otherwise stated.

The top-quark pair production background is simulated with \textsc{Powheg Box} r2129 [40–42] interfaced to \textsc{Pythia} 6.427 [43] for the fragmentation and hadronisation processes. The mass of the top quark is fixed at 172.5 GeV, and the next-to-leading order (NLO) parton distribution function (PDF) set CT10 [44] is used. The total cross section is calculated at next-to-next-to-leading-order (NNLO) including resummation of next-to-next-to-leading logarithmic (NNLL) soft gluon terms with TOP++2.0 [45–50]. The PZ011C [51] MC tune is used for this sample. Samples generated with \textsc{Alpgen} 2.14 [52] interfaced with \textsc{Herwig} 6.510 [53], including \textsc{Jimmy} 4.3 [54] for the underlying event description, are used to evaluate generator systematic uncertainties, while \textsc{Powheg Box} r2129 interfaced with \textsc{Herwig} 6.510 and \textsc{Acemc} 3.8 [55] interfaced to \textsc{Pythia} 6.426 are used for hadronisation and initial/final state radiation (ISR/FSR) uncertainty estimation respectively. Production of a single top quark in association with a W boson is simulated with \textsc{Powheg Box} r2129 interfaced to \textsc{Pythia} 6.426 using the diagram removal scheme [56]. The nominal samples describing \( t\bar{t} \) production in association with gauge bosons (\( t\bar{t}V \)) as well as single top production in association with a Z boson (\( t\bar{t}Z \)) in the t- and s-channels, and the \( t\bar{t}WZ \) process, are generated using the leading-order (LO) generator \textsc{MadGraph5} 1.3.33 [57] interfaced to \textsc{Pythia} 6.426 for the fragmentation and the hadronisation. The total cross sections of \( t\bar{t}W \) and \( t\bar{t}Z \) are normalised to NLO [58] while \( t\bar{t}Z \) is normalised to the LO cross section from the generator, since NLO calculations are currently only available for the \( t \)-channel [59]. To estimate generator and hadronisation systematic uncertainties for the \( t\bar{t}W \) and \( t\bar{t}Z \) processes, \textsc{Alpgen} 2.14 interfaced with \textsc{Herwig} 6.520, including \textsc{Jimmy} 4.3, is used. Samples of Z/\( \gamma^* \) production in association with up to five jets are produced with \textsc{Sherpa} 1.4.1 [60] where b- and c-quarks are treated as massive. MC samples of dibosons (\( ZZ, WZ \) and \( WW \)) decaying to final states with 2, 3 and 4 leptons are generated using \textsc{Powheg Box} r2129 interfaced to \textsc{Pythia} 8.163 [61]. Samples generated with \textsc{aMC@NLO} 6.2 [62] (in \textsc{MadGraph5} 2.0.0.beta) interfaced to \textsc{Pythia} 6.427 or \textsc{Herwig} 6.510 are used to evaluate generator, hadronisation and scale variation uncertainties. Samples of tribosons (\( WWW, ZWW \) and \( ZZZ \)) are generated with \textsc{MadGraph5} 1.3.33 interfaced to \textsc{Pythia} 6.426 and normalised to NLO [63]. Higgs boson production in association with a vector boson or \( t\bar{t} \) pair is simulated with \textsc{Pythia} 8.165, with cross sections calculated at NNLO QCD + NLO electroweak precision, except \( pp \rightarrow t\bar{t}h \), which is calculated at NLO QCD precision [64]. The multijet and \( \gamma \)-jet processes are simulated with \textsc{Pythia} 8.165 and \textsc{Pythia} 8.160 respectively.

Signal events are generated according to SUSY models using \textsc{Herwig++} 2.5.2 [65] with the CTEQ6L1 PDF set. Signal cross sections are calculated at NLO + NLL accuracy [66–68]. The nominal cross section and the uncer-
Direct $\tilde{t}_1$ pair production is studied using a simplified model, where all SUSY particles are decoupled except for the $t_2$, $\tilde{t}_1$ and $\tilde{\chi}^0_1$, assumed to be the LSP. The only decays included in this model are $\tilde{t}_2 \rightarrow Z\tilde{t}_1$ and $\tilde{t}_1 \rightarrow t\tilde{\chi}^0_1$. The mass of the top quark is fixed at 172.5 GeV. The mass difference between the lighter stop and the neutralino is set to 180 GeV, a region not excluded by previous searches [21], and signal samples are generated varying the masses of the $\tilde{t}_2$ and $\tilde{\chi}^0_1$. In addition, dedicated samples also including the $\tilde{t}_2 \rightarrow h\tilde{t}_1$ and $\tilde{t}_2 \rightarrow t\tilde{\chi}^0_1$ decay modes are used to interpret the results as a function of the $\tilde{t}_2$ branching ratios. Simulated samples corresponding to direct $\tilde{t}_1$ pair production for values of $m_{\tilde{t}_2} = m_{\tilde{\chi}^0_2} + 180$ GeV are also used in the analysis.

For the natural GMSB scenario, a very similar model to that of Ref. [34] is considered, with the Higgs boson assumed to be SM-like and with the mass set at 126 GeV, in agreement with the observation of a Higgs boson at the LHC [70, 71], and with $\tan \beta$, the ratio of the vacuum expectation value of the two neutral Higgs doublets of the MSSM, set to 5. The masses of the first and second generation squarks and gluinos (superpartners of the gluons) are above 5 TeV, and maximal mixing between the squark eigenstates is assumed for $\tilde{t}_1$. Only $\tilde{t}_1$ pair production is considered. $\tilde{\chi}^0_1$, $\tilde{\chi}^0_2$ and $\tilde{\chi}^±_1$ are assumed to be predominantly higgsino states. Hence, if $\tilde{\chi}^0_2$ or $\tilde{\chi}^±_1$ are produced in a decay chain, they decay to $\tilde{\chi}^0_1$ promptly with soft accompanying fermions. The branching fractions of the $\tilde{t}_1$ and higgsino decays are predicted by the model. If $m_{\tilde{t}_1} < m_t + m_{\tilde{\chi}^0_2}, \tilde{t}_1$ decays via $\tilde{t}_1 \rightarrow b\tilde{\chi}^±_1$ exclusively, while if $m_{\tilde{t}_1} > m_t + m_{\tilde{\chi}^0_2}, \tilde{t}_1$ may also decay with similar probability via $\tilde{t}_1 \rightarrow t\tilde{\chi}^0_1$ (or $t\tilde{\chi}^±_2$). For the model parameters considered, the $\tilde{\chi}^0_1$ predominantly decays to $Z\tilde{\chi}_1^0$ with branching ratios typically above 70 %. Signal samples are generated varying the $\tilde{t}_1$ and $\tilde{\chi}^0_1$ masses.

**4 Object identification and event selection**

After the application of beam, detector and data quality requirements, the total luminosity considered in this analysis corresponds to 20.3 fb$^{-1}$. The uncertainty on the integrated luminosity is ±2.8 %. It is derived, following the same methodology as that detailed in Ref. [72], from a preliminary calibration of the luminosity scale derived from beam-separation scans performed in November 2012.

Events are selected if they pass the single electron or muon triggers; these are fully efficient for lepton $p_T > 25$ GeV. The presence of at least one primary vertex, with at least five tracks with $p_T > 0.4$ GeV associated to it, is required. In order to optimize the analysis and to perform data-driven background estimations, two categories of jets, electrons, muons and photons are defined: “candidate” and “signal” (with tighter selection criteria).

Jets are reconstructed from three-dimensional calorimeter energy clusters by using the anti-$k_t$ algorithm [73] with a radius parameter of 0.4. Jet energies are corrected [74] for detector inhomogeneities, the non-compensating nature of the calorimeter, and the impact of multiple overlapping $pp$ interactions, using factors derived from test beam, cosmic ray and $pp$ collision data and from a detailed GÉANT4 detector simulation. Events with any jet that fails the jet quality criteria designed to remove noise and non-collision backgrounds [74] are rejected. Jet candidates are required to have $p_T > 20$ GeV and $|\eta| < 2.8$. Jets labelled as signal jets are further required to have $p_T > 30$ GeV and, for those with $p_T < 50$ GeV and $|\eta| < 2.4$, the jet vertex fraction, defined as the fraction of the sum of the $p_T$ of the tracks associated with the jet and matched to the selected primary vertex, normalised by the sum of the $p_T$ of all tracks associated with the jet, is required to be larger than 25 %.

Identification of jets containing b-quarks (b-tagging) is performed with a dedicated algorithm based on a neural-network approach which uses the output weights of several b-tagging algorithms [75] as input. A requirement is chosen corresponding to a 60 % average efficiency obtained for b-jets in simulated t$\bar{t}$ events. The rejection factors for mis-tagging light quark jets, c-quark jets and τ leptons in simulated SM t$\bar{t}$ events are approximately 600, 8 and 24, respectively. Signal jets with $|\eta| < 2.5$ which satisfy this b-tagging requirement are identified as b-jets. To compensate for differences between data and MC simulation in the b-tagging efficiencies and mis-tag rates, correction factors derived from different methods, such as the use of the $p_T$ of muons relative to the axis of the jet [76] and a dedicated study in t$\bar{t}$ dominated regions [77], are applied to the simulated samples. A sample of $D^{±}$ mesons is used for mis-tag rates of c-jets [78] and inclusive jet samples for mis-tag rates of a jet which does not originate from a b- or c-quark [79].

Electron candidates must satisfy the “medium” selection criteria described in Ref. [80], re-optimised for 2012 data, and are required to fulfil $p_T > 10$ GeV and $|\eta| < 2.47$. Signal electrons must pass the previous requirements and also need to be isolated, i.e. the scalar sum of the $p_T$ of charged-particle tracks within a cone of radius $\Delta R = 0.3$ around the candidate excluding its own track must be less than 16 % of the electron $p_T$. In addition, a longitudinal impact parameter requirement of $|z_0 \sin \theta| < 0.4$ mm is applied to signal electrons. The track parameter $z_0$ is defined with respect to the reconstructed primary vertex.

Muon candidates are required to have $p_T > 10$ GeV, $|\eta| < 2.4$ and are identified by matching an extrapolated inner detector track and one or more track segments in the muon spectrometer [81]. Signal muons are then required to
be isolated, i.e. the scalar sum of the $p_T$ of charged-particle tracks within a cone of radius $\Delta R = 0.3$ around the muon candidate excluding its own track must be less than 12% of the muon $p_T$. In addition, a longitudinal impact parameter requirement of $|z_0 \sin \theta| < 0.4$ mm is applied to signal muons.

A signal lepton with $p_T$ larger than 25 GeV is required to match the one that triggered the event such that the efficiency of the trigger is $p_T$ independent. The MC events are corrected to account for minor differences in the lepton trigger, reconstruction and identification efficiencies between data and MC simulation [80,81].

To resolve ambiguities between reconstructed jets and leptons, jet candidates within a distance of $\Delta R = 0.2$ of an electron candidate are rejected. Any electron or muon candidate within a distance of $\Delta R = 0.4$ of any remaining jet candidate is also rejected. To suppress the rare case where two distinct tracks are mistakenly associated with one calorimeter energy cluster forming two electron candidates, if two electron candidates are found within a distance $\Delta R = 0.1$, the one with a smaller transverse momentum is rejected. Finally, to suppress muon bremsstrahlung leading to an incorrect measurement of the transverse momentum, if an electron candidate and a muon candidate are within $\Delta R = 0.1$, both are rejected.

Photons are used only for the Z+jets estimation in the two-lepton signal regions described in Sect. 5 and the overlap removal between photons and jets described below is performed only in this case. Photon candidates are required to have $p_T > 25$ GeV, $|\eta| < 2.47$ and must satisfy the “tight” selection criteria described in Ref. [82]. Signal photons are further required to be isolated, i.e. the scalar sum of transverse energy deposition in the calorimeter observed within a cone of radius $\Delta R = 0.4$ around the photon candidate excluding its own energy deposition in the calorimeter must be less than 4 GeV. To resolve overlaps between reconstructed jets and photons, jet candidates within a distance of $\Delta R = 0.2$ of a photon candidate are rejected.

The calculation of the missing transverse momentum, where its magnitude is referred to as $E_T^{\text{miss}}$ [83], is based on the vector sum of the transverse momenta of all electron, muon and jet candidates, as well as photons with $p_T > 10$ GeV and calibrated calorimeter energy clusters with $|\eta| < 4.9$ not associated with these objects. Clusters associated with electrons, photons and jets make use of the calibrations of these objects. For jets, the calibration includes the pile-up correction described above, whilst the jet vertex fraction requirement is not considered when selecting jet candidates for computing the $E_T^{\text{miss}}$. Clusters not associated with these objects are calibrated using both calorimeter and tracker information [83].

Five signal regions (SRs) are defined in the analysis aiming at final states with a Z boson, $b$-jets, significant $E_T^{\text{miss}}$ and possibly additional leptons, as summarised in Table 1. They are characterised by the number of leptons (electrons or muons) required in the final state. For the two-lepton SRs (indicated as SR2A, SR2B and SR2C), events with exactly two leptons are selected, with the $p_T$ of the leading one required to be larger than 25 GeV. They are required to be signal leptons and form a SFOS pair with invariant mass $(m_{\ell\ell})$ within 5 GeV or 10 GeV of the Z-boson mass. At least one $b$-jet is required. SR2A and SR2B are optimised for the small $m_{\ell\ell} - m_{Z^0}$ region of the natural GMSB model where low jet multiplicity is expected, whilst SR2C is optimised for the large $m_{\ell\ell} - m_{Z^0}$ region where the jet multiplicity is

Table 1 Summary of the event selection in the signal and $t\bar{t}$ background control regions used in the analysis. The variables used are the number of leptons ($N_{\text{leptons}}$), the $p_T$ of the leading lepton ($p_T(\ell_1)$), the dilepton flavour (SF: same-flavour; DF: different flavour), the dilepton invariant mass $(m_{\ell\ell})$, the number of $b$-jets ($N_{b\text{-jets}}$), the number of jets regardless of their flavour ($N_{\text{jets}}$), the $p_T$ of the leading jet ($p_T(j_1)$), the $p_T$ of the $N_{\text{jets}}$-th jet required in each region ($p_T(j_N)$), the missing transverse momentum ($E_T^{\text{miss}}$), the transverse momentum of the dilepton system ($p_T(\ell\ell)$), and the angular separation in the transverse plane between the leptons forming the SFOS pair ($\Delta \phi^{\ell\ell}$).

give good sensitivity in the direct $\bar{t}_2-\bar{t}_1$ pair production model for different $m_2-\tilde{t}_1$ mass splittings. The SR3A is aimed at signal models with low mass splitting where the $Z$-boson is not boosted. The SR3B is optimised for high mass splitting where the $Z$-boson is boosted requiring a minimum $p_T$ of the dilepton system of 75 GeV. A high-$p_T$ leading lepton with a minimum $p_T$ requirement of 40 GeV or 60 GeV for SR3A and SR3B respectively, and at least one $b$-jet are required to suppress the diboson background. The signal is expected to have higher jet multiplicity than the SM background, due to the presence of two top quarks and two $Z$ bosons. This is illustrated by Fig. 1, which shows the jet multiplicity distribution after the lepton, $m_\ell\ell$, and $b$-jet requirements in SR3A are applied. Therefore at least five jets are required to increase the signal sensitivity.

5 Background estimation

Two main sources of background can be distinguished in this analysis: events containing at least one non-prompt or fake lepton (mainly production of multijets and $W$ boson in association with jets in the two-lepton SRs, and production of top pairs and $Z$ boson in association with jets in the three-lepton SRs) and events with two or three prompt leptons (mainly $Z$+jets and $t\bar{t}$ in the two-lepton SRs, and $t\bar{t}V$, $tZ$, diboson and triboson events in the three-lepton SRs).

Background from fake or non-prompt leptons

Fake leptons can originate from a misidentified light flavour quark or gluon jet (referred to as light flavour). Non-prompt leptons can originate from a semileptonic decay of a hadron containing a $b$- or $c$-quark (referred to as heavy flavour), or an electron from a photon conversion. The contribution from fake and non-prompt leptons is estimated from data with a matrix method similar to that described in Refs. [84,85].
loose non-prompt leptons to pass the tight selection criteria is determined from data separately for heavy flavour in a $b\bar{b}$ enriched sample and for photon conversions in a $Z \rightarrow \mu\mu\gamma$ sample. This probability is modelled as a function of $p_T$ and $\eta$ for electrons and of $p_T$ and the number of jets for muons. Simulation studies show that the contribution of fake leptons originating from a misidentified light flavour quark or gluon jet is negligible in all the signal and data control regions used for the background estimation. The probability for loose non-prompt electrons passing the tight selection is calculated according to the fraction of heavy flavour and photon conversion obtained in MC for the different regions.

For SRs with two leptons, relations are obtained for the observed event counts as a function of the number of events containing prompt and non-prompt leptons. These can be solved simultaneously to estimate the number of background events with two tight lepton candidates with at least one non-prompt lepton. In the three-lepton SRs, the background from non-prompt leptons is estimated as in the two-lepton case by considering the leading lepton to be prompt, which simulation studies show to be true in >99% of the events, and applying the same estimation method to the second and third leading leptons in the event. The results of the estimations have been validated with data in regions with similar background composition obtained by reversing the $E_T^{miss}$ or jet multiplicity cuts used in the SRs.

$tt\bar{t}$ background in the two-lepton channel

The dominant background in the two-lepton signal regions comes from $tt\bar{t}$. The background prediction is normalised to data in dedicated control regions (CRs), and then extrapolated to the SRs. The observed number of events in the CRs are used to derive $tt\bar{t}$ estimates in each of the SRs via a profile likelihood method [86].

The CRs are designed to have kinematic selections as similar as possible to the corresponding SRs in order to minimize systematic uncertainties on the extrapolation of the background to the SR. The CRs use both dilepton events with the same flavour (SF) and different flavour (DF) with the following dilepton mass requirements: 10 GeV < $m_{\ell\ell}$ - $m_Z$ < 50 GeV (SF), and |$m_{\ell\ell}$ - $m_Z$| < 50 GeV (DF). Except for lepton-flavour dependent systematic uncertainties, SF and DF events are treated in the same way. Apart from the $m_{\ell\ell}$ requirements the CR corresponding to SR2A/B (labelled CR2A) has exactly the same selections as SR2A, whereas the CR for SR2C (labelled CR2C) has a looser $E_T^{miss}$ selection than the SR to increase the number of events in the CR.

For the background estimation neglecting any possible signal contribution in the CRs, the fit takes as input the number of expected background events in each CR and SR taken from MC or data-driven estimations and the number of observed events in the CRs. For each SR, the free parameter is the overall normalisation of the $tt\bar{t}$ process. Each uncertainty source is treated as a nuisance parameter in the fit, constrained with a Gaussian function taking into account the correlations between different background sources. The likelihood function is the product of Poisson probability functions describing the observed and expected number of events in the CRs, and the Gaussian constraints on the nuisance parameters. The contribution from all other non-constrained processes are set at the theoretical expectation, but are allowed to vary within their uncertainties. The fitting procedure maximises this likelihood by adjusting the free and nuisance parameters. For the signal models considered in this paper the contamination of the CRs by signal events is small (typically less than 10%).

The expected and observed number of events in the control regions are shown in Table 2. The MC simulation before the fit overestimates the number of $tt\bar{t}$ events observed in both of the CRs. This mis-modelling at high $tt\bar{t}$ transverse momentum ($p_T,t\bar{t}$) has been observed in previous ATLAS analyses [87].

Z+jets background in the two-lepton channel

Background events from $Z$-boson production associated with jets typically contain fake $E_T^{miss}$ due to resolution effects in the jet momentum measurement. Due to the limited statistics and the difficulty of accurately reproducing fake $E_T^{miss}$ in MC simulations, a data-driven “jet smearing method” [88] is used to estimate this contribution in the high $E_T^{miss}$ tail. In this method, well-measured $Z$-jets events with low $E_T^{miss}$ are selected. By applying jet energy resolution smearing to these events a pseudo-data sample with fake $E_T^{miss}$ is gen-

erated. The pseudo-data sample is then normalised to data in the $E_T^{\text{miss}} < 80$ GeV region, after subtracting other SM background sources estimated by MC for real two lepton events and by the data-driven method for events with non-prompt leptons. Their contribution is less than 10%. The jet energy resolution smearing function ($p_T^{\text{reco}} / p_T^{\text{truth}}$) is initially obtained from multijet MC simulation, where $p_T^{\text{reco}}$ is the transverse momentum of the reconstructed jet and $p_T^{\text{truth}}$ is the transverse momentum of the jet constructed from stable truth particles excluding muons and neutrinos. Stable particles are defined as those with a lifetime of 10 ps or more in the laboratory frame. The function is corrected using $\gamma$+jet data events where the photon and the jet are balanced. These events are selected by a single photon trigger and require at least one signal photon and one baseline jet. To suppress soft radiation that would affect the $p_T$ balance between the jet and the photon, the angle between the leading jet and the leading photon in the transverse plane is required to be larger than 2.9 rad, and the second-leading jet is required to have $p_T$ of less than 20 % of the $p_T$ of the photon. Using the $p_T$ of the balanced photon as reference for that of the jet, the $p_T$ response of jets is measured in data and MC. The jet energy resolution smearing function is then modified to match $p_T$ response between data and MC. The method is validated by closure tests using MC simulation, and also using data in the 80 GeV < $E_T^{\text{miss}}$ < 160 GeV region.

Other backgrounds

The estimation of other background processes producing two or three prompt leptons, such as diboson, triboson, $t\bar{t}V$, $t\bar{t}Z$ or $Wt$ production, is performed using the MC samples described in Sect. 3.

Since $t\bar{t}Z$ is the main background in the three-lepton SRs and has a topology very similar to a $t\bar{t}1\ell1\ell$ signal, dedicated validation regions with an enhanced contribution from this background and orthogonal to the SRs are defined to verify the MC prediction in data. These regions are defined requiring at least three leptons and the same $m_{\ell\ell}$ and $b$-jet requirements as the SRs. In order to enhance the $t\bar{t}Z$ contribution and reduce the possible contamination from signal events, the events are required to have from three to five jets with $p_T > 30$ GeV and fewer than five jets with $p_T > 50$ GeV. The $E_T^{\text{miss}}$ is required to be less than 150 GeV except for events with 5 jets with $p_T > 30$ GeV where the $E_T^{\text{miss}}$ is required to be less than 60 GeV to avoid overlaps with the SRs. The third leading lepton is required to have $p_T > 20$ GeV to reduce the contribution from non-prompt leptons. Two separate validation regions are defined using the $p_T(\ell\ell)$ variable: VR3A with $p_T(\ell\ell) < 120$ GeV and VR3B with $p_T(\ell\ell) > 120$ GeV. The contamination from a potential signal can be large in these validation regions but would typically affect VR3A and VR3B differently depending on the $\tilde{t}_2-\tilde{t}_1$ mass splitting. Table 3 shows the expected number of events in these validation regions taken from MC or data-driven estimations together with the observed number of events. The expected contribution from selected signal models is also shown. The $t\bar{t}Z$ contribution is 40–50 % of the total expected event count, and a good agreement with data is observed in both regions.

### Table 3 Number of events in the VR3A and VR3B $t\bar{t}Z$ validation regions together with the expectation for some signal points in the $\tilde{t}_2$ simplified model. The errors on the backgrounds include both statistical and systematic uncertainties. Only statistical uncertainties are shown for the signal points

### 6 Systematic uncertainties

The dominant detector-related systematic effects are due to the jet energy scale (JES) and resolution (JER) uncertainties, and the uncertainties on the $b$-tagging efficiency and mistag rates.

The JES uncertainty is derived from a combination of simulation, test-beam data and in-situ measurements [74]. Additional terms accounting for flavour composition, flavour response, pile-up and $b$-jet scale uncertainties are taken into account. These uncertainties sum to 10–20 % of the total number of estimated background events depending on the SR. JER uncertainties are determined with an in-situ measurement of the jet response asymmetry in dijet events [89], and the impact on the SRs ranges between 1–10 %. Uncertainties associated with the $b$-tagging efficiency and mistagging of a $c$- and light-quark jet are obtained from the same techniques used in the derivation of their correction factors. The uncertainty on the expected number of background events in the SR due to $b$-tagging ranges between 4–10 %.

For the non-prompt lepton background estimation, uncertainties are assigned due to the statistical uncertainty on the...
number of data events with loose and tight leptons and due to the MC uncertainty on the relative composition of non-prompt electrons (heavy flavour and conversions). The uncertainties on the probabilities for loose leptons to pass the tight selections typically range between 10–45 %, are estimated by using alternative samples for their computation, and include possible dependencies on the lepton $p_T$, $\eta$ or jet multiplicity. The overall impact of the non-prompt lepton background uncertainties on the expected number of background events are below 2 % in the 2-lepton SRs and approximately 15 % in the 3-lepton SRs.

The uncertainties on the MC modelling of background processes are determined by testing different generators as well as parton shower and hadronisation models. The systematic uncertainties on the modelling of $t\bar{t}$+jets, used only to determine the transfer factors between control and signal regions in the two-lepton case, are evaluated by comparing results obtained with the POWHEG and ALPGEN generators. The hadronisation uncertainty is addressed by comparing POWHEG interfaced to PYTHIA6 with POWHEG interfaced to HERWIG+JIMMY. The uncertainty related to the amount of ISR/FSR is estimated using the predictions of dedicated ACERMC samples generated with different tuning parameters. The uncertainties on $t\bar{t}$ are dominated by these theoretical uncertainties after the fit. A 22 % cross section uncertainty is assumed for $t\bar{t}Z$ and $t\bar{t}W$ [58]. The uncertainties on the modelling of $t\bar{t}V$ are evaluated by comparing MADGRAPH interfaced to PYTHIA6 with ALPGEN interfaced with HERWIG+JIMMY. The uncertainty assigned on the diboson cross sections are 5 % for $ZZ$ [90] and 7 % for $WZ$ [91]. For diboson production processes, the uncertainties on the modelling are evaluated by comparing POWHEG interfaced to PYTHIA8 with the aMC@NLO generator interfaced to PYTHIA6 and HERWIG+JIMMY. For tribosons, $t\bar{t}h$ and $t\bar{t}Z$ production processes, which constitute a very small background in all signal regions, a 100 % uncertainty on the cross section is assumed. The uncertainties on these processes are large to account for kinematic effects, even though the inclusive cross sections are known to better precision.

### 7 Results and interpretation

The number of data events observed in each SR for the two-lepton and three-lepton analyses is reported in Table 4 together with the expected SM background contributions. Figs. 2 and 3 show the $E_T^{miss}$ distributions for data and background expectations for each SR.

No excess is observed in any of the SRs. The probability ($p_0$-value) of the SM background to fluctuate to the observed number of events or higher in each SR is also reported in Table 4, and has been truncated at 0.5. Upper limits at 95 % CL on the number of beyond the SM (BSM) events for each SR are derived using the $CL_s$ prescription [92] and neglecting any possible signal contamination in the control regions. After normalising these by the integrated luminosity of the data sample, they can be interpreted as upper limits on the visible BSM cross section, $\sigma_{vis}$, defined as the product of acceptance, reconstruction efficiency and production cross section. The limits are calculated from pseudo-experiments as well as with asymptotic formulae [86] for comparison. The results are given in Table 5.

These results are also interpreted in the context of the models described in Sect. 1. Exclusion limits are calculated by combining the results from several exclusive SRs. For the GMSB scenarios, SR2C and SR3A are combined with the region with best expected sensitivity between SR2A or SR2B. For the $\tilde{t}_2$ simplified models, SR2C is combined with the region with best expected sensitivity between SR3A or
SR3B. For model-dependent interpretations, the fit described in Sect. 5 is modified to include the expected signal contamination of the CRs and the observed number of events in the SRs as well as an extra free parameter for a possible BSM signal strength which is constrained to be non-negative. The expected and observed exclusion limits are calculated using asymptotic formulae for each SUSY model point, taking into account the theoretical and experimental uncertainties on the
SM background and the experimental uncertainties on the signal. The impact of the uncertainties on the signal cross section is also addressed for the observed limit only by showing the results obtained when moving the nominal cross section up or down by the ±1σ theoretical uncertainty. Quoted numerical limits on the particle masses refer to the signal cross sections reduced by 1σ.

Figure 4 shows the limit obtained in the $t\bar{t}$ simplified model, which excludes $m_{t\bar{t}} < 525$ GeV for $m_{\chi_1^0} < 240$ GeV and $m_{t\bar{t}} < 600$ GeV for $m_{\chi_1^0} < 200$ GeV. The interplay of the limit contours between the simulated points towards the $t\bar{t}$ decay mode has been established using MC generator level information. A reduction in acceptance of up to 20% is observed in the region where $m_{t\bar{t}} - m_{t\bar{t}}^{	ext{nominal}}$ is comparable to the $Z$ boson width. The region with $m_{t\bar{t}} - m_{t\bar{t}} < m_{Z}$, where the $t\bar{t}$ decay involves an off-shell $Z$, has not been considered since in that case other $t\bar{t}$ decay modes, such as $t\bar{t} \rightarrow t\chi_1^0$, would be dominant. If the assumption on the 100% branching ratio for the $t\bar{t}$ decay mode is relaxed, the $t\bar{t}$ can also decay via $t\bar{t} \rightarrow h\chi_1^0$ and $t\bar{t} \rightarrow t\chi_1^0$. Exclusion limits as a function of the $t\bar{t}$ branching ratios are shown in Fig. 5 for representative values of the masses of $t\bar{t}$ and $\chi_1^0$. For low $t\bar{t}$ mass ($m_{t\bar{t}} = 500$ GeV), SUSY models with BR($t\bar{t} \rightarrow Z\chi_1^0$) above 15–30% are excluded. For higher stop mass ($m_{t\bar{t}} = 500$ GeV), models with BR($t\bar{t} \rightarrow Z\chi_1^0$) above 15–30% are excluded, with a small dependence on the value of the neutralino mass, BR($t\bar{t} \rightarrow h\chi_1^0$) and BR($t\bar{t} \rightarrow t\chi_1^0$).

In Fig. 6 the expected and observed limits are shown for the GMSB scenarios on the $t\bar{t}$, $\chi_1^0$ mass plane. Stop
masses up to 540 GeV are excluded for neutralino masses of 100 GeV $< m_{\tilde{\chi}_1^0} < m_{\tilde{t}_1} - 10$ GeV. In the parameter space region where the $\tilde{t}_1$ only decays via $b\tilde{\chi}_1^\pm$, the exclusion extends up to stop masses of 660 GeV for neutralinos of 550 GeV. For illustration, the exclusion limits obtained with 2.05 fb$^{-1}$ of ATLAS data at $\sqrt{s} = 7$ TeV for the similar model are also shown, in which the maximum limit on the stop masses was 330 GeV. Due to the increase in statistics and the proton–proton collision energy, as well as the optimised selections for these conditions, much stronger constraints are now set on this model.

8 Summary and Conclusions

This paper presents a dedicated search for direct stop pair production in decays with an experimental signature compatible with the production of a Z boson, b-jets and missing transverse momentum. The analysis is performed with pp collision data at $\sqrt{s} = 8$ TeV collected with the ATLAS detector at the LHC corresponding to an integrated luminosity of 20.3 fb$^{-1}$. The results are interpreted in the framework of simplified models with production of $\tilde{t}_2$ as well as in a natural GMSB model.

In a simplified model characterised by the decay chain $\tilde{t}_2 \rightarrow Z\tilde{t}_1$ with $\tilde{t}_1 \rightarrow t\tilde{\chi}_1^0$ and the mass difference between $\tilde{t}_1$ and $\tilde{\chi}_1^0$ slightly larger than the top mass, parameter space regions with $m_{\tilde{t}_2} < 600$ GeV and $m_{\tilde{\chi}_1^0} < 200$ GeV are excluded at 95 % CL. When the $\tilde{t}_2 \rightarrow h\tilde{t}_1$ and $\tilde{t}_2 \rightarrow t\tilde{\chi}_1^0$ decays are included in the model, BR($\tilde{t}_2 \rightarrow Z\tilde{t}_1$) $> 10$–30 % are excluded for several mass configurations. These are the first experimental results on the search for $\tilde{t}_2$.

In the GMSB scenario, where the $\tilde{t}_1$ might decay to $b\tilde{\chi}_1^\pm$ or $t\tilde{\chi}_1^0$ or $t\tilde{\chi}_1^0$ and the $\tilde{\chi}_1^0$ decay in $Z$ or $h\tilde{\chi}_1^0$, parameter space regions with $\tilde{t}_1$ masses below 540 GeV are excluded at 95 % CL for 100 GeV $< m_{\tilde{\chi}_1^0} < m_{\tilde{t}_1} - 10$ GeV. These limits are much stronger than those set on the similar model considered in the search at $\sqrt{s} = 7$ TeV. For $\tilde{\chi}_1^0$ masses of about 550 GeV, better sensitivity is achieved and $\tilde{t}_1$ masses below 660 GeV are excluded.

Acknowledgments We thank CERN for the very successful operation of the LHC, as well as the support staff from our institutions without whom ATLAS could not be operated efficiently.
