The first part of this thesis concerns the query containment problem, a fundamental static analysis problem in database theory. Given two queries in a language under consideration, the containment problem is to decide whether the answers of one query form a subset of the answers of the other one, over arbitrary databases.

This problem finds applications in query optimization, query answering using views, query answering under constraints, etc. Because of its importance, the containment problem has been thoroughly studied for various query languages and data models in the past.

In this thesis we continue to study the containment problem for various query languages over trees and relational databases that share one structural property — acyclicity. Namely, we consider:

1. Conjunctive and Positive Xpath queries interpreted on trees expanded with negation and attribute value comparisons;
2. Tree Patterns expanded with the conditional descendant axis, interpreted over trees; and
3. Acyclic conjunctive queries expanded with atomic negation and arithmetic comparisons over relational structures.

We obtain complexity bounds for the containment problem for these languages.

The second part of the dissertation proposes a new formal framework for why-not explanations. Our why-not explanations leverage concepts from an ontology to provide high-level and meaningful reasons for why certain data is missing from the result of a query.

In this framework, we are interested in finding most general explanations relative to an ontology. We first address the problem of extracting an ontology from the database instance or schema. We show that this problem can be casted as the containment problem and provide the complexity analysis of it. Then we address the problem of computing a most general explanation. We study the complexity of this problem and associated problems, and present concrete algorithms for computing why-not explanations.

Acknowledgements

There are a number of people that have supported me in this four-year-long journey. Even if you are not mentioned in the list below, you should know that I am very grateful for all the good you have done for me.

Special thanks go to:

Maarten Marx, my supervisor. Thank you Maarten for the guidance, your open heart and remarkable creativity.

Balder ten Cate. Thank you Balder for having me in Santa Cruz, it was one of the greatest periods of my life. I am indebted to you for opening a totally new research direction to me.

Maarten Marx, Yoichi Hirai, Alessandro Facchini, Balder ten Cate, Cristina Civili, and Wang-Chiew Tan, co-authors of the chapters of this thesis. I am grateful for all the great ideas and discussions we have had together.

Maarten de Rijke, my promotor. Thank you for creating a very stimulating environment in the group.

Sergey P. Odintsov, my first supervisor back in Novosibirsk. Thank you Sergey Pavlovich for sparking my interest in logic.

The Netherlands Organisation for Scientific Research (NWO) for sponsoring my PhD project and the Dutch Research School for Information and Knowledge Systems (SIKS) for their additional support.

Former and current members of ILPS, for all the fun at coffee breaks, parties and elsewhere. I wish I could mention all your names, but ILPS is very large.

#Running and #Beachvolley teams at ILPS for sports during and after the work hours.

Katya and Abdo, my paranymphs.

Last but foremost my family for being there for me.

Evgeny Sherkhonov

### Samenvatting 163
Introduction

One of the main uses of computers is to store, manage, and retrieve information. Large amounts of data stored on computers and structured by a defined schema are called databases. Software that helps to manipulate and retrieve data (by means of querying) is called a database management system. Database theory is the field of computer science that studies the foundations underlying the design and use of such systems.

Static analysis for queries is one of the main themes in database theory. One of the main static analysis problems for query languages is containment. Ever since the creation of the relational model, and SQL query language, the containment problem has been a topic of considerable interest (Chandra and Merlin, 1977; Chekuri and Rajaraman, 2000; Gottlob et al., 2001). With the creation of other data models such as (tree) XML, data trees, graph databases, and corresponding languages (e.g., XPath and SPARQL, graph patterns or path queries) the containment problem has received renewed interest (Kostylev et al., 2014; Miklau and Suciu, 2004; Wood, 2003). Roughly, the containment problem for a query language $L$ over the data model $D$ can be formalized as follows. Let $Q_1$ and $Q_2$ be two queries from $L$. Then we say that $Q_1$ is contained in $Q_2$, denoted as $Q_1 \subseteq Q_2$, if for every $D$-database $I$, the answers to $Q_1$ over $I$ are among the answers to $Q_2$ over $I$. This problem has a number of important applications. We list a few of them.

**Query optimization.** The task of query optimization is to produce a query $Q'$ for a given query $Q$ such that the answers of the queries are the same (i.e., they are equivalent and denoted as $Q \equiv Q'$) and the “cost” of executing $Q'$ is lower than of $Q$. Thus, checking equivalence of two queries is an essential step for any optimization algorithm. Checking if $Q'$ is equivalent to $Q$ can be done by checking two containment relations: $Q \subseteq Q'$ and $Q' \subseteq Q$. Vice versa, for many query languages, the equivalence problem turns out to be equivalent to the containment problem. Indeed, if $L$ contains conjunction $\land$, then checking $Q \subseteq Q'$ amounts to checking $Q \equiv Q \land Q'$.

**Query answering using views.** Another problem involving containment is query answering using materialized views. This problem has received considerable attention in the literature because of its various applications in other areas such as speeding up query evaluation, mobile computing, semantic data caching, and data warehouse design, see (Levy et al., 1995) for references, and (Halevy, 2000) for an
1. Introduction

overview of the results in this area. Roughly, the problem can be stated as follows. Given a query $Q$ and a set of view definitions $V_1, \ldots, V_n$, can we answer $Q$ using only the answers computed for $V_1, \ldots, V_n$?

A common approach to solve this problem is query rewriting. That is, finding a query $Q'$ which uses only the views $V_1, \ldots, V_n$ such that $Q' \equiv Q$. This definition shows that checking equivalence is an essential step in query rewriting. As we have mentioned above, this problem is tightly connected with the containment problem.

Why-not explanations. A third application that we mention here has recently appeared in the context of explanations to why-not questions. A why-not question aims to explain why particular data is missing from the result of a query. A newly proposed framework for why-not explanations (ten Cate et al., 2015) makes use of ontologies. Roughly, an ontology is a hierarchy of concepts that models a domain of interest. As an example, assume that Woman and Man are two concepts that represent women and men, while the concept Human represents human beings. These concepts obey the following hierarchy: Woman $\subseteq$ Human and Man $\subseteq$ Human, which is read as “the concept Human subsumes the concepts Woman and Man”, and simply formalizes the fact that every woman and every man is a human being.

Without going too much into the details of the framework in (ten Cate et al., 2015), we point out that an explanation is a tuple of concepts that “generalizes” the missing data and thus gives a high level explanation to why this data is missing. As an example, given a database of train connections, and the query asking for pairs of cities reachable from each other, one can see that the tuple (New York, Amsterdam) is missing from the query result. One possible high-level explanation is the tuple (AmericanCity, EuropeanCity), which denotes that fact that there is no train connection between any two cities of America and Europe, and thus it explains the fact why (New York, Amsterdam) is missing. Note that the tuple of concepts (City, City) would not be an explanation, because there are cities that are connected to each other.

In this framework, we are interested in most general explanations. That is, in explanations such that there is no other explanation which is strictly more general (or which does not strictly subsume). Therefore, checking subsumption between two concepts is essential in algorithms for producing a most general explanation. Concepts are in fact queries and thus checking subsumption between concepts is the same as checking containment between queries.

The above list of applications, by no means exhaustive, is meant to demonstrate the importance of the containment problem. Note that these applications can also be casted in any query language and data model. This emphasizes the fact that we need to study the containment problem for various query languages and data models. In this thesis we dwell on fragments and expansions of popular query languages such as XPath and Conjunctive Queries over XML and relational data, respectively. One notable structural property that all the languages considered in this thesis share is acyclicity. The acyclicity condition on either languages or their underlying models, is prominent in database theory. Indeed, acyclicity has appeared in various settings where a problem at hand is intractable while acyclicity allows for efficient solutions. A notable example is the query evaluation
problem for conjunctive queries. It is known that the problem is NP-complete (Chandra and Merlin, 1977a), while acyclic conjunctive queries allow for fast parallelizable algorithms (Gottlob et al., 2001).

Next we elaborate more on the research questions that we address in the thesis.

1.1 Research outline and goals

This thesis is divided into two parts. The first part is devoted to the containment problem for expansions of fragments of XPath interpreted over trees and Conjunctive Queries (CQ) interpreted over both trees and relational structures. Concerning this part of the thesis, we list the classes of queries under consideration, with the corresponding expansions. Then we define the research questions addressed in this thesis.

XPath fragments

XPath (W3C, 1999a) is a standard language for selecting paths or patterns in XML documents. It is an essential component in query languages for XML, such as XQuery (W3C, 2010), the transformation language XSLT (W3C, 1999b), and constraint languages such as XML Schema (W3C). Because of its presence in practically all programming tools for manipulating XML documents, XPath and in particular its static analysis (query evaluation, satisfiability and containment) have received significant interest over the past few years (see an overview in (Benedikt and Koch, 2009), and Chapter 2 for an overview on the containment for fragments of XPath).

Although XPath has many features, we restrict our attention to its navigational part, also known as Core XPath (Gottlob et al., 2005b). The complexity of static analysis crucially depends on the syntactic constructs, or axes such as child and descendant, being used in queries. In particular, for a large class of fragments of XPath that contain full negation and filter expressions, the problems of satisfiability and containment are equivalent. For the latter problem, i.e., satisfiability, a rather complete picture of the complexity landscape is understood (Benedikt et al., 2008; Hidders, 2003), thus settling the containment problem for many fragments. On the other hand, for fragments without negation, or positive fragments, the containment and satisfiability are different. A lot of work has been devoted to positive fragments of XPath, a notable one of which is Tree Patterns (Amer-Yahia et al., 2002; Miklau and Suciu, 2004). Tree Patterns is a fragment that uses only downward axes, i.e., child and/or descendant, and that may also use filter expressions and the wildcard.

In this thesis we continue the study of the containment problem for fragments of Positive XPath but with a few additional constructs that allow to express some useful properties of trees. In particular, we single out the following additional constructs, which are formally defined in the corresponding chapters.

- Label negation. As opposed to full negation, in XPath formulas with label negation we allow the negation sign only in front of a label. An additional restriction that is prominent in this thesis is safety that allows an occurrence of a negated label only in conjunction with an occurrence of a positive label. In Chapter 3 we study the impact of safe label negation on the containment problem.
1. Introduction

- Attribute value comparisons. This type of construct allows us to reason over numeric values that sit in the attributes of tree nodes. As an example, the XPath query `//person/*[@age >= 18]` selects all adults present in a document about people. Likewise, in Chapter 3 we study the impact of expanding positive XPath with attribute value comparisons on the containment problem.

- Conditional descendent axis. We initiate the study on downward positive XPath expanded with a restricted form of the transitive closure of the child relation, called *conditional descendent* axis. This expansion can easily be explained pictorially: to descendent edges in usual Tree Patterns we add labels that are (conditional) Tree Patterns themselves. The meaning of a descendent edge labeled with $Q$ and ending in $P$ is a path of child steps ending in a $P$ node such that all the intermediate nodes are $Q$-nodes. This very much resembles the until operator from temporal logic (Kamp, 1968).

When boosting the expressive power, we can expect that the complexity of containment is higher than for usual Tree Patterns. In Chapter 5 we investigate what the exact complexity of containment is.

Conjunctive Queries

Conjunctive Queries (CQ) are one of the most popular query languages used in practice (Abiteboul et al., 1995). In SQL they correspond to select-from-where queries where the conditions can only be combined using “AND”. The containment problem for conjunctive queries interpreted over relational databases was one of the first fundamental problems in database theory, though under a different name. In particular, for this class of queries the containment problem is equivalent to the query evaluation problem that was studied in (Chandra and Merlin, 1977b). Furthermore, this problem has deep connections with other areas, and appears in a different disguise in AI as the Constraint Satisfaction Problem (Kolaitis and Vardi, 2000), and in graph theory as the H-coloring problem (Hell and Nesetril, 2004).

While being well studied over relational databases, the containment problem for conjunctive queries interpreted over unranked trees has been considered only recently (Björklund et al., 2011). In this contexts, conjunctive queries are built of unary relations, and the binary relations *Child*, *Descendent* and *Following*. In (Björklund et al., 2011) it is shown that containment for CQ over trees is $\Pi^P_2$-complete. In Chapter 3, we investigate the impact of the following constructs on the containment problem: (safe) label negation, and attribute value comparisons.

All in all, for every language $\mathcal{L}$ of Positive Xpath, Tree Patterns and Conjunctive Queries expanded with the new constructs mentioned above, we study the following research question.

**RQ 1** What is the complexity of the containment problem for $\mathcal{L}$ over unranked trees?

Tractable containment for expansions of Conjunctive Queries

From (Chandra and Merlin, 1977a) it is known that containment for CQ over relational databases is NP-complete. Because of the practical importance of this query language,
1.1. Research outline and goals

A lot of research has been devoted to finding natural and large classes of restrictions on CQ allowing for tractable containment. One such restriction is acyclicity (Gottlob et al., 2001) that allows for a fast parallelizable algorithm.

Various expansions of Conjunctive Queries over relational databases have been considered in the past. Atomic negation and arithmetic comparisons are among them (Ullman, 2000; van der Meyden, 1997). A conjunctive query is said to have atomic negation if the negation sign appears only in front of an atom (or a subgoal). A conjunctive query has arithmetic comparisons if it contains comparisons of the form $X \text{ op } c$ as subgoals, where $X$ is a variable appearing in some subgoal, $\text{ op }$ is a comparison operator and $c$ a constant.

It turns out that adding these new features results in higher complexity for containment – $\Pi_2^P$. However, it is rather surprising that tractable restrictions of these expanded languages have received little attention before. In Chapter 4 we start addressing this issue by considering a natural candidate for a restriction – acyclicity. Thus, we try to answer the following

**RQ 2** Does acyclicity make the complexity of containment for conjunctive queries expanded with atomic negation or arithmetic comparison tractable? If not, what additional restrictions can be imposed to make it tractable?

### Why-not explanations

The second part of this thesis is devoted to a new framework for why-not explanations. Given a (relational) database possibly with integrity constraints, a computed answer to a query, and a tuple that does not belong to the answer, a why-not question asks why the tuple is missing in the answer. This problem appears quite often during the process of debugging either a database system, or a query posed against the system. Explanations to why-not questions might pinpoint a possible source of error which could be the constraints, views, the query or gaps in the data.

The proposed framework makes use of ontologies and provides high-level explanations. Ontologies contain concepts and relationships between them. In this way, ontologies are a powerful way to model the domain of interest and provide a high-level view of the data. Our framework can make use of either an existing ontology (e.g., DBPedia) or an ontology extracted from the database and/or a schema that includes integrity constraints. Since an ontology is a central object in our framework, the first question that we try to answer in Chapter 6 is

**RQ 3** How to extract an ontology from a database instance or a schema?

It turns out that this problem can be cast as the containment problem. Indeed, an ontology can be represented as a set of concept subsumptions. In case we want to extract an ontology from a schema with integrity constraints, concepts have a form of a view (or a query) and thus subsumption is just a reformulation of the containment problem. The exact answer to the research question largely depends on the type of constraints available in the schema. In Chapter 6 we answer the questions for various constraints, including views, inclusion and functional dependencies.
1. Introduction

Next, in the framework, among all why-not explanations we are interested in “good” ones only. Intuitively, good explanations are those that are as general as possible with respect to the ontology, and thus they are “high-level” and capture a general gap/error in the system. Consider the following example. Suppose we have a database of publications that was obtained as the result of an integration process (say, from DBLP, Google Scholar, and PubMed). Then suppose we are asking for all publications of Ronald Fagin that were published between the year 2000 and 2005. When we query the database, it turns out that his most cited paper R. Fagin et al. “Reasoning about knowledge.” MIT Press, 2003, is not in the result. A possible “good” solution could be that “it is an MIT Press publication and all MIT Press publications are missing”.

We are interested in the following research question.

RQ 4 How to produce “good” explanations?

In the following research chapters we seek answers to all of the above research questions.

1.2 Main contributions and overview

In this section we outline the structure of the thesis and summarize the contributions of each chapter except the introduction chapter.

Chapter 2. In this chapter we review related work and introduce key concepts that are useful for presenting the main material. In particular, we review previous work on the containment problem for various fragments of XPath, as well as Conjunctive Queries over trees and relational structures. Related to why-not explanations, we review known results on why and why-not explanations.

Part I: Containment problem for Acyclic queries

Chapter 3. In this chapter we study the containment problem for queries over trees expanded with attribute value comparisons. Björklund et al. (2011) showed that containment for conjunctive queries (CQ) over trees and positive XPath is respectively $\Pi_2^P$ and coNP-complete. In this chapter we show that the same problem has the same complexity when we expand these languages with XPath’s attribute value comparisons. We show that different restrictions on the domain of attribute values (finite, infinite, dense, discrete) have no impact on the complexity. Making attributes required does have an impact: the problem becomes harder. We also show that containment of tree patterns without the wildcard $\ast$, which is in PTIME, becomes coNP hard when adding equality and inequality comparisons, i.e., comparisons of the form $@_a = c$ and $@_a \neq c$.

Chapter 4. In this chapter we study the containment problem for conjunctive queries (CQ) with atomic negation or arithmetic comparisons over relational databases. It is known that the problem is $\Pi_2^P$-complete (Ullman, 2000; Wei and Lausen, 2003). The aim of this chapter is to find restrictions on CQ that allow for tractable containment.
1.2. Main contributions and overview

In particular, we consider acyclic conjunctive queries. It turns out that even with the most restrictive form of acyclicity (Berge-acyclicity), containment is $\text{coNP}$-hard. We show that for a particular fragment of Berge-acyclic CQs with atomic negation, namely the class of child-only tree patterns with a restricted form of negation, containment is solvable in $\text{PTIME}$.

Chapter 5. In this chapter we consider an expansion of traditional tree patterns. A Conditional Tree Pattern (CTP) expands an XML tree pattern with labels attached to the descendant edges. These labels can be XML element names or Boolean CTP’s. The meaning of a descendant edge labelled by $A$ and ending in a node labelled by $B$ is a path of child steps ending in a $B$ node such that all intermediate nodes are $A$ nodes. In effect this expresses the $\text{until } B, A \text{ holds}$ construction from temporal logic.

This chapter studies the containment problem for CTP. For tree patterns (TP), this problem is known to be $\text{coNP}$-complete. We show that it is $\text{PSPACE}$-complete for CTP. This increase in complexity is due to the fact that CTP is expressive enough to encode an unrestricted form of label negation: $\ast \backslash a$, meaning “any node except an $a$-node”. Containment of TP expanded with this type of negation is already $\text{PSPACE}$-hard.

CTP is a positive, forward, first order fragment of Regular XPath. Unlike TP, CTP expanded with disjunction is not equivalent to unions of CTP’s. Like TP, CTP is a natural fragment to consider: CTP is closed under intersections and CTP with disjunction is equally expressive as positive existential first order logic expanded with the until operator.

Part II: Why-not explanations

Chapter 6. In this chapter we propose a foundational framework for why-not explanations, that is, explanations for why a tuple is missing from a query result. Our why-not explanations leverage concepts from an ontology to provide high-level and meaningful reasons for why a tuple is missing from the result of a query.

A key algorithmic problem in our framework is that of computing a most-general explanation for a why-not question, relative to an ontology, which can either be provided by the user, or it may be automatically derived from the data and/or schema. We study the complexity of this problem and associated problems, and present concrete algorithms for computing why-not explanations. In the case where an external ontology is provided, we first show that the problem of deciding the existence of an explanation to a why-not question is $\text{NP}$-complete in general. However, the problem is solvable in polynomial time for queries of bounded arity, provided that the ontology is specified in a suitable language, such as a member of the DL-Lite family of description logics, which allows for efficient concept subsumption checking. Furthermore, we show that a most-general explanation can be computed in polynomial time in this case. In addition, we propose a method for deriving a suitable (virtual) ontology from a database and/or a schema, and we present an algorithm for computing a most-general explanation to a why-not question, relative to such ontologies. This algorithm runs in polynomial-time in the case when concepts are defined in a selection-free language, or if the underlying schema is fixed. Finally, we also study the problem of computing short most-general explanations,
1. Introduction

and we briefly discuss alternative definitions of what it means to be an explanation, and to be most general.

Notably, in the above algorithms, it is important to decide the containment (or, subsumption) between two concepts. We provide a detailed complexity analysis for this problem when concepts are defined as projections of relations, or projections of relations with selection, or conjunctions thereof, with respect to different types of constraints.

1.3 Origins

We list publications and submissions on which the content chapters are based, and we discuss the role of co-authors.

Chapter 3 This chapter is based on M. Marx and E. Sherkhonov. “Containment for queries over trees with attribute value comparisons” (Marx and Sherkhonov, 2015), which is accepted for publication at *Information Systems* and an expanded version of E. Sherkhonov and M. Marx. “Containment for tree patterns with attribute value comparisons.” *Proceedings of the 16th International Workshop on the Web and Databases 2013, WebDB 2013*, 2013 (Sherkhonov and Marx, 2013). Both authors contributed to the proofs of the results and to the text.

Chapter 4 This chapter is based on a journal submission E. Sherkhonov and M. Marx. “Containment of Acyclic conjunctive queries with atomic negation and arithmetic comparisons”. (Sherkhonov and Marx, 2015), which is currently under review. Both authors contributed to the proofs of the results and to the text.

Chapter 5 This chapter is based on A. Facchini, Y. Hirai, M. Marx, and E. Sherkhonov. “Containment for conditional tree patterns”. *Logical Methods in Computer Science*, 2015 (Facchini et al., 2015). All authors contributed to the proofs of the results and to the text.

Chapter 6 This chapter is based on B. ten Cate, C. Civili, E. Sherkhonov and W-C. Tan. “High-Level Why-Not Explanations using Ontologies”. *Proceedings of the 34th ACM Symposium on Principles of Database Systems*, PODS 2015 (ten Cate et al., 2015). We introduce a new framework for why-not explanations. All authors contributed to the development of the framework, algorithms, proofs of the results and to the text. This work also appears in the PhD thesis of Cristina Civili titled “Processing Tuple-Generating Dependencies for Ontological Query Answering and Query Explanation”, Sapienza University of Rome. Technical contributions of Civili were Section 6.4.1 on the case of external ontology and Section 6.5 on algorithms for computing why-not explanations. Sherkhonov’s contributions include Section 6.5.3 on deriving an ontology from a schema, and Section 6.6 on variations of the framework.

The chapters are almost exact copies of the conference and journal papers, except for the related work sections of the papers. Relevant related work is discussed in Chapter 2.
In this chapter we introduce the main concepts that will be useful for explaining our ideas as well as for providing the background on known results in the field.

We introduce some underlying concepts from database theory. First we recall the relational data model and conjunctive queries. After that, we review XML and its tree model, together with the XPath query language and its fragments. In particular, we give special attention to Tree Patterns.

At the end of this chapter we discuss existing approaches to why and why-not explanations.

2.1 Containment for queries over relational data

Relational data

Relational databases, proposed by E. Codd (Codd, 1970) is the standard model for storing data. In this model, data is stored in tables, where each row represents an entity or an object with information about their properties. For instance, a row can contain information about a person with their name, address and contact information. A table then represents a collection of objects of a similar type. An attribute of a table is a particular type that the objects share. By a schema we mean the set of all table names, with a set of integrity constraints.

Mathematically, each table name is a relational name $R$ whose arity the same as the number of attributes in the table. Then each table in a given database defines the extension of the corresponding relation $R$, and each entry in the table is a tuple in the relation $R$. This way, a database defines a relational structure $I = (\text{dom}, \cdot^I)$ where $\text{dom}$ is the set consisting of all data elements of the database, and $\cdot^I$ is the interpretation function assigning to each relational name $R$ the set of tuples in the table corresponding to $R$. Alternatively, a database can be represented as a set of facts $R(\bar{a})$ such that $\bar{a}$ is an entry in the table of $R$.

Many systems are built upon the relational model, called Relational Database Management System (RDBMS), including MySQL, PostgreSQL, IBM DB2, Microsoft SQL Server and Oracle.
2. Background and Preliminaries

Conjunctive queries over relational databases

Querying is the basic operation of retrieving needed information from a database. Practically all database systems use SQL as the query language.

The most frequent class of SQL queries are select-from-where queries, or also known as conjunctive queries. Let $S$ be a relational schema. Then a $k$-ary ($k \geq 0$) conjunctive query is a first-order logic formula of the form $\exists \bar{x}. (P_1(\bar{x}, \bar{y}) \land \ldots \land P_n(\bar{x}, \bar{y}))$, where $P_i \in S$ for every $i \in [1, \ldots, n]$, such that the free variables are in $\bar{y}$ and $|\bar{y}| = k$. Each atom $P_i$ is also called a subgoal of the query. Often conjunctive queries are written in the following datalog notation:

$$Q(\bar{y}) ::= P_1(\bar{x}, \bar{y}), \ldots, P_n(\bar{x}, \bar{y}),$$

for a new relational symbol $Q$. In this case the atom $Q(\bar{y})$ is called the head, and the expression on the right hand side is the body of the query. We will be using either of these notations.

As an example,

$$Q(e.name, m.name) ::= \text{Employee}(id, p_id, e.name, b.date), \text{Project}(p_id, p.name), \text{Manager}(p_id, m.name)$$

is a conjunctive query which asks for employees and their supervisors. The semantics of conjunctive queries is as follows. We say that $Q$ holds in a database instance $I$ if there is an assignment $\theta$ of the variables of $Q$ to the domain of $I$ such that for every subgoal $P(\bar{x})$ of $Q$, the fact $P(\theta(\bar{x}))$ is in $I$. Then the answer of $Q(\bar{y})$ on $I$ is the set of tuples $\theta(\bar{y})$ for every such assignment $\theta$. If there is such an assignment $\theta$, the instance $I$ is called a model of $Q$.

Conjunctive queries are a major success in database theory. They are not only the most frequent class of queries used in practice, but also possesses some nice properties.

We start with the problem of query evaluation. Formally, given a database $I$ and a conjunctive query $Q$ and a tuple $\bar{a}$, the evaluation problem is to decide if $\bar{a} \in Q(I)$, i.e., if the tuple is present in the query result. When a database is considered part of the input, i.e., we talk about combined complexity, the evaluation problem for conjunctive queries is NP-complete (Chandra and Merlin, 1977b). However, when the query is fixed, i.e., we talk about data complexity, then the evaluation problem belongs to the low complexity class $\mathsf{AC}^0$. Due to this low data complexity and their reasonable expressive power, conjunctive queries have been extremely successful in databases.

One of the characteristic properties of conjunctive queries is that the evaluation and containment problems are equivalent (Abiteboul et al., 1995). This is proved via the canonical model of a conjunctive query. That is, each conjunctive query can be considered as a database instance itself, where each variable is replaced with a distinct constant. This database is a model of the query. Thus, the containment of a query $Q_1$ in a query $Q_2$ amounts to evaluating $Q_2$ on the corresponding canonical model $I_{Q_1}$. Vice versa, each database instance can be considered as a query, where each fact is considered as a subgoal of the query. Then evaluating $Q$ on a database instance $I$ is the same as checking containment $Q_1 \subseteq Q$, where $Q_1$ is the query that corresponds to $I$.

This characterization gives some more nice properties. An immediate one is the small counter-example property. The latter means that if containment between two queries does
not hold, then there is a witness for non-containment whose size is polynomial in the sizes of the input. Indeed, the canonical model of the left-hand side conjunctive query is already a counter-example and of linear size. Another nice property is that containment of \textit{unions} of conjunctive queries can be reduced to containment of conjunctive queries. This is due to the following disjunctive property. For a database instance $I$ and a union of conjunctive queries $\bigcup Q_i$ it holds that $I \models \bigcup Q_i$ if and only if $I \models Q_j$ for some $j$ (Sagiv and Yannakakis, 1980).

**Conjunctive queries with atomic negation and arithmetic comparisons**

Conjunctive queries are a good language for specifying positive information. However often in practice we need to express negative information as well. Certain negative information can be expressed by expanding conjunctive queries with atomic negation, or in other words by negating subgoals of the query. For instance, the following is a conjunctive query with atomic negation

$$Q'(\texttt{e.name}) :- \text{Employee}(\texttt{id}, \texttt{p.id}, \texttt{e.name}, \texttt{b.date}), \neg \text{Manager}(\texttt{p.id}, \texttt{e.name}),$$

which asks for the names of the employees for whom there is a project they are involved in but which they are not managing. The result of applying a conjunctive query with atomic negation to a database is essentially the same as for usual conjunctive queries. The only difference is that when we apply a substitution of constants for variables the atoms in the negated subgoals must be false in the database. We distinguish a restricted form of atomic negation, called \textit{guarded}. In conjunctive queries with guarded negation, for an occurrence of a negated subgoal $\neg R(\bar{x})$ in the query there must be an occurrence of a positive subgoal $P(\bar{y})$ in the query such that the variables $\bar{x}$ are contained in the variables $\bar{y}$. Note that the negation in the query $Q'$ above is guarded. In Chapter 4 we will see that this restricted form of negation helps to reduce the complexity of containment for acyclic conjunctive queries with atomic negation.

Another important expansion of conjunctive queries is arithmetic comparisons. In this case we assume that data values come from a total order $(\text{Const}, \textless)$. In real databases, $(\text{Const}, \textless)$ can be a numeric domain such as reals, rational or natural numbers, or the domain of strings with the lexicographic order. Syntactically, in addition to relational atoms we can have arithmetic comparisons of the form $X \text{op} c$ or $X \text{op} Y$, where $X$ and $Y$ are variables, $c \in \text{Const}$ a constant and \text{op} a comparison operator in $\{=, \neq, <, >, \le, \ge\}$. The semantics is obvious: when the constants are substituted for constants, every arithmetic comparison must hold in $(\text{Const}, \textless)$.

As an example, the simple query

$$Q''(\texttt{e.name}) :- \text{Employee}(\texttt{id}, \texttt{p.id}, \texttt{e.name}, \texttt{b.date}), \texttt{b.date} \ge '1980-01-01'$$

asks for names of the employees that were born in 1980 or after. Here the order $<$ is the natural order on the timeline.

Note that arithmetic comparisons also introduce some form of negative and disjunctive information.
Datalog

Datalog is another expansion which adds recursion capabilities to conjunctive queries. A datalog program \( \Pi \) consists of rules of the same form as conjunctive queries defined above. Now the relational schema is divided into two sets of extensional (EDB predicates) and intentional (IDB predicates) relations. Extensional relations can only appear in the body of the rules of the program. Intentional relation must appear in the head of some rule of the program, and can appear in the body of the rules. A distinguished intentional predicate \( G \) is called the goal predicate.

As an example, the following program computes the transitive closure of the extensional binary relation \( R \), where \( T \) is the goal predicate:

\[
T(x, y) :\leftarrow R(x, y)
\]
\[
T(x, y) :\leftarrow R(x, z), T(z, y).
\]

Let \( \Pi \) be a datalog program, \( P \) an IDB predicate and \( I \) a database instance interpreting EDB predicates. We define the semantics of \( P \) in \( I \) w.r.t. \( \Pi \) as the fixpoint of relations \( P(I) \) defined via the following process, starting with \( P_0(I) = \emptyset \):

- Let \( I^i \) be the expansion of \( I \) with \( P_i(I) \) for all IDB predicates \( P \).
- If \( r \) is a rule with \( P(x_1, \ldots, x_k) \) in the head, \( \bar{y} \) the bound variables of \( r \) and \( \varphi(\bar{x}, \bar{y}) \) is the body of \( r \), let \( P_{r+1}(I) \) be defined as \( \{ \bar{a} \mid I^i \models \exists \bar{y}\varphi(\bar{a}, \bar{y}) \} \).

We define \( P_{i+1}(I) \) to be the union of \( P_{r+1}(I) \) over all rules \( r \) with \( P \) in the head. Then the result of \( \Pi \) on \( I \) is \( G_{\Pi}(I) \), the result of evaluating the goal predicate. By \( \Pi(I) \) we denote the minimal model of \( \Pi \) on \( I \), i.e., the union of \( I \) and \( P_{\Pi}(I) \) over all intensional predicates \( P \) of \( \Pi \).

Datalog can also be considered as a language for expressing views. If datalog is not allowed to use recursion, then we talk about UCQ-view definitions. We say that a relation \( R \) depends on a relation \( P \) w.r.t. a datalog program if there is a rule in the program such that \( R \) appears in the head and \( P \) in the body of the rule. The program is called nonrecursive if the depends relation is acyclic. Expressivity-wise nonrecursive datalog programs are exactly the unions of conjunctive queries. Indeed, this can be seen by performing unfolding. Namely, we keep replacing each intensional predicate \( P \) with the union of the bodies of the rules with \( P \) in the head, and bring the union in front. This process terminates due to the acyclicity condition of the depends relation. This way, non-recursive Datalog is a macro facility for conjunctive queries, which is very succinct. More precisely, Datalog is doubly exponential more succinct than conjunctive queries (Benedikt and Gottlob, 2010).

Query containment

Containment for queries is one of the well studied problems in database theory. A celebrated result of (Chandra and Merlin, 1977b) is NP-completeness of CQ containment. As mentioned in Chapter 1, the conjunctive query containment problem is underpinning for many other problems and thus it has been studied under various settings since the work of (Chandra and Merlin, 1977b). We review the following settings related to conjunctive query containment.
2.1. Containment for queries over relational data

- Restrictions for tractable conjunctive query containment,
- Containment of expanded conjunctive queries,
- Conjunctive query containment under constraints.

Tractable restriction for containment of conjunctive queries

Because of its importance to practice, there has been a lot of work devoted to finding natural and large classes of conjunctive queries for which containment is tractable.

One of the most prominent restrictions is acyclicity. From the lower bound proofs, it follows that NP hardness for containment is due to certain cycles in the hypergraph representation of conjunctive queries. A hypergraph is a structure with a non-empty set of vertices, and a collection of subsets of the set of vertices called hyperedges. For a given conjunctive query, the corresponding hypergraph is constructed as follows. The set of variables in the query constitutes the set of vertices. Furthermore, for every atom in the query there is a hyperedge consisting of the variables of the atom. Note that in case a conjunctive query contains atoms of arity at most 2, the corresponding hypergraph is an ordinary graph.

There is a number of non-equivalent definitions of acyclicity for hypergraphs. They are in decreasing order of restrictiveness: Berge-acyclicity, $\gamma$-acyclicity, $\beta$-acyclicity and $\alpha$-acyclicity. We refer to (Fagin, 1983) for the definitions of acyclicity and examples that the order of restrictiveness is strict. All of them, however, collapse to ordinary acyclicity in case of graphs.

In (Yannakakis, 1981) it was shown that some problems that are NP-complete in general, have PTIME algorithms with the assumption of $\alpha$-acyclicity. The evaluation problem, and thus containment, is one of them. The algorithm proposed in (Yannakakis, 1981) is based on the notion of join forest, where each node is labeled with an atom such that if a variable occurs in two atoms, then the corresponding nodes are connected and the variable occurs in each node on the unique path connecting these two nodes. Then the evaluation algorithm works in a bottom up manner on each tree of the join forest by performing a number of semi-join operations. This algorithm runs in PTIME. Gottlob et al. (2001) show that the evaluation and containment problems for $\alpha$-acyclic conjunctive queries are in fact LOGCFL-complete. The latter is the class of decision problems that are logspace reducible to a context-free language, and which allow for highly parallelizable algorithms.

Since then there have been a number of publications on generalizing this tractability result. In this direction different notions of “width” have been introduced. Intuitively, these notions of width measure how “far” the query is from being acyclic.

One such notion of width is query width from (Chekuri and Rajaraman, 2000). In this paper the authors prove that if the query width of the left hand side of the containment problem is bounded by a fixed constant $k$, then containment is decidable in polynomial time. This result extends the result of (Yannakakis, 1981) since acyclic queries are exactly of query width 1. However, one drawback of the tractability result is that it is NP-complete to decide if the query width is bounded by a given constant (Gottlob et al., 2002). In (Gottlob et al., 2002) the authors further generalize the notion of query width, with the notion of hypertree width and show that containment is solvable in polynomial
2. Background and Preliminaries

time. Furthermore, boundedness of a hypertree width by a constant is recognizable in polynomial time.

**Containment for expansions of conjunctive queries**

It is not surprising that when conjunctive queries are expanded with more expressivity capabilities, the complexity of the containment problem increases. In (Ullman, 2000) it is argued that conjunctive queries with atomic negation is $\Pi_{2}^{P}$-complete. For the upper bound, canonical databases are used. In particular, the algorithm constructs canonical models of the left hand side of the containment problem and checks if the right hand side query is true on each model. Note, there might be an exponential number of canonical models for a conjunctive query with atomic negation. In (Wei and Lausen, 2003) the authors propose an algorithm for containment of conjunctive queries with safe negation (this is when a variable occurring in a negative subgoal must occur in some positive subgoal) that can terminate earlier, but in the worst case takes the same time as the algorithm in (Ullman, 2000). As for the lower bound, Farré et al. (2007) propose a method for proving a $\Pi_{2}^{P}$ lower bound where only safe (and thus guarded) unary atoms are negated.

Containment for conjunctive queries when expanded with arithmetic comparisons also turns out to be $\Pi_{2}^{P}$-complete (Klug, 1988; van der Meyden, 1997). Afrati et al. (2004) consider various restrictions on the type of comparison operations on either of the two input conjunctive queries with comparisons, as well as on interaction between the comparisons, so that the containment is in NP (cf. Table 1 in (Afrati et al., 2004)). However, it was left open what the exact complexity of containment of conjunctive queries with comparisons of the type $X \text{op} c$, where $c$ is a constant and $\text{op} \in \{=, \neq, \leq, \geq, <, >\}$. Note that $\Pi_{2}^{P}$-lower bound proof in (van der Meyden, 1997) uses inequalities of variables, i.e., the construct $X \neq Y$ for variables $X$ and $Y$. Nevertheless, restricting arithmetic comparisons to be of the form $X \text{op} c$ does not lower the complexity. This is argued in (Farré et al., 2007), where $\Pi_{2}^{P}$-hardness of containment for CQs with comparisons was shown, using comparisons of the form $X \neq c$. This proof can also be adapted to use comparisons of the form both $X \leq c$ and $X > c$ (Nutt, 2013).

The containment problem for Datalog has also been a subject of large interest. Unfortunately, for full Datalog, containment is undecidable (Shmueli, 1993). The reason for undecidability of containment is recursion. Chaudhuri and Vardi (1997) show that when the use of recursion is forbidden in the right hand side program, containment becomes decidable. In particular, they show that containment of a datalog program in a union of conjunctive queries is $2\text{ExpTIME}$-complete. Containment of a union of conjunctive queries in a Datalog program is $\text{ExpTIME}$-complete (Cosmadakis and Kanellakis, 1986), on the other hand. Furthermore, Benedikt et al. (2005) conduct a fine-grained complexity analysis of the containment problem for various fragments of nonrecursive Datalog programs. In particular, containment for nonrecursive datalog is $\text{CONExpTIME}$-complete. In Chapter 6 we will make use of these results for nonrecursive datalog, to establish complexity bounds for the problem of extracting an ontology from a set of views.

**Containment for conjunctive queries under constraints**

Constraints are used to validate databases and thus discard unwanted ones. Typical integrity constraints for relational databases can be classified into the classes of functional
dependencies, which include key dependencies, join dependencies which include multi-valued dependencies, and inclusion dependencies (Abiteboul et al., 1995). Query containment under constraints is defined in the same way as the usual containment with the difference that quantification is only over databases that conform to the constraints. Conjunctive query containment under constraints has been studied extensively as well. It is studied in (Johnson and Klug, 1984) for the case of inclusion and functional dependencies, in (Aho et al., 1979) for multi-valued and functional dependencies, in (Dong and Su, 1996) for constraints expressed as Datalog programs, and in (Calvanese et al., 2008) for constraints expressed in Description Logic.

2.2 Containment for XPath

In this section we recall the XML data model, the syntax and semantics of XPath, its popular fragments and results on the containment problem for these languages.

2.2.1 XML and tree models

The Extensible Markup Language (XML) is a standard markup language used to represent, store and transfer data across the web. It is used to describe hierarchical data with user defined nested tags. For instance, Figure 2.1 illustrates an XML document containing a piece of information about a company. As seen from this example, the structure of the document is hierarchical, and formed by nested tags. Each tag name is called an element type, and each occurrence of a tag is an element. Each element might contain attributes. In this example each department element contains an attribute code which denotes the unique code of the department.

Usually XML documents are abstracted as labeled sibling-ordered unranked trees. Here, each element type is a label. An element can have attributes. A tree structure explicitly illustrates the hierarchical structure of XML documents. For instance, the XML document from Figure 2.1 is represented as a tree in Figure 2.2.
2. Background and Preliminaries

Let $\Sigma$ be a countably infinite set of labels that correspond to the tag names, $A$ a set of attribute names, $\text{Const}$ a set of constants, all are pairwise disjoint. Formally, an XML tree with attributes, is a tuple $(N, E, <, r, \rho, \text{att})$, where $N$, the set of nodes of the tree, is a prefix closed set of finite sequences of natural numbers, $E = \left\{ (\langle n_1, \ldots, n_k \rangle, \langle n_1, \ldots, n_k, n_{k+1} \rangle) \mid \langle n_1, \ldots, n_k+1 \rangle \in N \right\}$ is the child relation, the sibling order $<$ is defined as $\left\{ (\langle n_1, \ldots, n_k \rangle, \langle n_1, \ldots, n_k + 1 \rangle) \mid \langle n_1, \ldots, n_k \rangle, \langle n_1, \ldots, n_k + 1 \rangle \in N \right\}$, $r = \langle \rangle$ is the root of the tree, $\rho$ is the function assigning to each node in $N$ an element of $\Sigma$, and $\text{att} : N \times A \rightarrow \text{Const}$ a partial function. In this thesis we also consider multi-labeled trees which are defined in the same way as XML trees with the exception that the function $\rho$ assigns to each node a finite subset of $\Sigma$.

2.2.2 XPath and its fragments

XPath is a popular query language for XML documents that lies at the heart of the more expressive language XQuery, the XML schema languages, and the transformation language XSLT. It is used to navigate and select nodes in an XML tree. In this thesis we consider fragments and expansions of the navigational part of XPath 1.0, called Core XPath in (Gottlob et al., 2005a). Its syntax allows for composing, and taking unions of path expressions, and all boolean operations in the filter expressions. We adopt the following syntax for XPath, where $\varphi$ is a node expression, and $\alpha$ a path expression.

$$
\begin{align*}
\text{step} & ::= \downarrow \mid \uparrow \mid \leftarrow \mid \rightarrow, \\
\varphi & ::= p \mid \top \mid \neg \varphi \mid \varphi \land \varphi \mid \varphi \lor \varphi \mid \langle \alpha \rangle \varphi \\
\alpha & ::= \text{step} \mid ? \varphi \mid \alpha ; \alpha \mid \alpha \cup \alpha \mid \text{step}^+ \mid \rightarrow f \mid \leftarrow p.
\end{align*}
$$

Given a tree $T = (N, E, <, r, \rho)$, the semantics of path and node expressions are defined by a mutual induction, where $R^*$ and $R^+$ denote the reflexive transitive and transitive closure of the relation $R$ respectively:

- $\Downarrow_T = E$,
- $\Uparrow_T = E^{-1}$,
2.2. Containment for XPath

- $\larrow_T = <$
- $\larrow_T = <^{-1}$
- $[\rightarrow_f]_T = \lceil \rceil^* \circ [\rightarrow]^* \circ \lfloor \rfloor^*$
- $[\leftarrow_p]_T = [\rightarrow_f]^{-1}$
- $[?\varphi]_T = \{(n, n) \in N \times N \mid T, n \models \varphi\}$
- $[\alpha; \beta]_T = [\alpha]_T \circ [\beta]_T$
- $[\alpha \cup \beta]_T = [\alpha]_T \cup [\beta]_T$
- $[\alpha^+]_T = ([\alpha]_T)^+ \text{ for } \alpha \in \{\downarrow, \uparrow, \rightarrow, \leftarrow\}$

and

- $T, n \models \top$
- $T, n \models p \text{ iff } p \in \rho(n)$
- $T, n \models \neg \varphi \text{ iff } T, n \not\models \varphi$
- $T, n \models \varphi \land \psi \text{ iff } T, n \models \varphi \text{ and } T, n \models \psi$
- $T, n \models \varphi \lor \psi \text{ iff } T, n \models \varphi \text{ or } T, n \models \psi$
- $T, n \models \langle \alpha \rangle \varphi \text{ iff there is a node } m \text{ with } (n, m) \in [\alpha]_T \text{ and } T, m \models \varphi$

Thus, $\text{step}$ selects a pair of nodes that are in the child, parent, next-sibling or previous-sibling relations in the tree. Furthermore, the $\rightarrow_f$ and $\leftarrow_p$ axes select nodes that are in the following and the preceding relations in the tree respectively. Note that $\top$ is the same as the wild card axis known in other variants of XPath syntax.

As an example, the following path expression $\downarrow^+; ?\text{department}; \downarrow; ?\text{manager}$ selects the managers of every department from the document in Figure 2.1.

Core XPath can be extended with attribute value comparisons of the form $(\alpha_1; @a) \text{op}(\alpha_2; @b)$ and $@a \text{opc}$ as node expressions, where $a$ and $b$ are attribute names, $c$ a constant and $\text{op} \in \{=, \neq, >, <, \geq, \leq\}$. Given a tree $T = (N, E, <, r, \rho, \text{att})$ with attributes, the semantics for these expressions is as follows:

- $T, n \models (\alpha_1; @a)\text{op}(\alpha_2; @b) \text{ iff there are nodes } n' \text{ and } n'' \text{ such that } (n, n') \in [\alpha_1]_T, (n, n'') \in [\alpha_2]_T \text{ and } \text{att}(n', a)\text{opatt}(n'', b)$
- $T, n \models @a\text{opc} \text{ iff } \text{att}(n, a)\text{opc}$

Note that these constructs are available in XPath 1.0. This expansion allows us to reason about the attribute values of trees. A number of other expansions of XPath have been proposed and used in practices. XPath expanded with Kleene star for path expressions results in Regular XPath (ten Cate, 2006). XPath expanded with $\text{conditional axes}$ results in Conditional XPath (Marx, 2005). Using Kleene star, the conditional axis can be expressed as $(?\varphi; \text{step})^*$. Notably, Conditional XPath is expressively complete for FO
on XML trees. That is, every query defined in FO (over the signature for trees) can be expressed in Conditional XPath as well (Marx, 2005).

A popular fragment of XPath that has received considerable attention in the past is Tree Patterns. They can be considered to be the analog of conjunctive queries for XML. Formally, Tree Patterns is the positive downward fragment of XPath. That is, this is the fragment where in path expressions step is restricted to \( \downarrow \) only, and only the test, the transitive closure and compositions of paths are allowed. In node expressions, disjunction and negation are disallowed. For instance, the expression \( \downarrow \; \) ?department; \( \downarrow \; \) ?manager is also a Tree Pattern. A much more succinct syntax is very common:

\[
q := l | \star | . | q/q | q//q | q[q]
\]

In this grammar, \( l \) is a label, \( \star \) is the wildcard, \( . \) denotes the current node. Then \( / \) and \( // \) denote the child and descendant constructs, and \( [ ] \) is a filter expression. In (Miklau and Suciu, 2004) this fragment is denoted as \( \text{XP}^{[\;],\star,\\}//) \). In this more succinct syntax, the above expression can be written as \( //\text{department}/\text{manager} \). Tree patterns allow for a nice graphical representation, just like XML documents. That is, a tree pattern can be considered as a tree where each node is labeled by a label or by a wildcard, and with two types of edges: child and descendant edges. For instance, the expression \( //\text{department}[/\text{"Supply"]}/\text{member}/\star \) asks for all members of the department of supply. It can be represented as a tree on Figure 2.3. The square node is the output node. With this tree representation, tree patterns admit an equivalent semantic characterization via an embedding (Miklau and Suciu, 2004). Let \( t \) be a tree pattern \( (N', E_f, E_{//}, r', l) \), where \( E_f \) and \( E_{//} \) are the child and descendant edges respectively, and \( T = (N, E, r, \rho) \) an XML tree (the order \( < \) is omitted since tree patterns are oblivious to the sibling order). Then a mapping \( e : N' \to N \) is called an embedding if all of the following conditions are met

**(root preservation)** \( e(r') = r \),

**(label preservation)** For every \( x \in N' \), \( \rho(x) = \star \) or \( \rho(x) = l(e(x)) \),
2.2. Contains for XPath

(child-edge preservation) If $x E / y$, then $e(x)Ee(y)$,

descendant-edge preservation) If $x E // y$, then $e(x)E^+e(y)$.

For complete results on the evaluation problem for XPath, we refer the reader to the overview paper (Benedikt and Koch, 2009).

2.2.3 XPath query containment

The containment problem for various XPath fragments has been a topic of wide interest for the past several years. A polynomial time algorithm for tree patterns without the wildcard based on homomorphism between queries was given in (Amer-Yahia et al., 2002). The main result of Miklau and Suciu (2004) is the \( \text{coNP} \)-completeness of containment of tree patterns with the wildcard. Almost a complete picture of the containment problem for the XPath fragments with disjunction, in the presence of DTDs and variables was given in (Neven and Schwentrick, 2006). Notably, it was shown that with a finite alphabet the containment problem rises to \( \text{PSPACE} \). Wood (2003) gives decidability results for various fragments with DTDs and a class of integrity constraints. XPath containment in the presence of dependency constraints was studied in (Deutsch and Tannen, 2001, 2005). A thorough investigation and overview of the results on the containment problem for tree patterns with or without constraints has recently been presented in (Czerwinski et al., 2015).

A closely related problem is XPath satisfiability (Benedikt et al., 2008; Hidders, 2003). Given an XPath expression, the satisfiability problem asks whether there exists a tree (conforming constraints if necessary) such that the result of evaluating the expression on the tree is not empty. Benedikt et al. (2008) contains an almost complete picture for the complexity of the satisfiability problem with or without the presence of constraints for various fragments of XPath. Query containment reduces to XPath satisfiability in fragments with enough expressive power (e.g. with negation and filter expressions).

Afrati et al. (2011) consider the containment problem for tree patterns with general arithmetic comparisons. They add the ability to compare the value of an attribute in two different nodes (note that this is not expressible in Core XPath) and show that containment for this fragment is \( \Pi_2^P \)-complete. As mentioned in the introduction, we extend their \( \text{coNP} \) result for tree patterns with attribute value comparisons.

We end with some results on tractable (\( \text{PTIME} \)) containment. As mentioned above, Amer-Yahia et al. (2002) provides a \( \text{PTIME} \) algorithm for containment of tree patterns without the wildcard. \( \text{PTIME} \) containment for acyclic conjunctive queries implies tractability for containment of tree patterns without descendant. Moreover, containment for tree patterns without filters is in \( \text{PTIME} \) as well (Miklau and Suciu, 2004). However, adding attribute value comparisons may raise the complexity. For instance, as shown below in Chapter 3 (Proposition 3.3.4), containment for tree patterns without the wildcard together with equality and inequality attribute comparisons is \( \text{coNP} \)-hard.

2.2.4 Conjunctive queries interpreted over trees and containment

Conjunctive queries can also be interpreted over unranked trees. In this case the relational schema consists of relation names corresponding to the axes relations \( \text{Child}, \ldots \)
2. Background and Preliminaries

NextSibling, Descendant, NextSibling\(^+\) and Following. Then the semantics of conjunctive queries on trees over such schema is defined in the same way as the semantics of conjunctive queries over relational databases.

A systematic study of conjunctive queries interpreted over trees started in (Gottlob et al., 2006), where the central problem was the evaluation problem. The authors established a \(\text{PTIME}\) and \(\text{NP}\) dichotomy of the problem. The containment problem for this language was considered in (Björklund et al., 2011), where it was shown to be \(\Pi^P_2\)-complete. The \(\Pi^P_2\) upper bound was shown via the small counter-example property, similar to the one in (Miklau and Suciu, 2004). On the other hand, the \(\Pi^P_2\) lower bound proof heavily relies on the DAG structure of conjunctive queries. Containment of conjunctive queries under schema constraints was studied in (Björklund et al., 2008), where \(2\text{ExpTIME}\)-completeness of the problem was established.

2.3 Why and why-not explanations

An increasing number of databases are derived, extracted, or curated from disparate data sources. Consequently, it becomes more and more important to provide data consumers with mechanisms that will allow them to gain an understanding of the data that they are confronted with. An essential functionality towards this goal is the capability to provide meaningful explanations about why data is present or missing from the result of a query. Explanations help data consumers gauge how much trust one can place on the result. Perhaps more importantly, they provide useful information for debugging the query or data that led to incorrect results.

There have been a number of publications on why explanations (that is, for why particular data is present in the query result) and why-not explanations (that is, for why particular data is missing from the query result). Why explanations have been thoroughly studied in the past in the context of provenance and lineage, see (Cheney et al., 2009). In contrast, models for why-not explanations have only appeared fairly recently. We now review the main approaches to both why and why-not explanations.

2.3.1 Why explanations

The general formulation of the why-problem is as follows. Given a database \(I\), a query \(Q\), its computed result \(Q(I)\) and a tuple \(\bar{a} \in Q(I)\), explain why this tuple is in the query result, i.e., why \(\bar{a} \in Q(I)\)? One of the first models for why explanations in the context of databases is called lineage which has been proposed in (Cui et al., 2000). In this model, the lineage of \(\bar{a}\) is a collection of “source” tuples from the database \(I\) which “helped” to produce \(\bar{a}\). For instance, let \(I\) be the database containing two tables \(T_1\) and \(T_2\) as in Figure 2.4. For convenience, each row of the database has a tag. Now suppose we pose the conjunctive query

\[
Q'(x, y) :- T_1(x, y), T_2(y, z),
\]

which has the answer set \(Q'(I) = \{(1, A), (2, B)\}\). Then the lineage of the tuple \((2, B)\) are the tuples \(t_2\) and \(t_6\). The lineage of \((1, A)\), on the other hand, consists of \(t_1\) and \(\{t_4, t_5\}\). The latter shows one of the shortcomings of the lineage model. That is, an
2.3. Why and why-not explanations

Figure 2.4: Example database.

<p>| | | | |</p>
<table>

<td>t_6 :</td>
</tr>
</tbody>
</table>

explanation might not be as precise as one might like, as it does not specify that the
tuples $t_4$ and $t_5$ need not be together to witness the tuple $(1, A)$.

In fact, either of the “witnesses” $\{t_1, t_4\}$ or $\{t_1, t_5\}$ would be enough for explaining
the tuple $(1, A)$. This is formalized in the notion of why provenance which captures such
different witnesses (Buneman et al., 2001). According to this model, an explanation (or a
witness) to why $\bar{a} \in Q(I)$ is a part of the database $I' \subseteq I$ that is enough to ensure that $\bar{a}$
is in the output, i.e., $\bar{a} \in Q(I')$. Besides the two witnesses provided above for the query
$Q'$, the set $\{t_1, t_4, t_5\}$ is a witness for the tuple $(1, A)$ as well. There might be multiple
witnesses, in fact exponentially many of them. For that reason, why provenance of $\bar{a}$ in
(Buneman et al., 2001) is defined as a particular set of small witnesses, called witness
basis of $\bar{a}$. The witness basis can be seen as a compact representation of the space of all
witnesses, as every element of a witness contains an element from the witness basis. In
our example, $\{\{t_1, t_4\}, \{t_1, t_5\}\}$ is the witness basis for $(1, A)$.

Another form for explanations that has been proposed in (Buneman et al., 2001)
is “where-provenance”. Where-provenance describes the way how the source and the
output locations are related. A location for a data value is a cell defined by a table name,
a tuple in the table and an attribute name. Then the where-provenance of an output value
is the location where this valued was copied from. For instance, the where-provenance
for the value “2” in the output of $Q'$ is $(T_1, t_2, 1)$, i.e., it is the first attribute of tuple $t_2$ in
table $T_1$.

The above models for why-provenance and where-provenance do not, however, explain how the source tuples contributed to the output tuple. This issue has been addressed in (Green et al., 2007b) using the notion of a provenance semiring. According to Green et al. (2007b), the provenance of an output tuple is represented by a polynomial using the semiring operations with integer coefficients where each variable is a source tuple. Such a polynomial hints to the structure of the proof (or the query plan) how the output tuple has been derived. Note that although query plans for equivalent queries are different, their provenance polynomials are always equivalent in the semiring. Moreover, from provenance polynomials we can easily read the why-provenance of an output tuple. As an example, let

\[ Q''(x, y) : = T_1(x, y), (T_1(x, z) \lor T_2(y, u)) \]

be a query, for which the tuple $(2, B)$ is in the output of $Q''(I)$. Then the provenance of
this tuple is the polynomial $t_2 \cdot (t_2 + t_6)$. This polynomial hints that $t_2$ and $t_6$ contribute
to the output of the inner query $(T_1(x, z) \lor T_2(y, u))$ and then $t_2$ contributes to the join.
For comparison, the why-provenance of this tuple according to (Buneman et al., 2001) is the set $\{t_2, t_6\}$.

It is worth to note that in all the models above there could be multiple solutions (explanations), many of which are not useful or redundant to the user. Thus, certain pref-
ference criteria are imposed in order to single out “good” or “interesting” explanations. Note also that the above models (except for the lineage model of (Cui et al., 2000)) assume the queries to be monotone. The presence of negation in queries causes some nice properties to disappear. Overall, the principles of provenance in the presence of negation and aggregation have not been fully understood yet (Cheney et al., 2009).

We end with some applications and implementations of the above models of the why problem. Algorithms for computing lineage have been implemented in the WHIPS data warehouse system (Cui and Widom, 2000). Minimal witnesses from (Buneman et al., 2001) have been used in (Buneman et al., 2002) for the view deletion problem, i.e., the problem of finding source tuples to remove in order to remove the tuple from the view expressed as the union of conjunctive queries. Where-provenance has been applied to study annotation propagation in (Buneman et al., 2002), and implemented in an annotation management tool (Bhagwat et al., 2005). An application of how-provenance based on semirings appears in the context of ORCHESTRA (Green et al., 2007a), a collaborative data sharing system.

### 2.3.2 Why-not explanations

The input for the why-not problem is almost the same as for why problem. Given a database $I$, a query $Q$, its computed result $Q(I)$ and a tuple $\bar{a} \not\in Q(I)$, explain why the tuple $\bar{a}$ is missing from the query result $Q(I)$. As opposed to why explanations in which the output tuple can be explained using the derivation or query plan, for why-not explanations the situation is different. Indeed, in this case we cannot talk about witnesses since there is no derivation to begin with. There have been a number of proposals for why-not explanations in the literature which can be classified into two groups: query-driven and data-driven approaches.

**Query-driven approaches.** In query-driven approaches, a reason for why a tuple is missing from the query result lies in the query itself. In (Chapman and Jagadish, 2009), an explanation is a query operator (e.g., selection) that prevented the given tuple from appearing in the query result. This approach was defined for the class of unions of conjunctive queries. In (Bidoit et al., 2014a) it was further extended to deal with aggregate queries. One of the shortcomings of the algorithms proposed in these articles is that the generated explanations are dependent on a particular query plan. As a consequence, these algorithms might produce different explanations for the same query and may miss some of them. To tackle this problem, Bidoit et al. (2014b) proposed explanations in the form of polynomials, similarly to the approach of (Green et al., 2007b).

In (Tran and Chan, 2010), an explanation is not an operator, but a relaxation (or refinement) of the original query such that it contains the missing tuple while retaining the previous results. As there are many possible refinements, a preference condition is imposed as well. A similar type of explanations are considered in (He and Lo, 2012) for reverse top-k queries and in (Islam et al., 2013) for reverse skyline queries.

**Data-driven approach.** In data-driven approaches, the assumption is that the query is correct and only the database lacks certain information allowing to infer the needed
2.3. Why and why-not explanations

query results. In (Huang et al., 2008b), an explanation is a sequence of updates to the database such that the missing tuple is present in the query result. In this paper the attention is restricted to conjunctive queries. Herschel and Hernández (2010) extend this approach to the class of unions of conjunctive queries with aggregation and grouping.

Calvanese et al. (2013) consider the why-not question in the context of ontology-based data access (OBDA). In this setting, queries are restricted to be unions of conjunctive queries and defined over a possibly richer vocabulary than the database schema. An explanation is now a database (or an ABox, in description logic notation) such that the tuple is present in the result of the query asked against the combination of the new and the original databases. Calvanese et al. (2013) phrase this problem as an abductive reasoning problem. In such a setting, one imposes a preference (or minimality) condition on the space of possible explanations which allows to leave out trivial explanations. As opposed to the previous papers on why-not explanations whose focus is the problem of producing explanations, the main focus of (Calvanese et al., 2013) is to study the computational complexity of associated problems (e.g., the problem of existence of an explanation).

In Chapter 6 we introduce a new framework for why-not explanations which is neither query-driven nor data-driven. In our approach we do not propose a fix to a query or a database, but rather give a hint to a possible general pattern or a gap in the data. In particular, an explanation is a tuple of concepts that “generalizes” the missing data and thus gives a high level explanation to why this data is missing. As an example, given a database of train connections, and the query asking for pairs of cities reachable from each other, one can see that the tuple ⟨New York, Amsterdam⟩ is missing from the query result. One possible high-level explanation is the tuple ⟨AmericanCity, EuropeanCity⟩, which denotes that fact that there is no train connection between any two cities of America and Europe, and thus it explains the fact why ⟨New York, Amsterdam⟩ is missing. As in (Calvanese et al., 2013) we impose a preference condition on explanations. More precisely, we prefer most general explanations, i.e., explanations such that there is no strictly more general explanation. For instance, the tuple ⟨AmericanCity, EuropeanCity⟩ is strictly more general concept tuple than ⟨NorthAmericanCity, DutchCity⟩.

In order to reason about concepts like AmericanCity and EuropeanCity, we make use of ontologies that provide a formal specification of the relationships between concepts. The use of ontologies to facilitate access to databases is not new. A prominent example is OBDA mentioned earlier, where queries are either posed directly against an ontology, or an ontology is used to enrich a data schema against which queries are posed with additional relations, namely, the concepts from the ontology (Bienvenu et al., 2013; Poggi et al., 2008). Answers are computed based on an open-world assumption and using the mapping assertions and ontology provided by the OBDA specification. However, unlike in OBDA, in our framework we consider queries posed against a database instance under the traditional closed-world semantics, and the ontology is used only to derive why-not explanations.
Part I

Containment Problem for Acyclic Queries
3

Containment for Queries over Trees with Attribute Value Comparisons

In this chapter we address RQ 1 for expanded conjunctive queries (CQ) and positive XPath (PosXPath) interpreted over trees. Björklund et al. (2011) showed that containment for CQ and PosXPath is respectively $\Pi^P_2$ and $\text{coNP}$-complete. In this chapter we show that the same problem has the same complexity when we expand these languages with XPath’s attribute value comparisons. We show that different restrictions on the domain of attribute values (finite, infinite, dense, discrete) have no impact on the complexity. Making attributes required does have an impact: the problem becomes harder. We also show that containment of tree patterns without the wildcard $\ast$, which is in PTIME, becomes $\text{coNP}$-hard when adding equality and inequality comparisons.

3.1 Introduction

In this chapter we study the containment problem for positive XPath (PosXPath) and conjunctive queries (CQ) interpreted over finite unranked ordered trees with respect to the axes $\text{Child}$, $\text{NextSibling}$, $\text{Descendant}$, $\text{NextSibling}^+$ and $\text{Following}$. PosXPath is a large fragment of Core XPath (Gottlob et al., 2005a) that contains all the axes and constructs except negation. Conjunctive queries over trees are an analog of relational conjunctive queries, which correspond to the select-from-where SQL queries in which the where-condition uses only conjunctions of equality comparisons, and are the most widely used query language in practice. A thorough study of the containment problem for CQ over trees has been carried out in (Björklund et al., 2011). Their main result is $\Pi^P_2$-completeness of the problem. In fact, conjunctive queries can be reformulated as the positive fragment of Core XPath with path intersection. Thus, the $\Pi^P_2$ hardness result also holds for the containment problem for this fragment. Inspection of the proof in (Björklund et al., 2011) also indicates that the containment for just PosXPath remains in $\text{coNP}$. This extends the result of Miklau and Suciu (2004), who showed that containment for tree patterns is $\text{coNP}$-complete.

The query language considered in these previous results ignores attributes. However, in many practical scenarios we deal with data that come from numeric domains, such as real or natural numbers. Thus, it is natural to consider conjunctive queries expanded with attribute value comparisons and study basic static analysis problems such as satis-
3. Containment for Queries over Trees with Attribute Value Comparisons

fiability and containment. Such an expansion has been considered for Tree Patterns in (Afrati et al., 2011), where a \( \Pi_2^p \)-completeness result for the containment has been established. However, the hardness proof relies on the construct that allows comparisons of attributes of two different nodes, a feature that is not expressible in Core XPath. As a positive counterpart, a \( \text{coNP} \) upper bound for containment was shown in the case when comparisons are restricted to either so-called left semi-interval or right semi-interval attribute constraints. For an attribute \( a \) and constant \( c \), an attribute constraint \( (\mathtt{@}a \text {op} c) \) is left semi-interval if \( \text{op} \in \{<,\leq,=\} \).

In this chapter we show that essentially the complexity does not increase if positive XPath and conjunctive queries over trees are expanded with both left and right semi-intervals constraints together with inequality constraint. Furthermore, the same upper bounds hold when we make certain assumptions on the underlying attribute domain \( D \). That is, we show that all the complexity results still hold for the cases when \( D \) is a dense or discrete infinite linear order, with or without endpoints, or a finite linear order. As another result, we show that by requiring at least one attribute to be defined in every node of a tree, the complexity of containment over such trees rises to \( \text{PSPACE} \). If, on the other hand, we require attributes to be defined only at nodes with a certain label (which can be expressed in DTDs) the complexity remains in \( \text{coNP} \).

All the upper bound results for both \( \text{PosXPath} \) and \( \text{CQ} \) are obtained from a suitable polynomial reduction to the containment problem in \( \text{PosXPath}^\neg \) and \( \text{UCQ}^\neg \) (\( \text{PosXPath} \) and \( \text{CQ} \) expanded with safe label negation and union) over trees in which nodes may have multiple labels, respectively. Safe label negation is the construct \( p \setminus \{q_1, \ldots , q_n\} \) which denotes \( p \)-labelled nodes that are not labelled with any of the labels \( q_1, \ldots , q_n \). Table 3.1 summarizes our results.

**Organization**

The chapter is organized as follows. Section 3.2 contains all the necessary preliminary notions. Section 3.3 contains the main results. In particular, in Subsection 3.3.1 we show that containment for \( \text{UCQ}^\neg \) and \( \text{PosXPath}^\neg \) is in \( \Pi_2^p \) and \( \text{coNP} \) respectively. Next in Subsection 3.3.2 we consider containment for \( \text{CQ}^{\neg \alpha} \) and \( \text{PosXPath}^{\neg \alpha} \) and show the same upper bounds by reducing to the previous problem. Then in Subsection 3.3.3 we show that the upper bounds of containment do not change in case of some natural restrictions on the attribute domain. Section 3.3.4 contains lower bounds: containment of tree patterns without wildcard rises from \( \text{PTIME} \) to \( \text{coNP} \) when we add equality and inequality comparisons; containment of tree patterns rises from \( \text{coNP} \) to \( \text{PSPACE} \) when we add equality and inequality comparisons and interpret them on trees in which at least one attribute is defined at each node (a so-called *required* attribute). We finish the chapter with conclusions and future work.

### 3.2 Preliminaries

We work with node-labelled ordered unranked finite trees, where the nodes are labeled by finite subsets of the infinite set of labels \( \Sigma \). Formally, a tree over \( \Sigma \) is a tuple \( (N,E,<,r,\rho) \), where \( N \), the set of nodes of the tree, is a prefix closed set of finite sequences of natural numbers, \( E = \{(\langle n_1, \ldots, n_k \rangle, \langle n_1, \ldots, n_k, n_{k+1} \rangle) \mid \langle n_1, \ldots, n_{k+1} \rangle \in N\} \) is

Table 3.1: Complexity results for containment of Positive XPath and CQ with attribute value comparisons.

the child relation, the sibling relation \(<\) is defined as \(\{(\langle n_1, \ldots, n_k \rangle, \langle n_1, \ldots, n_k + 1 \rangle) \mid (n_1, \ldots, n_k), (n_1, \ldots, n_k + 1) \in N\}, r = \langle \rangle\) is the root of the tree, and \(\rho\) is the function assigning to each node in \(N\) a finite subset of \(\Sigma\). If for every node \(n\) of a tree \(\rho(n)\) is singleton, we call such a tree as a single-labeled tree. Otherwise, it is multi-labeled. A pointed tree is a pair \(T, n\), where \(n\) is a node in \(T\).

Let \(A\) be a set of attribute names and \((D, <)\) a dense linear order without endpoints. Then a tree with attributes from \(A\) over \(\Sigma\) is a tuple \((N, E, <, r, \rho, \text{att})\) such that \((N, E, <, r, \rho)\) is a tree over \(\Sigma\) and \(\text{att} : N \times A \rightarrow D\) is a partial function.

By \(E^+\) and \(<^+\) we denote the descendant and the following sibling relations which are transitive closures of the child and sibling relations respectively. We will also use \(<_f\) for the following relation, i.e., the abbreviation for \((E^{-1})^* \circ <^+ \circ E^*\). For \(x, y \in N\) and \(R \in \{E, E^+, <, <^+, <_f\}\), by \(T \models xRy\) we denote the fact that \((x, y) \in R\).

Positive XPath with attribute value comparisons. We define the syntax of Positive XPath (denoted as PosXPath\(\text{\textregistered}\)) node and path formulas with attribute value comparisons with the following grammar.

\[
\begin{align*}
\text{step} & ::= \downarrow | \uparrow | \leftarrow | \rightarrow, \\
\varphi & ::= p | T | \oplus_a \text{op} c | \varphi \land \varphi | \varphi \lor \varphi | \langle \alpha \rangle \varphi \\
\alpha & ::= \text{step} | ?\varphi | \alpha;\alpha | \alpha \cup \alpha | \text{step}^+ | \rightarrow_\ell | \leftarrow_p,
\end{align*}
\]

where \(p \in \Sigma, a \in A, \text{op} \in \{\leq, \geq, <, >, =, \neq\}\), and \(c \in D\).

The semantics of PosXPath\(\text{\textregistered}\) path formulas \(\alpha\) and node formulas \(\varphi\) is defined as follows. Let \(T = (N, E, <, r, \rho, \text{att})\) be a tree over \(\Sigma\) with attribute names from \(A\). In a mutual induction we define the relation \([\alpha]_T \subseteq N \times N\) and the satisfaction relation \(T, n \models \varphi\).

- \([\downarrow]_T = E,\)
- \([\uparrow]_T = E^{-1},\)
- \([\rightarrow]_T = <,\)
- \([\leftarrow]_T = <^-,\)
- \([\rightarrow_\ell]_T = <_f,\)
- \([\leftarrow_p]_T = (<_f)^{-1},\)
- \([?\varphi]_T = \{(n, n) \in N \times N \mid T, n \models \varphi\},\)
3. Containment for Queries over Trees with Attribute Value Comparisons

- \([\alpha; \beta]_T = [\alpha]_T \circ [\beta]_T\),
- \([\alpha \cup \beta]_T = [\alpha]_T \cup [\beta]_T\),
- \([\alpha^+]_T = ([\alpha]_T)^+ \text{ for } \alpha \in \{\downarrow, \uparrow, \rightarrow, \leftarrow\}\),

and

- \(T, n \models T\),
- \(T, n \models p \iff p \in \rho(n)\),
- \(T, n \models @_a \alpha \circ p \iff (D, <) \models \text{att}(n, a) \circ \alpha \circ c\),
- \(T, n \models \varphi \land \psi \iff T, n \models \varphi \text{ and } T, n \models \psi\),
- \(T, n \models \varphi \lor \psi \iff T, n \models \varphi \text{ or } T, n \models \psi\),
- \(T, n \models (\alpha)\varphi \iff \text{there is a node } m \text{ with } (n, m) \in [\alpha]_T \text{ and } T, m \models \varphi\).

The step axes select a pair of nodes that are in the child, parent, next-sibling or previous-sibling relations in the tree. Furthermore, the \(\rightarrow_T\) and \(\leftarrow_p\) axes select nodes that are in the following and the preceding relations in the tree respectively. Note that \(T\) is the same as the wild card axis.

Sometimes we will write \(T \models \varphi\) to denote \(T, r \models \varphi\).

Conjunctive queries with attribute value comparisons. Let \(Var\) be a set of variables, \(A\) a set of attribute names and \((D, <)\) the attribute domain, which is a dense linear order without endpoints. A conjunctive query with attribute value comparisons (CQ\(^\circ\)) over \(\Sigma\), \(A\) and \(D\) is a positive existential first-order formula without disjunction in prenex normal form over a set of unary predicates \(p(x)\) and \(@_a (x) \alpha \circ c\), where \(p \in \Sigma\), \(x \in Var\), \(c \in D\) and \(\alpha \in \{\leq, \geq, <, >, =, \neq\}\); and the binary predicates \(Child, Descendant, NextSibling, NextSibling^+\) and Following. If \(Q\) is a CQ\(^\circ\), by \(Var(Q)\) we denote the set of variables occurring in \(Q\). By \(FVar(Q)\) we denote the set of free variables in \(Q\). If \(|FVar(Q)| = k \geq 0\), we call \(Q\) a \(k\)-ary conjunctive query. If \(|FVar(Q)| = 0\), we call \(Q\) a Boolean conjunctive query.

Let \(Q\) be a conjunctive query and \(T = (N, E, <, r, \rho, att)\) a tree over \(\Sigma\) and attributes from \(A\). A valuation of \(Q\) on \(T\) is a total function \(\theta : Var(Q) \rightarrow N\). A valuation is a satisfaction if it satisfies the query, that is, every atom of \(Q\) is satisfied by the valuation. Satisfaction of an atom in \(T\), given a valuation \(\theta\), is defined as follows.

- \(T, \theta \models p(x) \iff p \in \rho(\theta(x))\),
- \(T, \theta \models @_a (x) \alpha \circ c \iff (D, <) \models \text{att}(\theta(x), a) \circ \alpha \circ c\),
- \(T, \theta \models Child(x, y) \iff T \models \theta(x) E \theta(y)\),
- \(T, \theta \models Descendant(x, y) \iff T \models \theta(x) E^+ \theta(y)\),
- \(T, \theta \models NextSibling(x, y) \iff T \models \theta(x) < \theta(y)\),
- \(T, \theta \models NextSibling^+(x, y) \iff T \models \theta(x) <^+ \theta(y)\),
3.2. Preliminaries

- \( T, \theta \models Following(x, y) \) iff \( T \models \theta(x) <_f \theta(y) \)

A tree \( T \) models \( Q \), denoted as \( T \models Q \), if there is a satisfaction of \( Q \) on \( T \). If \( (x_1, \ldots, x_k) \) is the tuple of free variables in \( Q \), then the answer of \( Q \) over \( T \) is the set \( \text{answer}(Q, T) = \{(\theta(x_1), \ldots, \theta(x_k)) \mid \theta \text{ is a satisfaction of } Q \text{ on } T\} \). Note that tuples can be nullary as well. Thus, for a Boolean query \( Q \), \( \text{answer}(Q, T) = \{()\} \) (and we say \( Q \) is true on \( T \)) if there is a satisfaction of \( Q \) on \( T \) and \( \text{answer}(Q, T) = \emptyset \) (and we say \( Q \) is false on \( T \)) otherwise.

We also consider unions of conjunctive queries with attribute value comparisons, denoted as \( \text{UCQ}^\alpha \). These are formulas of the form \( \bigvee_{i=1}^n Q_i \), where \( Q_i \in \text{CQ}^\alpha \). The semantics of these formulas is defined in the obvious way.

\( \text{PosXPath}^\alpha \) formulas as \( \text{CQ}^\alpha \) formulas with disjunction. Every \( \text{PosXPath}^\alpha \) formula can be translated into an equivalent \( \text{CQ}^\alpha \) formula with disjunction in linear time. The translation is a standard translation of XPath into first-order logic language. It is defined by induction on the complexity of path and node formulas of \( \text{PosXPath}^\alpha \) as follows. Note that the translation can be easily modified to yield a translation into the three variable fragment of first order logic.

\[
\begin{align*}
TR_{xy}(\downarrow) & = Child(x, y) \\
TR_{xy}(\uparrow) & = Child(y, x) \\
TR_{xy}(\rightarrow) & = NextSibling(x, y) \\
TR_{xy}(\leftarrow) & = NextSibling(y, x) \\
TR_{xy}(? \varphi) & = x = y \land TR_x(\varphi) \\
TR_{xy}(\alpha_1; \alpha_2) & = \exists z. (TR_{xz}(\alpha_1) \land TR_{zy}(\alpha_2)) \quad \text{where } z \text{ is a fresh variable.} \\
TR_{xy}(\alpha_1 \cup \alpha_2) & = TR_{xy}(\alpha_1) \lor TR_{xy}(\alpha_2) \\
TR_{xy}(\downarrow^+) & = Descendant(x, y) \\
TR_{xy}(\uparrow^+) & = Descendant(y, x) \\
TR_{xy}(\rightarrow^+) & = NextSibling^+(x, y) \\
TR_{xy}(\leftarrow^+) & = NextSibling^+(y, x) \\
TR_{xy}(\rightarrow_+) & = Following(x, y) \\
TR_{xy}(\leftarrow_+) & = Following(y, x) \\
TR_x(p) & = p(x) \\
TR_x(\text{@}_a \text{op } c) & = \text{@}_a(x) \text{ op } c \\
TR_x(\top) & = \top \\
TR_x(\varphi_1 \land \varphi_2) & = TR_x(\varphi_1) \land TR_x(\varphi_2) \\
TR_x(\varphi_1 \lor \varphi_2) & = TR_x(\varphi_1) \lor TR_x(\varphi_2) \\
TR_x(\langle \alpha \rangle \varphi) & = \exists y. (TR_{xy}(\alpha) \land TR_{y\varphi}(\varphi)), \quad \text{where } y \text{ is a fresh variable.}
\end{align*}
\]

Query graphs and embeddings. It is convenient to consider \( \text{CQ}^\alpha \) and \( \text{PosXPath}^\alpha \) without path union and disjunction in the node formulas as graphs (Gottlob et al., 2006).

By \( \Sigma_A \) we denote the attribute labels of the form \( \text{@}_a \text{op } c \), where \( a \in A, c \in D \) and \( \text{op} \in \{\leq, \geq, <, >, =, \neq\} \).
3. Containment for Queries over Trees with Attribute Value Comparisons

**Definition 3.2.1** (Graph query). Let $Q$ be a CQ$^\oplus$. Then $G_Q = \langle V, E, E^+, <, <=, <f, \rho, \rho_{\text{att}} \rangle$, where $V$ is the set of nodes, $R \subseteq V \times V$ for $R \in \{E, E^+, <, <=, <f\}$, $\rho : V \to 2^A$, $\rho_{\text{att}} : V \to 2^{\Sigma_A}$, is a graph query of $Q$ if the following holds.

- $V = \text{Var}(Q)$.
- $p \in \rho(x)$ iff $p(x)$ occurs as a conjunct in $Q$.
- $@_a \text{op} c \in \rho_{\text{att}}(x)$ iff $@_a(x)\text{op} c$ occurs as a conjunct in $Q$.
- $(x,y) \in E$ iff $\text{Child}(x,y)$ occurs as a conjunct in $Q$.
- $(x,y) \in E^+$ iff $\text{Descendant}(x,y)$ occurs as a conjunct in $Q$.
- $(x,y) \in <$ iff $\text{NextSibling}(x,y)$ occurs as a conjunct in $Q$.
- $(x,y) \in <=$ iff $\text{NextSibling}^+(x,y)$ occurs as a conjunct in $Q$.
- $(x,y) \in <f$ iff $\text{Following}(x,y)$ occurs as a conjunct in $Q$.

By $\text{Nodes}(G)$ we denote the set of nodes $V$ of $G$. We write $G_Q \models u_1Ru_2$, to specify that $(u_1, u_2) \in R$ for $R \in \{E, E^+, <, <=, <f\}$. Note that for fragments without attribute value comparisons, the value of the labeling function $\rho_{\text{att}}$ is always the empty set. In these cases we omit $\rho_{\text{att}}$ in query graphs. The semantics of query graphs is given in terms of embeddings, which are essentially valuations for conjunctive queries.

**Definition 3.2.2** (Embedding). Let $T = (N, E, <, r, \rho, \text{att})$ be a tree over $\Sigma$ with attributes from $A$ and $G = (V, E, E^+, <, <=, <f, \rho, \rho_{\text{att}})$ a graph query. A function $g : V \to N$ is called an embedding of $G$ into $T$ if the following conditions are satisfied.

- **Edge preserving.** For every $u_1, u_2 \in V$, if $G \models u_1Ru_2$ then $T \models g(u_1)Rg(u_2)$, for any of the edge relations $R \in \{E, E^+, <, <=, <f\}$.
- **Label preserving.** For every $u \in V$, $\rho(u) \subseteq \rho(g(u))$.
- **Attribute comparison preserving.** For every $u \in V$, if $@_a \text{op} c \in \rho_{\text{att}}(u)$, then $(D, <) \models \text{att}(e(u), a) \text{op} c$.

**Proposition 3.2.1.** Let $T$ be a tree, $Q$ a CQ$^\oplus$ query, $G_Q$ its graph query, and $\theta$ a function from $\text{Nodes}(G_Q)$ to $T$. Then

$$T, \theta \models Q \ \text{iff} \ \theta \text{ is an embedding of } G_Q \text{ into } T.$$

**Containment.** Let $Q$ and $P$ be two $k$-ary conjunctive queries. We say that $P$ is contained in $Q$, denoted as $P \subseteq Q$, if for every single-labeled tree $T$, it holds that $\text{answer}(P,T) \subseteq \text{answer}(Q,T)$. We also say that $P$ is contained in $Q$ over multi-labeled trees and denote it by $P \subseteq_{\text{ML}} Q$ if $\text{answer}(P,T) \subseteq \text{answer}(Q,T)$ for every multi-labeled tree $T$.

In this chapter, the central problem is the following decision problem.

- Given two conjunctive queries $P$ and $Q$,
- Decide: is $P \subseteq Q$?
As pointed out in (Björklund et al., 2011), the containment of \(k\)-ary queries can be \(\text{PTIME}\) reduced to the containment of Boolean conjunctive queries, i.e., queries without free variables. The same reduction works for positive XPath and for containment over multi-labeled trees. Thus, in the remainder of this chapter we concentrate on Boolean query containment only.

Removing the attribute value comparisons. In our upper bound proofs we will treat the attribute value comparisons as ordinary labels, whose interpretation will be restricted by adding constraints. We make that precise using the translation \(\tilde{\cdot}\) which maps each \(\tilde{\alpha}\_a\op c\) to a new label \(p\_\alpha\_a\op c\). This translation can then be homomorphically extended to the translation \(\tilde{\cdot}\) from formulas in PosXPath\(\widehat{\alpha}\) and CQ\(\widehat{\alpha}\) over \(\Sigma, A\) and \(D\) to formulas without attribute value comparisons in respectively PosXPath and CQ over the alphabet \(\Sigma \cup \{p\_\alpha\_a\op c \mid \op \in \{=, \neq, <, >, \leq, \geq\}, a \in A, c \in D\}\).

PosXPath and CQ with safe negation

We define an expansion of the languages PosXPath\(\widehat{\alpha}\) and CQ\(\widehat{\alpha}\) (UCQ\(\widehat{\alpha}\)) with a restricted form of negation. That is, we define formulas of PosXPath\(\widehat{\alpha}\),\(\tilde{\cdot}\) as formulas of PosXPath\(\widehat{\alpha}\) with the additional node formulas \(p \land \neg q_1 \land \ldots \land \neg q_k\), whenever \(p, q_1, \ldots, q_k\) are labels from \(\Sigma\). We define \(T, n \models p \land \neg q_1 \land \ldots \land \neg q_k\) iff \(p \in \rho(n)\) and \(q_i \notin \rho(n), 1 \leq i \leq k\).

Similarly, formulas of CQ\(\widehat{\alpha}\),\(\tilde{\cdot}\) (UCQ\(\widehat{\alpha}\)) are formulas of CQ\(\widehat{\alpha}\) expanded with the construct \(p(x) \land \neg q_1(x) \land \ldots \land \neg q_k(x)\), where \(x \in \text{Var}\) and \(p, q_1, \ldots, q_k \in \Sigma\) with semantics: \(T, \theta \models p(x) \land \neg q_1(x) \land \neg q_k(x)\) iff \(p \in \rho(\theta(x))\) and \(q_i \notin \rho(\theta(x))\), for every \(1 \leq i \leq k\).

For a formula from CQ\(\widehat{\alpha}\),\(\tilde{\cdot}\) its corresponding graph query is defined in the same way as in Definition 3.2.1 with the addition that nodes can have negative labels. The notion of an embedding can also be extended for CQ\(\widehat{\alpha}\),\(\tilde{\cdot}\). The additional clause that has to be added to Definition 3.2.2 requires preservation of negated labels:

- For every \(u \in V\), if \(\neg p \in \rho(u)\) then \(p \notin \rho(g(u))\).

By PosXPath\(\tilde{\cdot}\), CQ\(\tilde{\cdot}\) and UCQ\(\tilde{\cdot}\) we denote the fragments of PosXPath\(\widehat{\alpha}\),\(\tilde{\cdot}\), CQ\(\widehat{\alpha}\),\(\tilde{\cdot}\) and UCQ\(\widehat{\alpha}\),\(\tilde{\cdot}\) without attribute value comparisons respectively.

3.3 Containment of PosXPath\(\widehat{\alpha}\) and CQ\(\widehat{\alpha}\)

This section contains the main result of this chapter. First, in Section 3.3.1 we show that containment for PosXPath and CQ expanded with safe negation are in \(\text{coNP}\) and \(\Pi^P_2\) respectively. Next we show that containment for these fragments expanded with attribute value comparisons remains the same by a polynomial reduction to the corresponding fragments without attribute value comparisons. This result holds under the assumption that attribute values come from a dense linear order without endpoints. In Section 3.3.3 we show that imposing different constraints on the linear domain of attribute values does not impact the complexity. However, making attributes required everywhere in a tree increases the complexity of containment, as shown in Section 3.3.4.
3. Containment for Queries over Trees with Attribute Value Comparisons

3.3.1 Containment of Positive XPath and CQs with safe negation

In Subsection 3.3.2 we will reduce the complexity of the containment problem for PosXPath® and CQ® to that of PosXPath + and UCQ +. The next theorem shows that adding safe negation to PosXPath and UCQ does not make the containment problem harder. The argument is similar to the one in (Björklund et al., 2011), but additional care needs to be taken when we deal with negation.

**Theorem 3.3.1.** The containment problem over multi-labeled trees for PosXPath + and UCQ + is in CONP and 1/2P respectively.

**Proof.** In both cases the proof strategy is the same. Throughout the proof we assume that we deal with multi-labeled trees without attributes. Our goal is to show that whenever ϕ ⊈ ψ, there is a small (polynomial in ϕ and ψ) counterexample witnessing this fact. In the proof, we start with an arbitrary counterexample T, and shrink it in two steps: in the first step (creating T*), we roughly restrict T to the image of ϕ and intermediate nodes. This can still be too large. In the second step we shrink long paths between image nodes.

Let ϕ = ∨₁ i ϕᵢ and ψ = ∨₂ j ψⱼ be UCQ + formulas. Let T = (N, E, <, r, ρ) be a tree such that T |= ϕ and T ⊈ ψ. Then there exist t and an embedding e : Nodes(Gₚᵢ) → T, where Gₚᵢ is the query graph of ϕᵢ. By e(Gₚᵢ) we denote the image of Nodes(Gₚᵢ). If Gₚᵢ |= u₁ <ₕ u₂, then there must exist nodes x₁ and x₂ such that e(u₁)(E⁻¹)x₁ <⁺ x₂E⁺e(u₂) in T. We call such x₁ and x₂ knee-nodes for G.

Our aim is to create a small tree out of T which is still a counterexample. For the first “shrinking step”, we color nodes that we must keep. We use three colors: {I, V, H}.

- Mark the root r with I,
- If x ∈ e(Gₚᵢ), mark x with I (“image” nodes),
- If Gₚᵢ |= u₁ <ₕ u₂, then there must exist knee-nodes x₁ and x₂. Mark x₁ and x₂ by I too,
- If there exist two nodes x and y marked by I such that T |= xE⁺y and there is no node z marked by I with T |= xE⁺z ∧ zE⁺y, then mark all the nodes on the path from x to y by V (“vertical” nodes),
- If there exist two nodes x and y marked by I or V such that T |= x <⁺ y and there is no node z marked by I or V with T |= x <⁺ z ∧ z <⁺ y, then mark all the sibling nodes between x and y by H (“horizontal” nodes),
- Let T* = (N*, E*, <*, r*) be the substructure of T restricted to the nodes marked by I, H or V.
- Let ρ*(n) = ρ(n) for n ∈ I and ρ*(n) = ∅ otherwise.

**Example 3.3.1.** Let T be a tree as in Figure 3.1 and Q the Boolean conjunctive query ∃xyzw(a(x) ∧ Descendant(x, y) ∧ b(y) ∧ Child(x, z) ∧ c(z) ∧ NextSibling⁺(z, w) ∧ d(w)). The corresponding query graph G_Q is depicted in Figure 3.1, where the downward and horizontal double line arrows denote E⁺ and <⁺ respectively, and the single line arrow denotes E. The embedding e is defined by the dashed arrows. The marking of nodes of T with the colors {I, V, H} is depicted in Figure 3.1.
Claim 3.3.1. \( T^* = (N^*, E^*, <^*, r^*, \rho^*) \) is a tree and \( T^* \models \varphi \) and \( T^* \not\models \psi \).

Proof of Claim 3.3.1. It is easy to check that adding the \( V \) and \( H \) nodes to \( I \) is the minimum needed to ensure that \( T^* \) is a tree. First, we argue that \( T^* \models \varphi_i \). Since we maintained the image of \( G_{\varphi_i} \) (nodes labeled by \( I \)), we have that \( e \) is a mapping from \( \text{Nodes}(G_{\varphi_i}) \) to \( N^* \). The node labels are preserved under \( e \) since we did not change the labeling of \( I \) nodes. Let \( (x, y) \) be an edge in \( G_{\varphi_i} \). If \( G_{\varphi_i} \models xEy \), or \( G_{\varphi_i} \models x < y \) then \( e(x) \) and \( e(y) \) are in child or next sibling relation in \( T^* \) respectively since both nodes are labeled with \( I \) and they were in that relation in \( T \). If \( G_{\varphi_i} \models xE^+y \) or \( G_{\varphi_i} \models x <^+ y \), then \( e(x) \) and \( e(y) \) are in the corresponding relations in \( T^* \) since the intermediate vertical (\( V \)) and horizontal (\( H \)) nodes were kept. In case \( G_{\varphi_i} \models x < f y \) we have \( T^* \models e(x) < f e(y) \) since we kept the knee-nodes which witness the following relation in \( T \). Thus, we obtain \( T^* \models \varphi \).

Now we show \( T^* \not\models \psi \). Suppose to the contrary that \( T^* \models \psi \). Then there exists an embedding \( g \) of \( G_{\psi_j} \) into \( T^* \) for some \( j \). Because \( T^* \) is a substructure of \( T \), \( g \) is also a mapping of \( \text{Nodes}(G_{\psi_j}) \) into \( \text{Nodes}(T) \) that preserves the edge relation. We show that \( g \) also preserves the labels. Note that by definition of \( T^* \), the label \( \rho^*(n) \) is either equal to \( \rho(n) \), when \( n \in I \), or empty otherwise. Positive labels are always preserved: \( \rho_j(u) \subseteq \rho^*(g(u)) \subseteq \rho(g(u)) \) for every node \( u \in \text{Nodes}(G_{\psi_j}) \), where \( \rho_j \) is the labeling function of \( G_{\psi_j} \). We show that negative labels are preserved too. Let \( u \in \text{Nodes}(G_{\psi_j}) \). If \( \neg p \in \rho_j(u) \), we have that \( p \notin \rho^*(g(u)) \), since \( g \) preserves negative labels. Since negation is safe, there must exist a label \( q \in \rho_j(u) \), which implies \( q \in \rho^*(g(u)) \), and, thus, \( \rho^*(g(u)) \) is not empty. In this case \( \rho^*(g(u)) = \rho(g(u)) \), and thus \( p \notin \rho(g(u)) \) as required. Thus, \( T \models \psi \), which is a contradiction since \( T \) is a counterexample for \( \varphi \nsubseteq \psi \).

Next, we prove two crucial lemmas. In particular, the following lemma claims that if we have a tree \( T \) with a long enough non-branching vertical path, where each node has the empty label, and a query \( Q \) with \( T \models Q \), then the path can be extended even more while preserving the fact that \( Q \) is true in the tree. We use the contrapositive of the lemma to \textit{shrink} such long paths while keeping the query \( \psi \ false \) in the smaller tree. The same reasoning applies for horizontal paths.
Lemma 3.3.1 (V-path). Let $G$ be a query graph with labels from $\Sigma$ and $T = (N, E, <, \rho, r)$ a tree such that there is an embedding of $G$ into $T$. Suppose $u_1 E u_2 E \ldots E u_n$ is a path in $T$, such that

- $\rho(u_i) = \emptyset$ for every $i \in \{1, \ldots, n\}$,
- If $T \models u_i E x$, then $x = u_{i+1}$ for $i < n$,
- $n > |\text{Nodes}(G)|$.

Let $\tilde{T}$ be the tree obtained from $T$ by inserting a node with the empty label in the middle of the path, i.e., by making $u_m$ the parent and $u_{m+1}$ a child of the new node, where $n = 2m$ (when $n$ is even) or $n = 2m - 1$ (when $n$ is odd). Then there exists an embedding from $G$ into $\tilde{T}$.

**Proof.** Let $G = (V, E, E^+, <, <^+, <_f, \rho)$ be the given query graph and $g$ an embedding of $G$ into $T$. Since the length $n$ of the path is strictly greater than the number of nodes in $G$, there must exist an index $k \leq n$ such that $u_k \notin g(V)$, $k \in \{1, \ldots, n\}$. Let $T' = (N', E', <', \rho', r')$ be the tree defined as follows:

- $r' = r$,
- $N' = N \cup \{u_k'\}, u_k' \not\in N$,
- $E' = (E \setminus \{(u_k, x) \in E \mid x \in N\}) \cup \{(u_k, u_k')\} \cup \{(u_k', x) \mid T \models u_k E x\}$,
- $<_' = <$,
- For every node $v \in N$, $\rho'(v) = \rho(v)$, and $\rho'(u_k) = \emptyset$.

We prove that in fact the same $g$ is an embedding of $G$ into $T'$. First, from the definition of $T'$ we obtain the following properties.

**Claim 3.3.2.** Let $T$ be from the statement of Lemma 3.3.1 and $T'$ as defined above. Then

(i) If $T \models x E^+ y$, then $T' \models x E'^+ y$,

(ii) If $x \neq u_k$ and $T \models x E y$, then $T' \models x E' y$,

(iii) If $T \models x < y$ (resp. $T \models x <^+ y$ and $T \models x <_f y$), then $T' \models x <' y$ (resp. $T' \models x <'^+ y$ and $T' \models x <'_f y$).

**Proof of Claim 3.3.2.** All items except (i) are immediate by the definition of $E'$. For (i), let $T \models x E^+ y$. We then consider two cases: First suppose $T \models u_k E y$. Then $T \models x E^+ u_k$ and thus $T' \models x E'^+ u_k$. Since $T' \models u_k E' u_k'$ and $T' \models u_k' E' y$, we have $T' \models x E'^+ y$. In the case that $T \not\models u_k E y$, we obtain $T' \models x E'^+ y$ by the definition of $E'$.

---

1Note that the defined $T'$ is isomorphic to the “real” intended tree $T'$ where the nodes are sequences of natural numbers. Here, we treat $g$ as the old $g$ composed with the isomorphism.
3.3. Containment of PosXPath® and CQ®

We prove that \( g : V \to N' \) is an embedding.

Preservation of labels follows from the fact that the image of \( g \) is in \( N \) and \( g \) is an embedding of \( G \) into \( T \) and thus preserves labels. We show that \( g \) still preserves the edge relations. Let \( xy \in E \) hold in \( G \). Then it holds that \( g(x) \neq u_k \) as \( u_k \) is not in the image of \( g \). Since \( g \) is an embedding of \( G \) into \( T \), it holds that \( T \models g(x)Eg(y) \). Then by Claim 3.3.2(ii), it holds that \( T' \models g(x)E'g(y) \).

Let \( G \models xE+y \). Since \( g \) is an embedding of \( G \) into \( T \), we have \( T \models g(x)E^+g(y) \). By Claim 3.3.2(i), it follows that \( T' \models g(x)E'^+g(y) \). Preservation of the relations \(<, <^+ \) and \(<_f \) under \( g \) follow from Claim 3.3.2(iii).

Now let \( \hat{T} \) be the tree defined in the statement of the Lemma. Formally, \( \hat{T} = (\hat{N}, \hat{E}, \hat{\varsigma}, \hat{\varrho}, \hat{r}) \) is defined as follows.

- \( \hat{r} = r \),
- \( \hat{N} = N \cup \{u'_m\}, u'_m \notin N \),
- \( \hat{E} = (E \setminus \{(u_m, x) \in E \mid x \in N\}) \cup \{(u_m, u'_m)\} \cup \{(u'_m, x) \mid T \models u_mEx\} \),
- \( \hat{\varsigma} = < \),
- For every node \( v \in N, \hat{\varrho}(v) = \rho(v) \), and \( \hat{\varrho}(u'_m) = \emptyset \).

The trees \( \hat{T} \) and \( T' \) are isomorphic. Recall the indexes \( m \) and \( k \) from the definitions of \( \hat{T} \) and \( T' \). We define a mapping \( f : N' \to \hat{N} \) as follows.

- If \( m \leq k \), then \( f(v) = \begin{cases} v & \text{if } v \in N \setminus \{u_{m+1}, \ldots, u_k\}, \\ u'_m & \text{if } v = u_{m+1}, \\ u_{i-1} & \text{if } v = u_i, m + 1 < i \leq k, \\ u_k & \text{if } v = u'_m. \end{cases} \)
- If \( m > k \), then \( f(v) = \begin{cases} v & \text{if } v \in N \setminus \{u_{k+1}, \ldots, u_m\}, \\ u_{k+1} & \text{if } v = u'_k, \\ u_{i+1} & \text{if } v = u_i, k + 1 \leq i < m, \\ u'_m & \text{if } v = u_{m+1}. \end{cases} \)

The function \( f \) is onto and 1-1. We show that the \( V \)-paths in \( T' \) and \( \hat{T} \) are isomorphic. We consider the case \( m \leq k \), the other case is similar. Let \( T' \models uE'v \) for \( u, v \in \{u_1, \ldots, u_k, u'_k, u_{k+1}, u_{k+2}, \ldots, u_n\} \). We need to show that \( T' \models uE'v \) iff \( \hat{T} \models f(u)E\hat{f}(v) \). There are the following possible cases.

- \( u = u_i \) and \( v = u_{i+1} \) with \( 1 \leq i < m \) or \( k < i < n \). In this case \( f(u_j) = u_j, j \in \{i, i+1\} \). By definition of \( T' \) and \( \hat{T} \) it holds that \( T' \models u_iE'u_{i+1} \) and \( \hat{T} \models u_i\hat{E}u_{i+1} \). Thus, \( T' \models uE'v \) iff \( \hat{T} \models f(u)E\hat{f}(v) \).
- \( u = u_m \) and \( v = u_{m+1} \). In this case \( f(u_m) = u_m \) and \( f(u_{m+1}) = u'_m \). By definition, it holds that \( T' \models u_mE'u_{m+1} \) and \( \hat{T} \models u_m\hat{E}u'_m \). Thus, \( T' \models uE'v \) iff \( \hat{T} \models f(u)E\hat{f}(v) \).
• \( u = u_{m+1} \) and \( v = u_{m+2} \). In this case, \( f(u_{m+1}) = u'_{m+1} \) and \( f(u_{m+2}) = u_{m+1} \). By definition, it holds that \( T' \models u_{m+1}E'u_{m+2} \) and \( T \models u'E'u_{m+1} \). Thus, \( T' \models uE'v \iff T \models f(u)Ef(v) \).

• \( u = u_i \) and \( v = u_{i+1} \) with \( m + 1 < i < k \). In this case, \( f(u_i) = u_{i-1} \) and \( f(u_{i+1}) = u_i \). By definition, it holds that \( T' \models u_iE'u_{i+1} \) and \( T \models u_{i-1}E'u_i \). Thus, \( T' \models uE'v \iff T \models f(u)Ef(v) \).

• \( u = u_k \) and \( v = u'_k \). In this case, \( f(u_k) = u_{k-1} \) and \( f(u'_k) = u_k \). By definition, it holds that \( T' \models u_kE'u'_k \) and \( \hat{T} \models u_{k-1}E'u_k \). Thus, \( T' \models uE'v \iff \hat{T} \models f(u)Ef(v) \).

• \( u = u'_k \) and \( v = u_{k+1} \). In this case, \( f(u'_k) = u_k \) and \( f(u_{k+1}) = u_{k+1} \). By definition, it holds that \( T' \models u_kE'u_{k+1} \) and \( \hat{T} \models u_kE'u_{k+1} \). Thus, \( T' \models uE'v \iff \hat{T} \models f(u)Ef(v) \).

Since \( f(v) = v \) for every \( v \in N \setminus \{u_1, \ldots, u_n, u'_k, u'_m\} \) and \( \rho(v) = \emptyset \) for every \( v \in \{u_1, \ldots, u_n, u'_k, u'_m\} \), the labels are preserved as well. Thus, the mapping \( f \circ g \) is an embedding of \( G \) into \( \hat{T} \).

Analogous to the above lemma for \( V \)-paths, we formalize one for \( H \)-paths. The crucial properties of \( H \)-paths are that their labels are empty and that all nodes in the path are leafs. We omit the proof.

**Lemma 3.3.2 (H-path).** Let \( G \) be a query graph with labels from \( \Sigma \) and \( T = (N, E, <, \rho, \nu) \) an ordered tree such that there is an embedding of \( G \) into \( T \). Suppose \( T \) has a horizontal path \( v_1 < v_2 < \ldots < v_n \) and \( v \) is their parent in \( T \), where

- \( \rho(v_i) = \emptyset \) for every \( i \in \{1, \ldots, n\} \),
- \( V_i = \{u \mid T \models v_iE'u \} = \emptyset \) for every \( i \in \{1, \ldots, n\} \),
- \( n > |\text{Nodes}(G)| \).

Let \( \hat{T} \) be the tree obtained from \( T \) by inserting a node with the empty label in the middle of the horizontal path, i.e., by making \( v_m \) the predecessor and \( v_{m+1} \) the successor of the new node, where \( n = 2m \) (when \( n \) is even) or \( n = 2m - 1 \) (when \( n \) is odd). Then there exists an embedding from \( G \) into \( \hat{T} \).

The proof of Theorem 3.3.1 relies on the small tree property which follows from the two lemmas above. We first show how, using Lemma 3.3.1, we can reduce the number of \( V \)-nodes. Let \( G_{\psi_j} \) be the query graph of maximal number of nodes among all \( G_{\psi_i} \). Let \( u_1E'u_2 \ldots E'u_n \) be a \( V \)-path in \( T^* \) of length greater than \( |\text{Nodes}(G_{\psi_j})| + 1 \). Then we remove the node \( u_m \), where \( n = 2m \) (i.e., if \( n \) is even) or \( n = 2m + 1 \) (i.e., if \( n \) is odd), from \( T^* \), and make \( u_{m+1} \) to be the child of \( u_{m-1} \). Let \( T^{**} \) be the resulting tree. We claim that \( T^{**} \models \varphi \) and \( T^{**} \not\models \psi \). The former follows from the fact that we did not change \( I \)-nodes in \( T^{**} \). For the latter, suppose \( T^{**} \models \psi \). Then there exists an embedding \( g : G_{\psi_i} \rightarrow T^{**} \) for some \( i \). Since \( n - 1 > |\text{Nodes}(G_{\psi_j})| \geq |\text{Nodes}(G_{\psi_i})| \), we can apply Lemma 3.3.1 to show that there is an embedding of \( G_{\psi_i} \) to \( T^* \), which contradicts to the fact \( T^* \not\models \psi \).
Thus, we can iteratively apply the same argument to make long $V$-paths shorter and while preserving the fact that $T^* \not| \psi$ and $T^* \models \varphi$. Similar for $H$-paths, if they are longer than $|\text{Nodes}(G_{\psi_j})| + 1$, we can apply Lemma 3.3.2 to shorten them.

Let us find out how the size of the small tree is bounded. The number of $I$ nodes in $T^*$ is bounded by $|\text{Nodes}(G_{\psi_i})|$. Each $I$ node has at most one $V$ path above it, one $H$ path to its right, and one $H$ path through its children. The number of nodes in all these paths is, by the argument above, maximally $|\text{Nodes}(G_{\psi_j})| + 1$. Thus after repeated application of the Lemmas to $T^*$ the resulting size is bounded by $O(|\varphi| \cdot |\psi|)$.

A $\Pi^P_2$ algorithm for deciding the UCQ$^{-s}$ containment then works as follows. It first guesses a tree $T$ of size $O(|\varphi| \cdot |\psi|)$ and then checks in NP if $T \models \varphi$ and in coNP if $T \not| \psi$. The coNP algorithm for PosXPath$^{-s}$ works similarly. It also guesses a tree $T$ of polynomial size and checks if $T \models \varphi$ and $T \not|= \psi$ which can be done in PTIME (Gottlob et al., 2005a).

Note that the safeness condition for negation turns out to be crucial. Indeed, in Chapter 5 we will see that containment for tree patterns with unrestricted label negation is already PS$^{\text{PSPACE}}$-complete.

3.3.2 Adding attributes

Now we are ready to provide upper bounds for our fragments with attribute value comparisons.

**Theorem 3.3.2.** The containment problem over trees with attributes is

- in coNP for PosXPath$^{\oplus, \neg^s}$,
- in $\Pi^P_2$ for UCQ$^{\oplus, \neg^s}$.

Given the containment problem $\varphi \subseteq \psi$ for $\varphi, \psi \in \text{PosXPath}^{\oplus, \neg^s}$ (UCQ$^{\oplus, \neg^s}$), we reduce it to the containment problem $\varphi' \subseteq_{\text{ML}} \psi'$ in PosXPath$^{-s}$ (UCQ$^{-s}$), which is known to be in coNP ($\Pi^P_2$) by Theorem 3.3.1. Thus Theorem 3.3.2 is a consequence of the following lemma.

**Lemma 3.3.3.** Let $\varphi$ and $\psi$ be PosXPath$^{\oplus, \neg^s}$ (UCQ$^{\oplus, \neg^s}$) formulas. Then there exist PTIME computable PosXPath$^{-s}$ (UCQ$^{-s}$) formulas $\varphi'$ and $\psi'$ such that

$\varphi \subseteq \psi$ iff $\varphi' \subseteq_{\text{ML}} \psi'$.

This holds for both single-labeled and multi-labeled trees.

**Proof.** The idea behind the proof is as follows. We abstract away from arithmetic comparisons by replacing each of them with a new label. These labels have to obey certain constraints, like comparisons do. To this purpose, we define a list of axioms (Figure 3.2) that faithfully encode these constraints.

In case of PosXPath$^{\oplus, \neg^s}$ we define $\varphi' := \tilde{\varphi}$ and $\psi' := \tilde{\psi} \lor Ax$, where $\tilde{\cdot}$ replaces comparisons with labels (definition is in Section 3.2) and $Ax$ is the disjunction of the formulas in Figure 3.2. In the definition of $Ax$, $\Sigma_p$, $\Sigma_a$ and $\Sigma_c$ are respectively the
sets of labels, attributes and constants appearing in $\varphi$ or $\psi$. We use the abbreviation $(\downarrow^*)\theta = \theta \lor (\downarrow^+\theta)$. Note that the formula $Ax$ is in $\text{PosXPath}^\ominus$. In case of $\text{UCQ}_{\ominus,=}$ the translation $(\cdot)^\prime$ is defined essentially the same. The only difference is that we take $\exists x.TR_x(Ax)$ instead of $Ax$. Notice that the resulting formulas $\varphi'$ and $\psi'$ are in $\text{UCQ}^\ominus$.

We first argue that the size of $Ax$ is $O((|\varphi| + |\psi|)^3)$. Since the sets $\Sigma_p$, $\Sigma_a$ and $\Sigma_c$ are respectively the sets of labels, attributes and constants appearing in $\varphi$ or $\psi$, their sizes are bounded by the combined size $|\varphi| + |\psi|$. The axioms in $Ax$ are in fact axiom schemas. Each schema has at most 3 parameters from $\{\Sigma_p, \Sigma_a, \Sigma_c\}$ and 1 parameter from the set of possible operators from $\{\neq, \neq, <, >, \leq, \geq\}$. Thus each schema stands for at most $6 \cdot (|\varphi| + |\psi|)^3$ disjuncts. The number of axioms and their size does not depend on $\varphi$ and $\psi$. Whence the size of $Ax$ is bounded by $O((|\varphi| + |\psi|)^3)$.

We give some intuition behind $Ax$. In order to prove this lemma, we need to show that there is a counterexample for $\varphi \subseteq \psi$ iff there is a counterexample for $\varphi' \subseteq_{\text{ML}} \psi'$. Note that every counterexample tree $T$ for $\varphi' \subseteq_{\text{ML}} \psi'$ must refute every disjunct (axiom) in $Ax$. Intuitively, the axioms enforce the following properties of $T$:

- (Label): each node has at most one label from $\Sigma_p$,
- (SName): each attribute of a node can take only at most one value,
- (MExcl),(Eq): there is no inconsistent comparison,
- (DNeg): if a node contains a comparison with a constant, then it must contain a comparison with all other constants from $\Sigma_c$,
- (LEQ1) – (LEQGEQ): the natural interaction between the comparisons with a constant,
- (Order1) – (Order4): the order is preserved.

The following claim is crucial for constructing a counterexample tree for $\varphi \subseteq \psi$ from a counterexample for $\varphi' \subseteq_{\text{ML}} \psi'$.

**Claim 3.3.3.** Let $T = (N, E, <, r, \rho)$ be a multi-labeled tree over $\Sigma'$ such that $T, r \not\models Ax$. Then for every $a \in \Sigma_a, c \in \Sigma_c$, node $n \in N$, exactly one of the following holds.

(i) there is no $p_{\ominus a, \text{opc}} \in \rho(n)$ for every $\text{op} \in \{\neq, \neq, \leq, \leq, \geq, >\}$,

(ii) there is exactly one $p_{\ominus a, =c} \in \rho(n)$ and for every $c_1 \in \Sigma_c$ it holds that $p_{\ominus a, \text{opc}_1} \in \rho(n) \iff D \models c \text{ op } c_1$,

(iii) there is no $p_{\ominus a, =c} \in \rho(n)$ and there exists $c' \in D \setminus \Sigma_c$ such that for every $c_1 \in \Sigma_c$ it holds that $p_{\ominus a, \text{opc}_1} \in \rho(n) \iff D \models c' \text{ op } c_1$.

**Proof of Claim.** Let $T$ be as stated in the Claim, $a \in \Sigma_a$ an attribute name, $c \in \Sigma_c$ a constant, $n \in N$ a node in $T$. Assume that there exists $p_{\ominus a, \text{opc}} \in \rho(n)$. Otherwise, item (i) holds. Assume that $\text{op}$ is in fact “$=$”. Because $T, r \not\models Ax$, the formula (SName) is false and thus there cannot be another $p_{\ominus a, =c_1} \in \rho(n)$.

We show, for every $c_1 \in \Sigma_c$ and $\text{op} \in \{\neq, \neq, >, <, \leq, \geq\}$, that $p_{\ominus a, \text{opc}_1} \in \rho(n) \iff D \models c \text{ op } c_1$.

(i) $\text{op}$ is $=$. Assume $p_{\ominus a, =c_1} \in \rho(n)$, then we have $c = c_1$ by (SName). The converse implication holds since $p_{\ominus a, =c} \in \rho(n)$ by the assumption.
For every $p_i, p_j \in \Sigma_p, p_i \neq p_j$:

$$\langle \downarrow^* \rangle (p_i \land p_j),$$  \hspace{1cm} \text{(Label)}

For every $a \in \Sigma_a, c, c_1, c_2 \in \Sigma_c, c_1 \neq c_2$

$$\langle \downarrow^* \rangle (p_{\overline{a}}=c_1 \land p_{\overline{a}}=c_2),$$  \hspace{1cm} \text{(SName)}

$$\langle \downarrow^* \rangle (p_{\overline{a}}=c \land p_{\overline{a}}\neq c),$$  \hspace{1cm} \text{(Eq)}

For every $a \in \Sigma_a, c \in \Sigma_c$ and $R, S$ in $\{<, =, >\}$ with $R \neq S$

$$\langle \downarrow^* \rangle (p_{\overline{a}}Rc \land p_{\overline{a}}Sc),$$  \hspace{1cm} \text{(MExcl)}

For every $a \in \Sigma_a, c, c_1 \in \Sigma_c$ and $R \in \{\neq, \leq, \geq, <, >\}$

$$\langle \downarrow^* \rangle (p_{\overline{a}}Rc_1 \land \neg p_{\overline{a}}=c \land \neg p_{\overline{a}}>c \land \neg p_{\overline{a}}<c),$$  \hspace{1cm} \text{(DNeg)}

$$\langle \downarrow^* \rangle (p_{\overline{a}}\leq c \land \neg p_{\overline{a}}=c \land \neg p_{\overline{a}}<c),$$  \hspace{1cm} \text{(LEQ1)}

$$\langle \downarrow^* \rangle (p_{\overline{a}}\geq c \land \neg p_{\overline{a}}=c \land \neg p_{\overline{a}}>c),$$  \hspace{1cm} \text{(GEQ1)}

$$\langle \downarrow^* \rangle (p_{\overline{a}}=c \land \neg p_{\overline{a}}\leq c),$$  \hspace{1cm} \text{(LEQ2)}

$$\langle \downarrow^* \rangle (p_{\overline{a}}=c \land \neg p_{\overline{a}}\geq c),$$  \hspace{1cm} \text{(GEQ2)}

$$\langle \downarrow^* \rangle (p_{\overline{a}}<c \land \neg p_{\overline{a}}\leq c),$$  \hspace{1cm} \text{(LEQ3)}

$$\langle \downarrow^* \rangle (p_{\overline{a}}>c \land \neg p_{\overline{a}}\geq c),$$  \hspace{1cm} \text{(GEQ3)}

$$\langle \downarrow^* \rangle (p_{\overline{a}}<c \land \neg p_{\overline{a}}\neq c),$$  \hspace{1cm} \text{(LNEQ)}

$$\langle \downarrow^* \rangle (p_{\overline{a}}>c \land \neg p_{\overline{a}}\neq c),$$  \hspace{1cm} \text{(GNEQ)}

$$\langle \downarrow^* \rangle (p_{\overline{a}}\neq c \land \neg p_{\overline{a}}<c \land \neg p_{\overline{a}}>c),$$  \hspace{1cm} \text{(TRI)}

$$\langle \downarrow^* \rangle (p_{\overline{a}}\geq c \land \neg p_{\overline{a}}\leq c \land \neg p_{\overline{a}}=c),$$  \hspace{1cm} \text{(LEQGEQ)}

For every $c_1 < c_2, c_1, c_2 \in \Sigma_c$, add the disjuncts,

$$\langle \downarrow^* \rangle (p_{\overline{a}}<c_1 \land \neg p_{\overline{a}}<c_2),$$  \hspace{1cm} \text{(Order1)}

$$\langle \downarrow^* \rangle (p_{\overline{a}}>c_2 \land \neg p_{\overline{a}}>c_1),$$  \hspace{1cm} \text{(Order2)}

$$\langle \downarrow^* \rangle (p_{\overline{a}}=c_1 \land \neg p_{\overline{a}}<c_2),$$  \hspace{1cm} \text{(Order3)}

$$\langle \downarrow^* \rangle (p_{\overline{a}}=c_2 \land \neg p_{\overline{a}}>c_1).$$  \hspace{1cm} \text{(Order4)}

Figure 3.2: The disjuncts of the formula $Ax$ from the proof of Lemma 3.3.3.

(ii) $op$ is $\neq$. Assume $p_{\overline{a}}\neq c_1 \in \rho(n)$. By Eq, it follows that $c_1 \neq c$. Thus, $D \models c \neq c_1$. Conversely, assume $D \models c \neq c_1$. It means that either $c > c_1$ or $c < c_1$. First assume that $c > c_1$. Since $p_{\overline{a}}=c \in \rho(n)$ and $c > c_1$, by (Order4) we obtain $p_{\overline{a}}=c_1 \in \rho(n)$. Then, by (GNEQ), it follows that $p_{\overline{a}}\neq c_1 \in \rho(n)$, as desired. Similarly for the case $c < c_1$, using (Order3) and (LNEQ), we can show $p_{\overline{a}}\neq c_1 \in \rho(n)$. 

(iii) \( \text{op} \) is \( > \). Assume \( p_{\bar{a},>c_1} \in \rho(n) \). We show that \( D \models c > c_1 \). Suppose the opposite, i.e., either \( c = c_1 \) or \( c_1 > c \). In the first case, it would mean that both \( p_{\bar{a},=c} \) and \( p_{\bar{a},>c} \) occur in \( \rho(n) \), which is a contradiction with \((MExcl)\). In the second case, by \((Order3)\), both \( p_{\bar{a},<c_1} \) and \( p_{\bar{a},>c_1} \) are in \( \rho(n) \), which is again a contradiction with \((MExcl)\).

Now suppose \( D \models c > c_1 \). Then by \((Order4)\), it follows that \( p_{\bar{a},>c_1} \in \rho(n) \), as needed.

(iv) \( \text{op} \) is \( < \). Similar to the previous case.

(v) \( \text{op} \) is \( \geq \). Assume \( p_{\bar{a},\geq c_1} \in \rho(n) \). If \( c_1 = c \), then we immediately obtain \( D \models c \geq c_1 \). Now suppose \( c \neq c_1 \) and we show that \( D \models c \geq c_1 \). Suppose the opposite, i.e., \( D \models c < c_1 \). Then by \((Order3)\), we have \( p_{\bar{a},<c_1} \in \rho(n) \). By \((LEQ3)\), it implies that \( p_{\bar{a},\leq c_1} \in \rho(n) \), which in turn by \((LEQGEQ)\) implies that \( p_{\bar{a},=c_1} \in \rho(n) \). The latter is a contradiction with \((SName)\).

Now assume \( D \models c \geq c_1 \). This means that either \( c = c_1 \) or \( c > c_1 \) in \( D \). In the first case, we have \( p_{\bar{a},=c} \in \rho(n) \) by the assumption. Thus by \((GEQ2)\), we have that \( p_{\bar{a},\geq c} \in \rho(n) \). In the second case, similarly to the case when \( \text{op} \) is \( > \), we can show that \( p_{\bar{a},>c_1} \in \rho(n) \). Then by \((GEQ3)\), we have \( p_{\bar{a},\geq c_1} \in \rho(n) \), as needed.

(vi) \( \text{op} \) is \( \leq \). Similar to the previous case.

Thus we have proved item (ii).

Let us consider (iii). Now there is no \( p_{\bar{a},=c} \in \rho(n) \) for any \( c \in D \). We define \( c_1 = max\{c \mid p_{\bar{a},>c} \in \rho(n)\} \) and \( c_2 = min\{c \mid p_{\bar{a},<c} \in \rho(n)\} \). If the former set is empty, we let \( c_1 = -\infty \), and if the latter set is empty, we let \( c_2 = +\infty \). We claim that at least one of \( c_1 \) and \( c_2 \) is finite. Indeed, there must be \( p_{\bar{a},Rc} \in \rho(n) \) for some \( R \in \{\neq, <, >, \leq, \geq\} \) since otherwise item (i) would hold. By \((DNeg)\) it follows that either \( p_{\bar{a},<c} \) or \( p_{\bar{a},>c} \) is in \( \rho(n) \), which means that \( c_1 \) or \( c_2 \) is finite.

We also claim that \( c_1 < c_2 \). It is trivially true if one of \( c_1 \) and \( c_2 \) is infinity, thus assume both are finite. If \( c_1 = c_2 \), then both \( p_{\bar{a},>c_1} \) and \( p_{\bar{a},<c_1} \) appear in \( \rho(n) \) at the same time, which is forbidden due to \((MExcl)\). If \( c_1 > c_2 \), then by \((Order1)\), both \( p_{\bar{a},>c_1} \) and \( p_{\bar{a},<c_1} \) are in \( \rho(n) \), which is again forbidden by \((MExcl)\).

Now, since \( c_1 < c_2 \) and the assumption that \( D \) is a dense order, there exists \( c' \in D \) such that \( c_1 < c' < c_2 \).

We claim that \( c' \notin \Sigma_c \). Suppose the opposite. Then since \( p_{\bar{a},=c'} \notin \rho(n) \) by the assumption and the fact that \( p_{\bar{a},Rc'} \in \rho(n) \) for some \( R \) and \( c'' \) (otherwise we would be in case (i)), we obtain either \( p_{\bar{a},<c'} \in \rho(n) \) or \( p_{\bar{a},>c'} \in \rho(n) \), by \((DNeg)\). If \( p_{\bar{a},<c'} \in \rho(n) \), then \( D \models c' \geq c_2 \) which contradicts the fact that \( D \models c < c_2 \). Similarly, if \( p_{\bar{a},>c'} \in \rho(n) \), then \( D \models c' \leq c_1 \), which contradicts with \( D \models c' > c_1 \).

We now show that for every \( c \in \Sigma_c \) and \( \text{op} \in \{=, \neq, >, <, \geq, \leq\} \), \( p_{\bar{a},\text{op}c} \in \rho(n) \) iff \( D \models c' \text{ op } c \).

(i) \( \text{op} \) is \( = \). The equivalence holds since for every \( c \in \Sigma_c \), there is no \( p_{\bar{a},=c} \) in \( \rho(n) \) and \( D \models c' = c \) since \( c' \notin \Sigma_c \).

(ii) \( \text{op} \) is \( \neq \). Assume \( p_{\bar{a},\neq c} \in \rho(n) \). Then we have that \( D \models c' \neq c \) because \( c' \) is not in \( \Sigma_c \). Conversely, assume \( D \models c' \neq c \). By \((DNeg)\), since there is no \( p_{\bar{a},=c} \)
in \( \rho(n) \) for every \( c \in \Sigma_c \) and there is \( p_{\rho,c} \) for some \( c_1 \), it follows that either \( p_{\rho,c} < c \in \rho(n) \) or \( p_{\rho,c} > c \in \rho(n) \). Applying \((LNEQ)\) or \((GNEQ)\), respectively, we obtain \( p_{\rho,c} \neq c \in \rho(n) \), as desired.

(iii) \( \text{op} \) is \( > \). Assume \( p_{\rho,c} > c \in \rho(n) \). Then \( D \models c' > c \) by definition of \( c' \). Conversely, assume \( D \models c' > c \). We show that \( p_{\rho,c} > c \in \rho(n) \). Since there is no \( p_{\rho,c} = c \in \rho(n) \) and there exists \( p_{\rho,c} < c \in \rho(n) \), we obtain either \( p_{\rho,c} < c \) or \( p_{\rho,c} > c \) in \( \rho(n) \), by \((DNeg)\). The first case is impossible since it would imply \( c' < c \) which contradicts the assumption. Thus we have \( p_{\rho,c} > c \in \rho(n) \), as desired.

(iv) \( \text{op} \) is \( < \). Similar to the previous case.

(v) \( \text{op} \) is \( \geq \). If \( p_{\rho,c} \geq c \in \rho(n) \), then by \((GEQ1)\) either \( p_{\rho,c} = c \in \rho(n) \) or \( p_{\rho,c} > c \in \rho(n) \). The first case is impossible by the assumption. In the second case, we obtain that \( D \models c' > c \) by definition of \( c' \). Thus, \( D \models c' \geq c \).

Now assume \( D \models c' \geq c \). This means that either \( c' = c \) or \( c' > c \) in \( D \). The first case is impossible, since \( c' \notin \Sigma_c \). In the second case, as with the case \( \text{op} = "<" \), we can show that \( p_{\rho,c} > c \in \rho(n) \). Then by \((GEQ3)\), it holds that \( p_{\rho,c} \geq c \in \rho(n) \).

(vi) \( \text{op} \) is \( \leq \). Similar to the previous case.

This concludes the proof of the claim. \( \square \)

We now prove that \( \varphi \subseteq \psi \iff \varphi' \subseteq_{ML} \psi' \).

\((\Rightarrow)\) Let \( T = (N, E, <, r, \rho) \) be a multi-labeled tree such that \( T, r \models \varphi' \) and \( T, r \not\models \psi' \). Note that then \( T, r \not\models Ax \). Then we define a single-labeled tree \( T': = (N, E, <, r, \rho', att) \), where \( att \) is a partial function assigning a value in \( D \) to a given node and an attribute name, as follows:

- For \( p \in \Sigma_p \), \( \rho'(n) = p \) iff \( p \in \rho(n) \). If there is no \( p \in \Sigma_p \) such that \( p \in \rho(n) \), we set \( \rho'(n) = z \) for a fresh symbol \( z \).
- \( att(n, a) = \begin{cases} \text{undefined} & \text{if there is no } p_{\rho,c} \text{ in } \rho(n), \\ c & \text{if } p_{\rho,c} \in \rho(n), \\ c' & \text{from Claim 3.3.3, (iii), otherwise.} \end{cases} \)

We claim that \( T' \) is well defined. Indeed, \((Label)\) ensures that every node is labeled by exactly one label from \( \Sigma_p \) or by \( z \). Moreover, the function \( att \) is well defined since exactly one of the conditions in the definition of \( att \) is fulfilled, according to Claim 3.3.3. By induction, using Claim 3.3.3, we can show that for every \( \theta, T, n \models \theta \iff T', n \models \theta \). Thus, it follows \( T', r \models \varphi \) and \( T', r \not\models \psi \), which was desired.

\((\Leftarrow)\) Let \( T = (N, E, <, r, \rho, att) \) be a single-labeled tree such that \( T \models \varphi \) and \( T \not\models \psi \). We define the tree \( T' := (N, E, <, r, \rho') \), where \( \rho' \) is defined as follows:

- For \( p \in \Sigma_p \), \( p \in \rho'(n) \) iff \( \rho(n) = p \),
- \( p_{\rho,c} \in \rho'(n) \) iff \( att(n, a) = c \),
- \( p_{\rho,c} \in \rho'(n) \) iff \( D \models att(n, a) \land c \lor c' \), where \( c \in \Sigma_c \).

It is straightforward to check that \( T' \) does not satisfy any of the disjuncts in \( Ax \). Thus, we obtain \( T' \models \varphi' \) and \( T' \not\models \psi' \).

The same argument goes through for multi-labeled trees, except that we must not include formulas \((Label)\) as disjuncts of \( Ax \). \( \square \)
3.3.3 Restricting the attribute domain

We now show that the same complexity results for the containment problem hold in presence of various restrictions on the domain of attribute values. A linear order $D$ has a smallest (largest) element if there exists $c' \in D$ such that $c' \leq c$ ($c \geq c'$) for every $c \in D$. We say $D$ has an endpoint if there exists a smallest or a largest element in $D$. $D$ is discrete if any point which has a successor also has an immediate successor. $D$ is dense linear order if for every $x < y$ in $D$ there exists $z \in D$ such that $x < z < y$.

**Proposition 3.3.1.** Let $D$ be one of the following linear orders:

(i) finite,

(ii) discrete,

(iii) dense or discrete with one or two endpoints.

Then the containment problem for $\text{PosXPath}^{\ominus,-}$ and $\text{UCQ}^{\ominus,-}$ over single-labeled trees with the domain of attribute values $D$ is in $\text{coNP}$ and $\Pi^p_2$ respectively.

**Proof.** Let $\varphi$ and $\psi$ be $\text{PosXPath}^{\ominus,-}$ ($\text{UCQ}^{\ominus,-}$) formulas over $D$ and $\Sigma_c \subseteq D$, $\Sigma_a$ and $\Sigma_p$ the sets of constants, attribute names and labels in $\Sigma$ appearing in $\varphi$ or $\psi$. We then construct in $\text{PTIME}$ formulas $\varphi'$ and $\psi'$ over $\Sigma' = \Sigma_p \cup \{a \in \Sigma_a, c \in \Sigma_c, \text{op} \in \{=, \not=, <, >, \leq, \geq\}\}$ such that

$$\varphi \subseteq \psi \text{ if and only if } \varphi' \subseteq_{\text{ML}} \psi'.$$

Namely, we take $\varphi' := \tilde{\varphi}$ and $\psi' := \tilde{\psi} \lor Ax \lor Ax_k$, where $\tilde{\cdot}$ is defined in Section 3.2. $Ax$ is from Figure 3.2 and $Ax_k, k \in \{(\text{Fin}), (\text{Discr}), (\text{End})\}$ is constructed according to the cases (i), (ii) and (iii) of the Proposition. Note that the formulas $\varphi'$ and $\psi'$ in all the cases are in fact $\text{PosXPath}^{\ominus,-}$ formulas. In case of $\text{UCQ}^{\ominus,-}$, the translation $\langle \cdot \rangle'$ is defined essentially the same. The difference is that we use $\exists x.TR_x(Ax)$ and $\exists y.TR_y(Ax_k)$ instead. Note that the result of $\langle \cdot \rangle'$ is a union of $\text{CQ}^{\ominus,-}$ formulas. The upper bounds then follow from Theorem 3.3.1.

Now we construct the formulas $Ax_k, k \in \{(\text{Fin}), (\text{Discr}), (\text{End})\}$.

(i). Assume $D = \{c_1 < c_2 < \ldots < c_k\}$ is a finite linear order. We then write down the formulas of $Ax_{(\text{Fin})}$. It is the disjunction of the following formulas. For every $a \in \Sigma_a, c \in \Sigma_c$ and $\text{op} \in \{=, \not=, <, >, \leq, \geq\}$:

$$\langle \downarrow^\ast \rangle(p_{a,\text{op}c} \land \neg p_{a,\text{op}c}=c_1 \land \ldots \land \neg p_{a,\text{op}c}=c_k).$$

(\text{Fin})

This axiom enforces that whenever an attribute is defined, its value equals one of $c_i, 1 \leq i \leq k$. The following claim, which is easy to verify using (Fin), is crucial.

**Claim 3.3.4.** Let $T = (N, E, <, r, \rho)$ be a multi-labeled tree over $\Sigma'$ such that $T, r \not\models Ax \lor Ax_{(\text{Fin})}$. Then for every $a \in \Sigma_a, c \in \Sigma_c$, node $n \in N$ and $\text{op} \in \{=, \not=, \geq, \leq, <, >\}$, exactly one of the following holds:

(i) there is no $p_{a,\text{op}c} \in \rho(n)$,
3.3. Containment of PosXPath® and CQ®

(ii) there is exactly one \( p_{\@_a=c} \in \rho(n) \) and for every \( c_1 \in \Sigma_c \) it holds that \( p_{\@_a op c_1} \in \rho(n) \) iff \( D \models c op c_1 \).

Now we prove the equivalence (I). For the direction from left to right, given a multilabeled tree \( T \) over \( \Sigma' \) such that \( T \models \phi' \) and \( T \models \not\phi' \), we construct a single-labeled tree with attributes \( T' \) as it was done in Lemma 3.3.3. The only difference is in the definition of the attribute function \( att \). In our case we take

\[
att(n,a) = \begin{cases} 
\text{undefined} & \text{if there is no } \@_a \text{ op } c \text{ in } \rho(n), \text{op} \in \{=, \neq, <, >, \geq, \leq\}, c \in \Sigma_c \\
c & \text{if } \@_a = c \in \rho(n).
\end{cases}
\]

Using Claim 3.3.4 we can show that for every \( n \in T, \theta \) over \( \Sigma, A \) and \( D, T, n \models \tilde{\theta} \) iff \( T', n \models \theta \).

The direction from right to left of (I) can be proved exactly as in Lemma 3.3.3.

(ii). \( D \) is a discrete linear order. We assume that \( D \) is infinite, as the finite case is covered by the case (i). We take \( Ax_{(Discr)} \) as the disjunction of the following formulas. For every \( a \in \Sigma, c_1, c_2 \in \Sigma_c \) such that \( c_1 < c_2 \) in \( D \) and there is no \( c' \) in \( D \) with \( c_1 < c' < c_2 \),

\[
\langle \downarrow^* \rangle (p_{\@_a>c_1} \land p_{\@_a<c_2}), \quad (Discr)
\]

This axiom enforces the requirement that a value for \( a \)-attribute cannot be between an element in \( D \) and its immediate successor.

Similarly to Lemma 3.3.3 we can show that the reduction is correct. To this purpose we need the claim which is a reformulation of Claim 3.3.3 where instead of \( Ax \) we take \( Ax \lor Ax_{(Discr)} \) and \( D \) is the discrete linear order.

We highlight the difference with the proof of Claim 3.3.3. The only nontrivial difference is item (iii). Assume the conditions (i) and (ii) of Claim 3.3.3 do not hold for \( a \in A \) and \( n \in T \). We define \( c_1 = max\{c \mid p_{\@_a>c} \in \rho(n)\} \) and \( c_2 = min\{c \mid p_{\@_a<c} \in \rho(n)\} \). As in Claim 3.3.3 we can show that \( D \models c_1 < c_2 \). Having that, there exists \( c' \) such that \( c_1 < c' < c_2 \). Indeed, suppose the opposite. Then both \( p_{\@_a>c_1} \) and \( p_{\@_a<c_2} \) are in \( \rho(n) \) and \( c_2 \) is the immediate successor of \( c_1 \) in \( D \), which is a contradiction with \( (Discr) \). It follows from \( (DNeg) \) that \( c' \notin \Sigma_c \). Moreover, for every \( c'' \in \Sigma_c, p_{\@_a op c''} \in \rho(n) \) iff \( D \models c' op c'' \). This can be verified as it was done in Claim 3.3.3. Thus we have proved the claim. Having this claim at hand, we can prove the equivalence (I) in the same way as in Lemma 3.3.3.

(iii). \( D \) is dense or discrete linear order with one or two endpoints. If \( D \) is dense, take \( Ax_{(End)} \) as the disjunction of the following formulas:

If \( D \) has the least endpoint \( c_l \), for every \( a \in \Sigma_a \):

\[
\langle \downarrow^* \rangle p_{\@_a<c_l} \quad (LEnd)
\]

If \( D \) has the greatest endpoint \( c_g \), for every \( a \in \Sigma_a \):

\[
\langle \downarrow^* \rangle p_{\@_a>c_g} \quad (REnd)
\]

In case \( D \) is discrete linear order, \( Ax_{(End)} \) additionally has \( (Discr) \) as a disjunct.
3. Containment for Queries over Trees with Attribute Value Comparisons

The axioms \((LEnd)\) and \((REnd)\) enforce the requirement that attributes cannot take their values outside of the bounds in \(D\). As in the previous case, we can prove the variant of Claim 3.3.3, where we consider \(Ax(End)\) and \(D\) a dense or discrete linear order with one or two endpoints. We do not spell out the proof, but the crucial difference is that in item (iii) axioms \((LEnd)\) and \((REnd)\) ensure the fact that \(c'\) is chosen within the interval \([c_l, c_g]\).

Having this claim, we can prove the equivalence \((1)\) in the same way as in Lemma 3.3.3. Clearly, the constructed \(\varphi'\) and \(\psi'\) are \(PTIME\) computable from \(\varphi\) and \(\psi\). □

3.3.4 Lower bounds

In this section we show a number of lower bounds on containment for \(CQ^{\mathbb{N}}\) and \(PosXPath^{\mathbb{N}}\). The following lower bound was shown in (Björklund et al., 2011).

**Proposition 3.3.2** (Björklund et al. (2011)). Containment is \(\Pi^P_2\)-hard for \(CQ(Child, Descendant)\), i.e., conjunctive queries that use only the predicates \(Child\) and \(Descendant\).

For \(PosXPath^{\mathbb{N}}\), the \(coNP\) lower bound for containment follows from hardness of containment for tree patterns (Miklau and Suciu, 2004), which is a fragment of \(PosXPath^{\mathbb{N}}\). To compare our results to those in (Miklau and Suciu, 2004), we follow their notation. Let \(XP[\{\}^*,/\}^{=,\neq}\) denote the fragment of \(PosXPath\) without union and disjunction, only the \(\downarrow\) step, and no occurrence of the following and preceding axes. These are called tree patterns in the literature. Let \(XP[\{\}^{=,\neq}\) denote \(XP[\{\}^*,/\}^{=,\neq}\) in which no wildcard (denoted by \(\top\) in \(PosXPath\)) occurs.

Containment of \(XP[\{\}^*,/\}^{=,\neq}\) and \(XP[\{\}^{=,\neq}\) patterns is in \(PTIME\) and \(CONP\)-complete, respectively. Let \(XP[\{\}^{=,\neq}\) and \(XP[\{\}^*,/\}^{=,\neq}\) denote the expansions of \(XP[\{\}^{=,\neq}\) and \(XP[\{\}^*,/\}^{=,\neq}\) with equality and inequality attribute value comparisons, respectively. We show that containment of \(XP[\{\}^{=,\neq}\) patterns becomes \(CONP\) hard. Containment of \(XP[\{\}^*,/\}^{=,\neq}\) patterns becomes \(PSPACE\) hard when interpreted over trees with at least one required attribute.

The following property is used in our lower bound arguments. The proof can be found in (Miklau and Suciu, 2004, Lemma 3).

**Proposition 3.3.3.** Let \(L\) be \(XP[\{\}^*,/\}^{=,\neq}\) or \(XP[\{\}^{=,\neq}\). Let \(\varphi\) be an \(L\) formula and \(\Delta\) a finite set of \(L\) formulas. Then there are \(PTIME\) computable \(L\) formulas \(\varphi'\) and \(\psi'\) such that

\[
\varphi \subseteq \bigvee \Delta \text{ iff } \varphi' \subseteq \psi'.
\]

The same holds for the case of multi-labeled trees.

**Proposition 3.3.4.** The containment problem for \(XP[\{\}^{=,\neq}\) is \(CONP\)-hard.

**Proof.** We reduce the 3SAT problem to the non-containment problem in \(XP[\{\}^{=,\neq}\).

Firstly, we can use a union of tree patterns on the right side of the containment problem, due to Proposition 3.3.3.
Let $Q$ be the conjunction of clauses $C_i = (X_i^1 \lor X_i^2 \lor X_i^3)$, $1 \leq i \leq k$ over the variables $\{x_1, \ldots, x_n\}$, where $X_i^j$ are literals. From $Q$, we construct in PTIME two formulas over the signature $\Sigma = \{r, b\}$, attribute names $A = \{a_1, \ldots, a_n\}$ and an attribute domain $D$ containing values $\{0, 1, 2\}$ as follows.

We define

$$\varphi := r \land \langle \downarrow \rangle (b \land \ominus_{a_1} \neq 2 \land \ldots \land \ominus_{a_n} \neq 2)^2$$

and

$$\psi := \bigvee_{i=1}^k \langle \downarrow \rangle (b \land B_i^1 \land B_i^2 \land B_i^3),$$

where $B_i^j = (\ominus_{a_i} = 0)$ iff $X_i^j = x_i$ in $C_i$ and $B_i^j = (\ominus_{a_i} \neq 0)$ iff $X_i^j = \lnot x_i$ in $C_i$.

We claim that $Q$ is satisfiable if and only if $\varphi \not\subseteq \psi$. First assume that $Q$ is satisfiable, i.e., there is a variable assignment $V : \{x_1, \ldots, x_n\} \rightarrow \{0, 1\}$ such that $V \models Q$. We then define the following tree $T = ((v_1, v_2), \{(v_1, v_2)\}, \rho, \text{att})$, where the labeling $\rho$ is defined as $\rho(v_1) = \{r\}$, $\rho(v_2) = \{b\}$ and att$(v_2, a_i) = 1$ iff $V(x_i) = 1$ and att$(v_2, a_i) = 0$ iff $V(x_i) = 0$ for every $l, 1 \leq l \leq n$. Clearly, $T$ satisfies $\varphi$. Suppose $T, v_1 \not\models \psi$. This means there exists an index $i$ such that $T, v_1 \models \langle \downarrow \rangle (b \land B_i^1 \land B_i^2 \land B_i^3)$, which implies $T, v_2 \models B_i^j, j = 1, 2, 3$. Hence, by the definition of the attribute function we obtain that if $B_i^j = (\ominus_{a_i} = 0)$, then $V(X_i^j) = V(x_i) = 0$ and, similarly, if $B_i^j = (\ominus_{a_i} \neq 0)$, then $V(X_i^j) = V(\lnot x_i) = 0$. Thus, we obtain $V \not\models C_i$, which is a contradiction with the fact that $V$ is a satisfying variable assignment. Thus, $T \not\models \psi$.

We now prove the converse. Assume there is a tree $T$ with $T \models \varphi$ and $T \not\models \psi$. The former implies that there exists a child of the root of $T$, $v$ such that $T, v \models b$ and the attributes $a_1, \ldots, a_n$ are defined at $v$. Moreover since $T \not\models \psi$, for every $i, 1 \leq i \leq n$ it holds that $T, v \not\models b \land B_i^1 \land B_i^2 \land B_i^3$. We define the variable assignment $V : \{x_1, \ldots, x_n\} \rightarrow \{0, 1\}$ as follows: $V(x_i) := 0$ iff att$(v, a_i) = 0$ and $V(x_i) := 1$ iff att$(v, a_i) \neq 0$. We claim that $V \models Q$. Assume the opposite, i.e., there exists a clause $C_j$ which is mapped to 0 under $V$. By definition of $V$, it follows that $T, v \models B_j^1 \land B_j^2 \land B_j^3$ and therefore, $T, v \models b \land B_j^1 \land B_j^2 \land B_j^3$, which is a contradiction. \hfill \Box

**Required attributes**

In Section 3.3.2 we dealt with the case when attributes are optional. We now consider the case when some attributes are required. We say that an attribute $a \in A$ is required in a tree $T$ with domain $N$ if the function att : $N \times \{a\} \rightarrow D$ is total. We show that when at least one attribute is required, containment of tree patterns with equality and inequality comparisons rises to PSPACE.

**Theorem 3.3.3.** The containment problem for $\text{XP}[[\text{\textunderscore }=/\text{\textunderscore }\neq]]$ interpreted over trees with at least one required attribute is PSPACE-complete.

**Proof.** We show the upper bound for $\text{XP}[[\text{\textunderscore }=/\text{\textunderscore }\neq]]$ expanded with the other equality operators (i.e., $\langle, \rangle, \leq$ and $\geq$). For that, we reduce the containment problem in this fragment to containment for unions of $\text{XP}[[\text{\textunderscore }=/\text{\textunderscore }\neq]]$ (tree pattern formulas with unrestricted

---

2 The purpose of the inequalities $\ominus_{a_i} \neq 2$ is to guarantee that the attribute $a_i$ is defined in the $b$-node of a model of $\varphi$. We could express the same with the comparison $\ominus_{a_i} \leq 1$ or $\ominus_{a_i} \geq 0$. 47
3. Containment for Queries over Trees with Attribute Value Comparisons

label negation) similar to Lemma 3.3.3. The additional axiom in Ax (Figure 3.2) is 
\langle \downarrow^* \rangle (\neg p_{a=c} \land \neg p_{@a \neq c}) for every required \( a \in A \), where \( c \) is a constant (note that this axiom contains unsafe negation). This axiom enforces that the attribute \( a \) is defined everywhere in the tree. In (Facchini et al., 2015) and Chapter 5 we show that containment for unions of \( \text{XP}\{[1],*,/,-\} \) is solvable in \( \text{PSPACE} \).

For proving the lower bound we encode the corridor tiling problem, which is known to be hard for \( \text{PSPACE} \) (Chlebus, 1986). Our lower bound proof uses the construction from the \( \text{PSPACE}-\)hardness proof for the containment problem in tree patterns with disjunction over a finite alphabet in (Neven and Schwentick, 2006).

The corridor tiling problem is formalized as follows. Let \( \text{Til} = (D, H, V, \bar{b}, \bar{t}, n) \) be a tiling system, where \( D = \{ d_1, \ldots, d_m \} \) is a finite set of tiles, \( H, V \subseteq D^2 \) are horizontal and vertical constraints, \( n \) is a natural number in unary notation, \( \bar{b} \) and \( \bar{t} \) are tuples over \( D \) of length \( n \). Given such a tiling system, the goal is to construct a tiling of the corridor of width \( n \) using the tiles from \( D \) so that the constraints \( H \) and \( V \) are satisfied. Moreover, the bottom and the top row must be tiled by \( \bar{b} \) and \( \bar{t} \) respectively.

Let \( a \in A \) be a required attribute. Now we construct two \( \text{XP}\{[1],*,/\} \) expressions \( \varphi \) and \( \psi \) such that \( \varphi \not\sqsubseteq \psi \) over trees with a required attribute \( a \) iff there exists a tiling for \( \text{Til} \). To this purpose, we use a string representation of a tiling. Each row of the considered tiling is represented by the tiles it consists of. If the tiling of a corridor of width \( n \) has \( k \) rows, it is represented by its rows separated by the special symbol \( \downarrow \). Thus, a tiling is a word of the form \( u_1\uparrow u_2\downarrow \cdots \downarrow u_k\downarrow \), where each \( u_i \) is the word of length \( n \) corresponding to the \( i \)-th row in the tiling, and \( \downarrow \) denotes the end of tiling. Note \( u_1 = \bar{b} \) and \( u_k = \bar{t} \).

For the sake of readability, for expression \( r \), we use the abbreviation \( r^i \) to denote the path formula \( ?r; \downarrow; ?r; \ldots; \downarrow; ?r \) with \( i \) occurrences of \( r \).

We then define the formulas over attributes \( \{ a \} \) and attribute domain containing \( D \cup \{ \sharp \} \).

Define \( \varphi' \) as

\[
\langle ?(a = b_1); \downarrow; ?(a = b_2); \ldots; \\
\downarrow; ?(a = b_n); \downarrow; ?(a = \#); \downarrow^+; ?(a = t_1); \downarrow; \ldots; \downarrow; ?(a = t_n); \downarrow \rangle \sharp
\]

Intuitively, this expression enforces a tiling to start with a path starting with \( \bar{b} \) and finishing with \( \bar{t} \). Now the formula \( \psi' \) defines all incorrect tilings and additional constraints. It is the disjunction of the following \( \text{XP}_{\{1\},*,/,-}\) formulas.

1. Incorrect length of a row.
   (1a) \( \bigvee_{n=0}^{n-1} \langle \downarrow^+; ?(a = \#); \downarrow; T^i; \downarrow \rangle \langle @a = \# \rangle \), a row is too short,
   (1b) \( \langle \downarrow^+; @(a \neq \#)^{n+1}; T \rangle \), a row is too long.

2. (\( \downarrow^+; ?(a \neq d_1 \land \ldots \land a \neq d_m \land \# ; \downarrow^+ \rangle \sharp \)), neither the delimiter or a tile on a position,

3. Horizontal or vertical constraints are violated.
   (3a) \( \bigvee_{(d_1,d_2) \notin H} \langle \downarrow^+; ?(a = d_1); \downarrow; ?(a = d_2) \rangle T \), a horizontal constraint is violated,
   (3b) \( \bigvee_{(d_1,d_2) \notin V} \langle \downarrow^+; ?(a = d_1); \downarrow; T^n; \downarrow; ?(a = d_2) \rangle T \), a vertical constraint is violated.
We show that there exists a tree with a required attribute \( a \) such that \( T \models \varphi' \) and \( T \not\models \psi' \) iff there exists a tiling for \( \text{Til} \).

\((\Leftarrow)\). Assume that there exists a tiling of the corridor. Let \( s \) be the string representation of it. Then, \( s = u_1 \sharp u_2 \sharp \ldots \sharp u_k \$, where \(|u_i| = n\), \( u_i \in D^n\), \( u_1 = \bar{b} \) and \( u_k = \bar{t} \). Moreover, on the one hand if \( x \cdot y \) is an infix of some \( u_i \), then \((x, y) \in H\), and on the other hand for every infix \( x \cdot u' \cdot y \) of length \( n + 1 \) of \( u_i \sharp \cdot u_{i+1} \), it holds that \((x, y) \in V\). Let \( T_s \) be the corresponding tree, i.e., a single path of \(|s|\) nodes \( \{v_1, \ldots, v_{|s|}\} \) where the label of each node \( v_i, i < |s| \) is \( z \), the label of \( v_{|s|} \) is \( \$ \) and attribute function is defined according to \( s \), i.e., \( \text{att}(v_i, a) = s_i \). Clearly, \( T_s \) is a model of \( \varphi' \) and not of \( \psi' \).

\((\Rightarrow)\). Let \( T \) be a tree such that \( T, r \models \varphi' \), \( T, r \not\models \psi' \) and \( \text{att}(n, a) \) is defined for every \( n \in \text{Nodes}(T) \). Since \( T, r \models \varphi' \), there must exist a path \( r = v_1, \ldots, v_m \) in \( T \) such that \( \text{att}(v_1, a) = b_i, 1 \leq i \leq n \) and \( \text{att}(v_{m-n+i}, a) = t_j, 1 \leq j \leq n \). Moreover, either \( \$ \) or a symbol from \( D \) is in the attribute of every node \( v_i, 1 \leq i < m \), according to (2).

We define a tiling function \( g : \{0, \ldots, n - 1\} \times \mathbb{N} \rightarrow D \) assigning a tile to every position in the corridor as follows:

\[
g(i,j) = \text{att}(v_{(n+1)\times j+i+1}, a), 1 \leq i \leq n, \quad \text{where } l \text{ is the labeling function of } T.
\]

Indeed, this function is well defined, as (1) ensures the correct counting.

By formulas (3a) and (3b) the tiling defined by \( g \) satisfies the horizontal and vertical constraints.

We then apply Proposition 3.3.3 to remove the outermost disjunction in \( \psi' \) to obtain the equivalent containment problem \( \varphi \subseteq \psi \) in \( \text{XP}_{=,\neq} \).

Theorem 3.3.3 provides a lower bound for the containment problem for \( \text{PosXPath}^\$ 
\text{and UCQ}^\$ \) over trees with required attributes. Only for tree patterns we know that the problem is \( \text{PSPACE-complete} \). Using the same reduction as in the proof of the upper bound in Theorem 3.3.3, and the results on containment for XPath (Marx, 2005) and XPath with path intersection (ten Cate and Lutz, 2009), we obtain \( \text{ExpTIME} \) and \( 2\text{ExpTIME} \) upper bounds for containment for \( \text{PosXPath}^\$ \) and \( \text{UCQ}^\$ \) over trees with required attributes, respectively.

However, if we restrict attributes to be required at nodes labeled with a certain symbol, then the containment is still in \( \text{CoNP} \) and \( \Pi^P_2 \). Let \( p \in \Sigma \) be a label and \( a \in A \) an attribute name. We say that \( a \) is required at label element \( p \) if \( \text{att}(n, a) \) is defined whenever \( p \in \rho(n) \) for every tree \( T \) and node \( n \in \text{Nodes}(T) \).

**Proposition 3.3.5.** The containment problem for \( \text{PosXPath}^\$ \) and \( \text{UCQ}^\$ \) with required attributes at certain labeled nodes is in \( \text{CoNP} \) and \( \Pi^P_2 \) respectively.

**Proof.** As before, we can prove a variant of Lemma 3.3.3. Let \( c \) be a constant name. Whenever attribute \( a \) is required at nodes labelled by \( p \) we add the axiom \( (\downarrow^*) (p \land \neg p_{\text{att}_{a} = c} \land \neg p_{\text{att}_{a} \neq c}) \) to the set \( Ax \). Note that the negation is safe. This axiom is obviously sound, and it enforces that whenever \( p \) holds, at least one \( p_{\text{att}_{a} \neq c} \) label holds as well. This ensures that in the construction of the tree with attributes \( a \) is defined at each \( p \) node.
3. Containment for Queries over Trees with Attribute Value Comparisons

3.3.5 Tractable cases

In this section we consider fragments of PosXPath\(^{\ominus}\) where the containment problem remains in PTIME. It is known that containment in XP\([()]//\) and XP\([()]\ast\) is decidable in PTIME (Amer-Yahia et al., 2002; Miklau and Suciu, 2004).

**Proposition 3.3.6.** Let XP\(^{x}\) be any fragment whose containment problem over multi-labeled trees is in PTIME. Then the containment problem in XP\(^{\ominus,x}\) over multi-labeled trees with attributes is also in PTIME.

**Proof.** Let \(\varphi\) and \(\psi\) be formulas in XP\(^{\ominus,x}\). Our algorithm first checks (in PTIME) if \(\varphi\) is consistent, i.e., if it contains both \(\ominus a = c\) and \(\ominus a = d\) in the label of a node in \(\varphi\) for some \(a \in A, c, d \in D\). If \(\varphi\) is inconsistent, we output \(\varphi \subseteq \psi\). Otherwise, we proceed as in the proof of Lemma 3.3.3 by reduction to a containment of attribute-free formulas using the translation \((\cdot)\) and the formula \((Label)\) only.

3.4 Conclusion

We have considered the containment problem for positive XPath and conjunctive queries over trees expanded with attribute value comparisons. We have shown that in general attribute value comparisons do not increase the complexity of containment. The main idea behind the upper bound was to extend the small counterexample technique to positive XPath and conjunctive queries expanded with a restricted form of negation. Then by axiomatizing the needed constraints in the corresponding expanded fragment, we could abstract away the attribute value comparisons.

The complexity, however, does increase from PTIME to coNP for the fragment XP\([//[,]\)]\) of XPath that uses child, descendant and filter expressions when we add equality and inequality comparisons. Another parameter that affects the complexity is optionality of attributes. If we restrict our trees to have at least one required attribute in every node, then the complexity rises to PSPACE. If, however, attributes are required at elements with specific labels only, the complexity of containment remains the same: coNP for positive XPath and \(\Pi_2^P\) for conjunctive queries.

We end by listing some open problems. Proposition 3.3.6 shows that adding equality comparison only does not affect the PTIME complexity of containment for fragments XP\([//[,]\)]\) and XP\([[,]\ast\)\). We do not know what happens when only inequality comparison is added.

For conjunctive queries over trees, it is known that the fragments CQ(Child) and CQ(NextSibling) have PTIME containment. It is open whether the complexity increases if we add attribute value comparisons.

In this chapter we have introduced safe label negation and showed that if we add this construct to CQ or PosXPath, complexity of containment remains the same. In Chapter 5 we show that when label negation is unrestricted, containment becomes PSPACE-complete already for tree patterns. In Chapter 4 we show that containment for child-only tree patterns with label negation is solvable in PTIME.
In the previous chapter (Chapter 3) we have considered containment for conjunctive queries that are expanded with (safe) negation and attribute value comparisons and that are interpreted over trees. In this chapter we consider conjunctive queries (CQ) expanded with atomic negation or arithmetic comparisons and that are interpreted over relational instances. It is known that the containment problem for this language is \( \Pi_2^p \)-complete (Ullman, 2000; Wei and Lausen, 2003). The aim of this chapter is to find restrictions on CQ that allow for tractable containment. In particular, we consider acyclic conjunctive queries and we seek an answer for RQ 2. We show that even with the most restrictive form of acyclicity (Berge-acyclicity), containment is \( \text{coNP} \)-hard. But for a particular fragment of Berge-acyclic CQ with atomic negation or arithmetic comparisons—child-only tree patterns—containment is solvable in PTIME.

### 4.1 Introduction

We revisit the containment problem for conjunctive queries, one of the classic fundamental problems in database theory. As explained in Chapter 2, conjunctive queries (CQ) correspond to select-from-where SQL queries, a class of most frequent queries used in practice. The containment problem is to decide, given two conjunctive queries \( Q_1 \) and \( Q_2 \), whether the answers of \( Q_1 \) are contained in the answers of \( Q_2 \) over every database. A well-known result of Chandra and Merlin (1977a) is NP-completeness of the containment problem for CQ. Because of the topic’s relevance to practice, there have been a number of papers dedicated to finding syntactic restrictions of conjunctive queries allowing polynomial-time algorithms for containment. Acyclic conjunctive queries have been studied as one of the restrictions (Gottlob et al., 2001; Yannakakis, 1981).

Conjunctive queries expanded with atomic negation or arithmetic comparisons are used in practice as well. The containment problem is harder for these classes than for CQ – \( \Pi_2^p \)-complete (Klug, 1988; Ullman, 2000; van der Meyden, 1997). There has been little work on finding fragments of CQ with negation or comparisons that have tractable query containment. Even the restriction of acyclicity for CQ has not been considered in
4. Containment for ACQ with Atomic Negation and Arithmetic Comparisons

presence of atomic negation or arithmetic comparisons. Indeed, it is a restriction of CQ allowing polynomial-time containment and, furthermore, the known $\Pi_2^P$-lower bounds (both in presence of atomic negation and comparisons) involve cyclic queries.

We show that in some cases the acyclicity condition does reduce the complexity of containment. We show a $\text{coNP}$ upper bound for acyclic conjunctive queries with negated atoms of bounded arity, and where, furthermore, the negation is guarded. We call this fragment $\text{ACQ}(\neg g)$. Atomic negation in a conjunctive query $Q$ is guarded if the variables of each negated atom occur in a positive atom of $Q$ (Bárány et al., 2011). Moreover, we show that containment for acyclic conjunctive queries with arithmetic comparisons of the form $x \text{op} c$, where $x$ is a variable, $c$ a constant and $\text{op}$ a comparison operator from $\{=, \neq, <, >, \leq, \geq\}$, is also solvable in $\text{coNP}$. We obtain several $\text{coNP}$-hardness results for containment of acyclic queries with atomic negation or comparisons. These lower bounds indicate that the usual notions of acyclicity are not enough to obtain tractability, even with guarded negation and the most restrictive form of acyclicity – Berge acyclicity (Fagin, 1983). On the positive side we show that containment for a particular fragment of Berge-acyclic conjunctive queries with guarded negation, namely child-only tree patterns, is decidable in PTIME. We extend this PTIME result to the case with arithmetic comparisons. The PTIME results are based on a characterization of containment in terms of the existence of a homomorphism. The latter can be checked by reducing to known efficient algorithms for positive acyclic queries (Gottlob et al., 2001).

The contributions of this chapter are summarized in Table 4.1. In particular,

- We identify a fragment of CQ with atomic negation for which containment is $\text{coNP}$-complete: acyclic conjunctive queries with guarded negation with bounded arity of negated atoms. We derive the same bound for acyclic CQ with arithmetic comparisons.

- Consider the following three conditions on a conjunctive query $Q$ with guarded atomic negation (resp. with arithmetic comparisons). Let $\text{root}$ be a fixed constant.
  
  (i) $Q$ contains an atom with $\text{root}$ as an argument,
  (ii) $Q$ is connected,
  (iii) $Q$ is Berge-acyclic.

We call queries satisfying conditions (i)–(iii) pointed Berge-acyclic with guarded atomic negation (with arithmetic comparisons). We show that for a class of conjunctive queries with guarded atomic negation or comparisons (containing a binary relational name) satisfying at most two of the conditions (i)–(iii), containment is $\text{coNP}$-hard.

- We show that containment for a particular fragment of pointed Berge acyclic conjunctive queries with guarded atomic negation is in PTIME using the homomorphism characterisation of containment. It is the class of conjunctive queries with guarded atomic negation that express rooted child-only tree patterns with label negation, or more precisely, queries $Q$ that are built over unary and binary relational names, contain a constant $\text{root}$ such that it can only appear in the first
4.2 Preliminaries

A relational schema $S$ is a set of relational names with associated arities. We assume countably infinite disjoint sets of variables and constants $\text{Var}$ and $\text{Const}$. A term is an element from $\text{Var} \cup \text{Const}$. We also assume a dense linear order $<$ on $\text{Const}$. For tuples of terms $\bar{x}$ and $\bar{y}$, by $\bar{x} \subseteq \bar{y}$ we denote the fact that every element of $\bar{x}$ is an element of $\bar{y}$. An instance $I$ over $S$ is a set of facts of the form $R(a_1, \ldots, a_n)$, where $R \in S$ is a relational name of arity $n$ and each $a_i \in \text{Const}$. By $\text{dom}(I)$ we denote the domain of $I$, i.e. all the constants appearing in $I$. A positive atom (or just an atom) and a negative atom are expressions of the form $R(x_1, \ldots, x_n)$ and $\neg R(x_1, \ldots, x_n)$, respectively, where $R \in S$ is a relational name of arity $n$ and each $x_i$ is a term.

A $k$-ary conjunctive query ($k \geq 0$) over $S$ is an expression $Q(\bar{x}) = \exists \bar{y}. \varphi(\bar{x}, \bar{y})$, where $\bar{x}$ is a $k$-tuple of variables and $\varphi(\bar{x}, \bar{y})$ is a conjunction of positive atoms over $S$ containing all the terms in $\bar{x}, \bar{y}$. A 0-ary query is called Boolean. We say that $Q(\bar{x}) = \exists \bar{y}. \varphi(\bar{x}, \bar{y})$ is a

Table 4.1: Known results and the results of this chapter. Here $\neg g$ denotes guarded atomic negation.

In Section 4.2 we introduce the needed concepts and notation. In Section 4.3 we show $\text{coNP}$ completeness for containment of acyclic conjunctive queries with guarded negated atoms of bounded arity, or comparisons. In Section 4.4 we provide PTIME results for tree patterns with label negation or arithmetic comparisons. We end with conclusions, open problems and future work.
4. Containment for ACQ with Atomic Negation and Arithmetic Comparisons

A conjunctive query with atomic negation if \( \varphi(\bar{x}, \bar{y}) \) is a conjunction of positive or negative atoms. We say that an atom \( R(\bar{x}) \) is negated in \( Q \) if \( \neg R(\bar{x}) \) is a conjunct of \( Q \). Negation is guarded in \( Q \) if for every negative atom \( \neg R(\bar{x}) \) in \( Q \) there is a positive atom \( P(\bar{y}) \) in \( Q \) such that \( \bar{x} \subseteq \bar{y} \), where \( \bar{x} \) are the variables in \( \bar{x} \). In this case, we call \( P(\bar{y}) \) a guard of \( \neg R(\bar{x}) \) in \( Q \), and \( \neg R(\bar{x}) \) a guarded negated atom in \( Q \). Query \( Q \) is inconsistent if an atom and its negation appear in \( Q \) at the same time. Otherwise, it is consistent.

We say that \( Q(\bar{x}) = \exists \bar{y} \varphi(\bar{x}, \bar{y}) \) is a conjunctive query with arithmetic comparisons if \( \varphi(\bar{x}, \bar{y}) \) is a conjunction of atoms and expressions of the form \( x \text{ op } c \), where \( \text{op} \in \{=, \neq, <, >, \leq, \geq \} \), \( x \in \text{Var} \) is a variable from \( \bar{x}, \bar{y} \), and \( c \in \text{Const} \). Note that we do not allow comparisons of the form \( x \text{ op } y \), where \( x \) and \( y \) are variables. We say that \( Q \) is consistent if the comparisons of \( Q \) are consistent.

For a positive or a negative atom \( P \) and conjunctive query \( Q, P \in Q \) denotes the fact that \( P \) is a conjunct of \( Q \). We denote by \( \text{Var}(Q) \), \( \text{Const}(Q) \) and \( \text{Term}(Q) \) the sets of variables, constants and terms occurring in \( Q \). We say that \( Q \) is connected if for every pair \( t \) and \( t' \) of terms in \( Q \), there is a sequence of atoms \( P_1, \ldots, P_n \) in \( Q \) such that \( t \in \text{Term}(P_1) \), \( t' \in \text{Term}(P_n) \) and \( \text{Term}(P_i) \cap \text{Term}(P_{i+1}) \neq \emptyset \), for every \( i, 1 \leq i < n \).

The answer of a \( k \)-ary conjunctive query with atomic negation \( Q(\bar{x}) \) on an instance \( I \) is a \( k \)-ary relation \( \text{Ans}(Q,I) \subseteq \text{Const}^k \) that consists of all tuples \( \theta(\bar{x}) \) such that \( \theta : \text{Var}(Q) \rightarrow \text{dom}(I) \) is a substitution such that for every positive atom \( R(\bar{u}) \in Q \) it holds that \( R(\theta(\bar{u})) \subseteq I \), and for every negative atom \( \neg P(\bar{v}) \in Q \) it holds that \( P(\theta(\bar{v})) \notin I \) (here we assume that \( \theta \) is identity on \( \text{Const} \) ). A Boolean conjunctive query \( Q \) evaluates to true in \( I \) (denoted as \( I \models Q \)) if the empty tuple is the answer of the query on \( I \), and false otherwise. If \( I \models Q \), we refer to \( \theta \) that witnesses that fact as a satisfying assignment for \( Q \) in \( I \). The semantics for conjunctive queries with comparisons is defined similarly. Now instead of preserving negation, a substitution \( \theta \) must preserve the comparisons.

Let \( Q_1 \) and \( Q_2 \) be conjunctive queries of the same arity (with atomic negation or comparisons). We say that \( Q_1 \) is contained in \( Q_2 \), denoted as \( Q_1 \subseteq Q_2 \), if for every instance \( I \) it holds \( \text{Ans}(Q_1,I) \subseteq \text{Ans}(Q_2,I) \). In case \( Q_1 \) and \( Q_2 \) are Boolean, \( Q_1 \) is contained in \( Q_2 \) if \( I \models Q_1 \) implies \( I \models Q_2 \), for every instance \( I \).

Let \( C \) be a class of conjunctive queries. The containment problem for \( C \) is the following decision problem:

- Given: \( Q_1 \) and \( Q_2 \) from \( C \),
- Decide: \( Q_1 \subseteq Q_2 \)?

We follow Gottlob et al. (2001) in the definition of acyclic conjunctive queries. Acyclicity is defined using the notion of a hypergraph. A hypergraph is a pair \( H = (V,E) \), where \( V \) is a set of vertices and \( E \subseteq 2^V \) a set of hyperedges. Given a hypergraph \( H = (V,E) \), the GYO-reduct, denoted as \( \text{GYO}(H) \), is the hypergraph obtained from \( H \) by repeatedly applying the following rules in exhaustive manner:

- Remove hyperedges that are empty or contained in other hyperedges,
- Remove vertices that appear in at most one hyperedge.

A hypergraph \( H \) is \((\alpha-)\text{acyclic} \) if \( \text{GYO}(H) \) is the empty hypergraph. The hypergraph \( H(Q) = (V,E) \) of a conjunctive query \( Q \) is defined as follows. The set of vertices
4.2. Preliminaries

$V = \text{Var}(Q)$, and for each atom $R(\bar{x})$ in $Q$, the set $E$ contains a hyperedge consisting of all variables occurring in $\bar{x}$. If $H(Q)$ is acyclic, then $Q$ is an acyclic conjunctive query. By $\text{ACQ}(-^8)$ we denote the class of acyclic conjunctive queries with guarded atomic negation, that is, the class of conjunctive queries with guarded atomic negation whose positive part (the conjunctive query obtained by removing all negative atoms) is acyclic. Acyclic conjunctive queries with arithmetic comparisons is a class of conjunctive queries whose “relational part” (that is, the query obtained by removing the comparisons in the original query) is acyclic. Here we assume that if the comparisons of a query entail that $x = y$, then every occurrence of $y$ in the query is replaced by $x$.

There is a number of notions of acyclicity for hypergraphs (Fagin, 1983). $\alpha$-acyclicity is the least restrictive among those. The most restrictive one is Berge-acyclicity (Berge, 1985) defined next.

**Definition 4.2.1** (Berge cycle). Let $H$ be a hypergraph. A Berge cycle in $H$ is a sequence $(S_1, x_1, S_2, x_2, \ldots, S_m, x_m, S_{m+1})$ such that

(i) $x_1, \ldots, x_m$ are distinct vertices in $H$,

(ii) $S_1, \ldots, S_m$ are distinct hyperedges in $H$, and $S_{m+1} = S_1$,

(iii) $m \geq 2$, that is, there are at least 2 hyperedges involved, and

(iv) $x_i$ is in $S_i$ and $S_{i+1}$, $1 \leq i \leq m$.

We say that $H$ is Berge-cyclic if it has a Berge cycle, otherwise it is Berge-acyclic. We say that a conjunctive query $Q$ is Berge-cyclic (Berge-acyclic) if its hypergraph is Berge-cyclic (respectively Berge-acyclic). Similarly to $\alpha$-acyclicity, we can define Berge-acyclic conjunctive queries with guarded atomic negation or arithmetic comparisons. Note that if a hypergraph contains two hyperedges that share two or more vertices then the hypergraph is Berge-cyclic. By Berge tree queries we mean the class of conjunctive queries $Q$ with unary guarded negation (that is, negation occurs only in front of a unary atom) or arithmetic comparisons such that

- $Q$ uses only unary and binary relational names,
- $Q$ contains no self-loops, i.e., atoms of the form $E(x, x)$,
- $Q$ contains a constant root which may appear only in the first position of atoms in $Q$, and $Q$ contains no other constant,
- $Q$ is Berge-acyclic,
- $Q$ is connected,
- If $E_1(x_1, y) \land E_2(x_2, y) \in Q$, then $E_1 = E_2$ and $x_1 = x_2$. In other words, the (hyper)graph of $Q$ is a tree.

It is easy to see that this class of queries defined over a schema with a single binary relation and (possibly many) unary relations, is precisely the class of child-only tree patterns (with negated labels or comparisons) used in an XML context (Miklau and Suciu, 2004).
We give the definition of Tree Patterns that can contain labeled child and descendent edges, and that capture Berge tree queries.

Let $\Sigma$ and $\Sigma_e$ be disjoint sets of node and edge labels. A tree pattern with label negation is a tree $(N, E, E_{//}, r, l_e, l^+, l^-)$, where $N$ is the set of nodes, $E \cup E_{//} \subseteq N^2$ is the edge relation consisting of disjoint child and descendant relations respectively, $r \in N$ the root node, $l_e : E \cup E_{//} \rightarrow \Sigma_e$ the edge labeling function and $l^+, l^- : N \rightarrow 2^{\Sigma}$ are positive and negative node labeling functions. For a tree pattern $P$, by $\text{Nodes}(P)$ we denote the set of nodes of $P$. Let additionally $A$ be a set of attribute names. By $\Sigma_A$ we denote the set $\{ \oplus_a \circ \circ c \mid a \in A, \circ \circ \in\{=, \neq, <, \leq, \geq\}, c \in \text{Const}\}$. A tree pattern with attribute comparisons is a tree $(N, E, E_{//}, r, l_e, l)$, such that $N, E, E_{//}, r, l_e$ are as above, and $l : N \rightarrow 2^{\Sigma_e \cup \Sigma_A}$ is a node labelling function.

We define what it means that a tree pattern is true in a graph as follows. Let $G = (\text{dom}(G), E', \rho_e, \rho_n, r')$ be a graph, where $\text{dom}(G)$ is the set of nodes, $E' \subseteq \text{dom}(G)^2$ the edge relation, $\rho_e : E' \rightarrow 2^{\Sigma_e}$ and $\rho_n : \text{dom}(G) \rightarrow 2^{\Sigma}$ are the edge and node labelling functions, and $r' \in \text{dom}(G)$ is a fixed designated node. We say that a tree pattern with label negation $P$ is true in $G$, or $G$ satisfies $P$, denoted as $G \models P$, if there is a function $e : N \rightarrow \text{dom}(G)$, called embedding of $P$ in $G$, such that all of the following hold:

1. If $(x, y) \in E$ and $l_e((x, y)) = \alpha$, then $(e(x), e(y)) \in E'$ and $\alpha \in \rho_e((e(x), e(y)))$;
2. If $(x, y) \in E_{//}$ and $l_e((x, y)) = \alpha$, then there exist nodes $n_1, \ldots, n_k$ in $\text{dom}(G)$ such that $n_1 = e(x), n_k = e(y)$, $(n_i, n_{i+1}) \in E'$ and $\alpha \in \rho_e((n_i, n_{i+1}))$, for every $i, 1 \leq i \leq k - 1$;
3. For every $x \in N$, $l^+(x) \subseteq \rho_n(e(x))$;
4. For every $x \in N$, $l^-(x) \cap \rho_n(e(x)) = \emptyset$.

We say that $G$ strongly satisfies $P$, denoted as $G \models_s P$, if there is an embedding $e$ of $P$ in $G$ such that it additionally satisfies the following condition:

0. $e(r) = r'$.

The semantics of tree patterns with attribute comparisons is defined over graphs that are additionally equipped with a partial function $\text{att} : \text{dom}(G) \times A \rightarrow \text{Const}$. The definition of $G \models P$ and $G \models_s P$, where $P$ is a tree pattern with attribute comparisons, is defined similarly to the above definition, where (3) and (4) are replaced with the following conditions:

3’. For every $x \in N$, $l(x) \cap \Sigma \subseteq \rho_n(e(x))$;
4’. For every $x \in N$, if $\oplus_a \circ \circ c \in l(x)$, then $\text{att}(e(x), a) \circ \circ c$.

We say that a tree pattern $P = (N, E, E_{//}, r, l_e, l^+, l^-)$ is consistent if for every $x \in N$ it holds $l^+(x) \cap l^-(x) = \emptyset$. Similarly, a tree pattern with attribute comparisons is consistent if the comparisons of every attribute in every node are consistent. Note that a tree pattern $P$ is consistent if and only if there is a structure $G$ such that $G \models P$. Furthermore, consistency of a tree pattern can be checked in PTIME.

For tree patterns with label negation or comparisons $P$ and $Q$, we say that $P$ is contained in $Q$ (resp. strongly contained), denoted as $P \subseteq Q$ ($P \subseteq_s Q$), if for every $G$ it holds that $G \models P \models_s Q$. We denote $G \models Q$ if $G \models_P Q$ and $G \models_s P$.

4. Containment for ACQ with Atomic Negation and Arithmetic Comparisons
We say that a tree pattern is child-only if the set $E_1$ is empty, and descendant-only if $E$ is empty. In these cases we omit the relations $E_1$ and $E$ respectively. It is easy to see that every child-only tree pattern with label negation is equivalent (in a strong sense) to a Berge tree query and vice versa. Likewise, every child-only tree pattern with comparisons (with one attribute name) is equivalent to a Berge tree query with comparisons, and vice versa. We omit details of the translations. Thus, child-only tree patterns can be seen as particular fragments of acyclic conjunctive queries. We show in Section 4.4 that containment for this fragment is in PTIME.

4.3 Containment for acyclic conjunctive queries with guarded atomic negation or comparisons

We first state the known result on the containment for CQ with atomic negation or comparisons.

**Theorem 4.3.1** (Klug (1988); Nutt (2013); van der Meyden (1997)). The containment problem for conjunctive queries with atomic negation or arithmetic comparisons is $\Pi^P_2$-complete.

As noted in the introduction of this chapter, the known proofs for the $\Pi^P_2$ lower bound involve conjunctive queries that are cyclic.

In this section we show that containment for acyclic conjunctive queries with guarded negated atoms of bounded arity or comparisons is coNP-complete. We also provide several coNP lower bounds that help to identify the sources of intractability. W.l.o.g. we can consider containment for acyclic Boolean conjunctive queries. Indeed, the containment problem for non-Boolean CQ can be reduced in PTIME to containment of Boolean CQ while preserving the acyclicity restriction.

**Proposition 4.3.1.** Let $P$ and $Q$ be acyclic conjunctive queries with guarded atomic negation (with comparisons). Then there exist PTIME computable acyclic Boolean conjunctive queries with guarded atomic negation (with comparisons) $P'$ and $Q'$ such that $P \subseteq Q$ iff $P' \subseteq Q'$.

This also holds for Berge-acyclic queries.

**Proof.** Let $P(x)$ and $Q(y)$ be acyclic conjunctive queries with guarded atomic negation (comparisons). We check if $P$ and $Q$ are inconsistent which can be done in PTIME (van der Meyden, 1997; Wei and Lausen, 2003). If $P$ is inconsistent, let $P' = Q' = \exists x. P(x)$. If $Q$ is inconsistent or the length of $x$ and the length $y$ are different, let $P' = \exists x. P_1(x)$ and $Q' = \exists y. P_2(y)$. In case $P$ and $Q$ are consistent, let $x = (x_1, \ldots, x_n)$ and $y = (y_1, \ldots, y_n)$, and $P_1, \ldots, P_n$ be unary relational names that do not appear in $P$ or $Q$. Then we define $P' = \exists x. P_1(x_1) \land \ldots \land P_n(x_n) \land P(x)$ and $Q' = \exists y. P_1(y_1) \land \ldots \land P_n(y_n) \land Q(y)$. Clearly, $P'$ and $Q'$ are PTIME computable. Moreover, if $P$ and $Q$ are $p$-acyclic ($p \in \{\alpha, \text{Berge}\}$), then $P'$ and $Q'$ are $p$-acyclic as well. It is easy to show that $P \subseteq Q$ iff $P' \subseteq Q'$.

57
Thus, in the rest of the chapter we only consider containment for Boolean acyclic CQ with guarded atomic negation or comparisons.

Now we show that restricting conjunctive queries with atomic negation to be acyclic and with guarded negated atoms of bounded arity makes the containment problem \textsc{coNP}-complete.

**Theorem 4.3.2.** The containment problem for acyclic conjunctive queries with guarded negated atoms of bounded arity (or with arithmetic comparisons), is in \textsc{coNP}.

**Proof.** Let \( P \) and \( Q \) be input queries. A \textsc{coNP} algorithm then works as follows. We first guess a potential counterexample \( I \), and, second, check whether \( I \models P \) and \( I \not\models Q \). Lemma 4.3.1 below guarantees that it is enough to guess a counterexample with size polynomial in the sizes of \( P \) and \( Q \). By Lemma 4.3.2 below, the second step can be done in \textsc{ptime}. The guardness condition is not used in the proof of Lemma 4.3.1, but it is crucial in the proof of Lemma 4.3.2. \( \square \)

**Lemma 4.3.1.** Let \( Q_1 \) and \( Q_2 \) be Boolean ACQ\((-\bar{g})\) queries such that the arity of negative atoms is bounded by a fixed constant \( k \) (resp. with arithmetic comparisons). If \( Q_1 \not\subseteq Q_2 \), then there is an instance \( I \) such that \( I \models Q_1 \), \( I \not\models Q_2 \), and the size of \( I \) is polynomial in the sizes of \( Q_1 \), \( Q_2 \).

**Proof.** We first consider the case of ACQ\((-\bar{g})\). By assumption, for every negative atom \( \neg R \) in \( Q_2 \), the arity of \( R \) is bounded by a constant \( k \). Let \( I' \) be a counterexample for \( Q_1 \subseteq Q_2 \). Since \( I' \models Q_1 \), there is a satisfying assignment \( \theta : \text{Var}(Q_1) \rightarrow \text{dom}(I') \). By \( \theta(\text{Var}(Q_1)) \) we denote the range of \( \theta \). Furthermore, by \( \theta(Q_1) \) we denote the image of positive atoms in \( Q_1 \) wrt \( \theta \), i.e., the set \( \{ R(\theta(x)) \mid R(x) \in Q_1 \} \). We then define the instance \( I \) as the set

\[
\theta(Q_1) \cup \{ P(a) \in I' \mid P \text{ occurs negatively in } Q_2, \quad \bar{a} \subseteq \theta(\text{Var}(Q_1)) \cup \text{Const}(Q_1) \cup \text{Const}(Q_2) \}.
\]

Note that \( I \) is a subinstance of \( I' \) and its size is bounded by \( |Q_1| + |Q_2| \cdot (|Q_1| + |Q_2|)^k \).

Firstly, \( \theta \) is a satisfying assignment for \( Q_1 \) in \( I \), and thus \( I \models Q_1 \). Indeed, the positive atoms are preserved since \( \theta(Q_1) \subseteq I \). Furthermore, no negative atom in \( Q_1 \) becomes true under \( \theta \) since \( I \) is a subinstance of \( I' \) and \( \theta \) is a satisfying assignment for \( Q_1 \) in \( I' \).

Secondly, we show \( I \not\models Q_2 \). Suppose the opposite. This means there is a satisfying assignment \( h : \text{Var}(Q_2) \rightarrow \text{dom}(I) \). We show that \( h \) is also a satisfying assignment for \( Q_2 \) in \( I' \), which contradicts the assumption.

- Let \( R(\bar{x}) \in Q_2 \). Then \( R(h(\bar{x})) \in I \subseteq I' \).

- Let \( \neg R(\bar{x}) \in Q_2 \). Then \( R(h(\bar{x})) \not\in I \). Note that \( h(\bar{x}) \subseteq \theta(\text{Var}(Q_1)) \cup \text{Const}(Q_1) \cup \text{Const}(Q_2) \). Thus, because of that and the fact that \( R \) occurs negatively in \( Q_2 \), it follows that \( R(\bar{a}) \not\in I' \) by the definition of \( I \).

We now prove the lemma for the case of arithmetic comparisons. Let \( \theta \) be a satisfying assignment for \( Q_1 \) in \( I' \). We take \( I \) as \( \theta(Q_1) = \{ R(\theta(\bar{x})) \mid R(\bar{x}) \in Q_1 \} \). The size of \( I \) is obviously polynomial. \( I \models Q_1 \) holds because \( \theta \) is a satisfying assignment for \( Q_1 \) in \( I \). Furthermore, \( I \not\models Q_2 \) holds since any satisfying assignment for \( Q_2 \) in \( I \) is a satisfying assignment for \( Q_2 \) in \( I' \). \( \square \)

58
The evaluation problem for a class of Boolean queries $\mathcal{C}$ is the following decision problem. Given an instance $I$, a Boolean query $Q \in \mathcal{C}$, decide whether $Q$ evaluates to true in $I$, i.e., $I \models Q$.

**Lemma 4.3.2.** The evaluation problem is in PTIME for each of the following classes of Boolean queries:

(i) Boolean acyclic conjunctive queries with guarded negated atoms of bounded arity, and

(ii) Boolean acyclic conjunctive queries with arithmetic comparisons.

**Proof.** We prove item (i). Let $I$ be an instance and $Q$ a Boolean acyclic query with guarded atomic negation such that each negated atom is bounded by a constant $k$. We make a polynomial reduction to the evaluation problem for (positive) acyclic Boolean conjunctive queries which is known to be in PTIME (Gottlob et al., 2001; Yannakakis, 1981).

For every relational name $R$ that occurs negatively in $Q$, we introduce a new relational name $\tilde{R}$ of the same arity as $R$. By $\tilde{Q}$ we denote the result of replacement of each negated atom $\neg R(\bar{x})$ in $Q$ by $\tilde{R}(\bar{x})$. Note that $\tilde{Q}$ now is an ordinary CQ. Moreover, $\tilde{Q}$ is acyclic because (1) $Q$ is acyclic and (2) every hyperedge in $H(\tilde{Q})$ corresponding to an atom $\tilde{R}(\bar{x})$ is contained in a hyperedge corresponding to an (positive) atom $P(\bar{y})$ that appears in $Q$ and $\tilde{Q}$. We then define the instance

$$\tilde{I} = I \cup \{\tilde{R}(\bar{a}) \mid \bar{a} \subseteq dom(I), \neg R(\bar{x}) \in Q, \text{ and } R(\bar{a}) \not\in I\}.$$ 

Note that the size of $\tilde{I}$ is bounded by $|I| + |Q| \cdot |dom(I)|^k$ which is polynomial in the sizes of $I$ and $Q$. We claim that $I \models Q$ if and only if $\tilde{I} \models \tilde{Q}$.

($\Rightarrow$). Suppose $I \models Q$, i.e., there is a satisfying variable assignment $\theta : Var(Q) \rightarrow dom(I)$. Note that $Var(Q) = Var(\tilde{Q})$ and $dom(I) = dom(\tilde{I})$. We show that $\theta$ is a satisfying assignment for $\tilde{Q}$ in $\tilde{I}$. The positive atoms from $Q$ are still preserved since we did not remove any facts from $I$. Let $\tilde{R}(\bar{x}) \in \tilde{Q}$. This means that $\neg R(\bar{x}) \in Q$. Hence, $R(\theta(\bar{x})) \not\in I$. Since also $\theta(\bar{x}) \subseteq dom(I)$, we have that $R(\theta(\bar{x})) \in \tilde{I}$, as needed.

($\Leftarrow$). Suppose $\tilde{I} \models \tilde{Q}$, i.e., there is a satisfying assignment $\theta : Var(\tilde{Q}) \rightarrow dom(\tilde{I})$. We show that $\theta$ is a satisfying assignment for $Q$ in $I$. Positive atoms in $Q$ are preserved since they are positive atoms in $\tilde{Q}$ as well and $\theta$ preserves them in $\tilde{I}$ and thus in $I$. Let $\neg R(\bar{x}) \in Q$. This means that $\tilde{R}(\bar{x}) \in \tilde{Q}$. Hence $\tilde{R}(\bar{x}) \in \tilde{I}$ and, in particular, $\tilde{R}(\bar{x}) \in \{\tilde{R}(\bar{a}) \mid \bar{a} \subseteq dom(I), \neg R(\bar{x}) \in Q, \text{ and } R(\bar{a}) \not\in I\}$. It follows that $R(\theta(\bar{x})) \not\in I$.

Item (ii) is shown similarly. Now each arithmetic comparison $x op c$ that occurs in $Q$ is replaced with a new unary atom $P_{op c}(x)$. Let $\tilde{Q}$ be the result of this replacement. Let $\Sigma_c$ be the constants occurring in the comparisons of $Q$. Note that $|\Sigma_c| \leq |Q|$. We define the instance

$$\tilde{I} = I \cup \{P_{op c}(a) \mid a \in dom(I), op \in \{=, \neq, <, >, \leq, \geq\} \text{ and } a op c\}.$$ 

Note that the size of $\tilde{I}$ is bounded by $|I| + 6 \cdot |Q| \cdot |dom(I)|$, which is polynomial in the sizes of $I$ and $Q$. It is straightforward to show that $I \models Q$ if and only if $\tilde{I} \models \tilde{Q}$. □
We show that the corresponding coNP lower bound for containment already holds for child-only tree patterns with negated labels (or comparisons). For this, we first show that we can allow disjunction on the right hand side query of the containment problem.

We extend the definition of containment for unions of tree patterns with label negation, i.e., expressions of the form $\bigvee_{i=1}^{k} Q_i$ where each $Q_i$ is a tree pattern with label negation. Let $P$ be a tree pattern and $Q = \bigvee_{i=1}^{k} Q_i$ a union of tree patterns with label negation. We say that $P$ is contained (resp. strongly contained) in $Q$ if for every $G$ it holds that $G \models P$ ($G \models_s P$) implies that there is a $j \in \{1, \ldots, k\}$ such that $G \models Q_j$ ($G \models_s Q_j$).

**Lemma 4.3.3.** Let $P$ be a child-only tree pattern with label negation (resp. attribute comparisons) and $Q = \bigvee_{i=1}^{k} Q_i$ a union of child-only tree patterns with label negation (attribute comparisons). There exist PTIME computable child-only tree patterns with label negation (attribute comparisons) $P'$ and $Q'$ such that

$$P \subseteq_s Q \text{ if and only if } P' \subseteq Q'.$$

**Proof.** The proof is similar to the one of Lemma 3 in (Miklau and Suciu, 2004). Let $a, b$ be node labels not occurring in $P$ or $Q$. Let $S^b$ be the child-only tree patterns corresponding to (written as conjunctive queries) $b(x) \land \bigwedge_{i=1}^{k} (e(x, y_i) \land Q_i)$, where $y_i$ is the root of $Q_i$, $x$ is not among the variables of every $Q_i$ and $e$ is the child relation. We define $P'$ and $Q'$ as in Figure 4.1.

Clearly $P'$ and $Q'$ are child-only tree patterns with label negation and PTIME computable. We verify that $P \subseteq_s Q$ if and only if $P' \subseteq Q'$.

$(\Rightarrow)$. Assume $P \subseteq_s Q$. Let $I$ be an instance (graph) such that $I \models P'$. That means there is an embedding $\theta : \text{Nodes}(P') \rightarrow \text{dom}(I)$. Note that $\theta$ is also an embedding for $P$ in $I$ as well, since $P$ is a subquery of $P'$. Thus, $I \models Q$, i.e., there exists an index
4.3. Containment for ACQ with guarded atomic negation or comparisons

Figure 4.2: The instance $I'$ from Lemma 5.4.2.

$j, 1 \leq j \leq k$, such that $I \models Q_j$. The latter implies there is an embedding $h'$ of $Q_j$ in $I$. Moreover, since the containment of $P$ in $Q$ is strong, we must have that $h'$ maps the root of $Q_j$ to the $\theta$-image of the root of $P$. Then we define a mapping $\theta' : \text{Nodes}(Q') \rightarrow I$ as the composition of $h$ with $\theta$, where $h$ is a mapping from $\text{Nodes}(Q')$ to $\text{Nodes}(P')$ that extends $h'$ and is defined for the other nodes as follows. For every $i, 1 \leq i \leq k$, we define $h(x'_i) := x_{k-j+i}$, $h(y'_i) = y_{k-j+i}$ and the nodes of $Q_i$ ($i \neq j$) in $Q'$ are mapped "canonically" to the corresponding nodes in $S^i$. It is easy to see that $\theta'$ is indeed an embedding of $Q'$ in $I$.

$(\Leftarrow)$. Assume $P' \subseteq Q'$. Let $I$ be an instance such that $I \models P$ and $h$ an embedding of $P$ in $I$. Let also $I_i$ be the canonical tree (instance) of $Q_i$ (i.e., the instance containing only the positive atoms of $Q_i$ and replacing each variable by a fresh constant). Then we construct the instance $I'$ depicted in Figure 4.2. Note that $I$ is connected via the $b$-node to the $h$-image of the root of $P$. By the assumption, it holds that $I' \models Q'$, i.e., there is an embedding $\theta : \text{Nodes}(Q') \rightarrow \text{dom}(I')$. In particular, since $a$ only appears in the vertical span of $2k - 1$ nodes in Figure 4.2, the span of $k$ $a$-nodes of $Q'$ can only be mapped on that vertical span in $I'$. Because of this and the fact that a $b$-node in $Q'$ must be mapped to a $b$-node in $I'$, there must exist an index $j$ for which $\theta$ is an embedding of $Q_j$ in $I$. Moreover, this embedding maps the root of $Q_j$ to the $h$-image of the root of $P$. Thus, $I \models_s Q_j$ and, therefore, $I \models_s Q$.

The case of tree patterns with comparisons is proved similarly.

Lemma 4.3.4. The containment problem $\varphi \subseteq_s \bigvee_{i=1}^{m} \psi_i$ is \textsc{coNP}-hard for each of the following cases:

(i) $\varphi, \psi_i$ are propositional conjunctive formulas with guarded atomic negation,
(ii) \( \varphi, \psi_i \) are child-only tree patterns with attribute comparisons.

Proof. (i). We reduce 3SAT to the complement of the containment problem for the stated fragment. Let \( \varphi' \) be a conjunction of clauses \( C_i = (b_1^i \lor b_2^i \lor b_3^i) \), \( 1 \leq i \leq k \), over the variables \( \{x_1, \ldots, x_n\} \), where \( b_j^i \) are literals, i.e., variables or their negations. For a literal \( l \), by \( \neg l \) we denote \( \neg p \) if \( l = p \) and \( p \) if \( l = \neg p \).

For every clause \( C_i \), we introduce a propositional variable \( c_i \). Then we define propositional conjunctive formulas with atomic negation \( \varphi \) and \( \psi_i \) over the propositional variables \( c_i, 1 \leq i \leq k \), and \( x_i, 1 \leq j \leq n \), as follows. We define \( \varphi = c_1 \land \ldots \land c_k \) and \( \psi_i = c_i \land \neg b_1^i \land \neg b_2^i \land \neg b_3^i \).

We claim that \( \varphi' \) is satisfiable iff \( \varphi \models s \lor_{i=1}^{k} \psi_i \). This is easy to see using de Morgan's laws. In particular, \( \varphi \models s \lor_{i=1}^{k} \psi_i \) iff \( \neg \varphi \land \lor_{i=1}^{k} \neg \psi_i \) is satisfiable iff \( c_1 \land \ldots \land c_k \land \lor_{i=1}^{k} \neg c_i \lor b_1^i \lor b_2^i \lor b_3^i \) is satisfiable, i.e., \( \varphi' \) is satisfiable.

Item (ii) is proved as follows. Let \( \varphi' \) be as above. The tree pattern \( \varphi \) is defined as \( \{r, m_1, \ldots, m_n\}, \{r, m_1, \ldots, m_n\}, r, l_e, l \), where for every \( i \in \{1, \ldots, n\}, l_e(r, m_i) = \alpha \), for some \( \alpha \), and \( l(m_i) = \{p_i, @_a \neq 2\} \). Each \( \psi_i \) is defined as \( \{r_1, n_1^i, n_2^i, n_3^i\}, \{r_1, n_1^i, n_2^i, n_3^i\}, \{r_1, n_1^i, n_2^i, n_3^i\}, r_1, l_e, l_i \), where \( l_e((r_i, n_j^i)) = \alpha \) and \( l(n_j^i) = \{p_i, B_j^i\} \), where \( B_j^i = (@_a = 0) \) iff \( b_j^i = x_i \) and \( B_j^i = (@_a \neq 0) \) iff \( b_j^i = \neg x_i \) in \( C_i \). It is straightforward to show that \( \varphi' \) is satisfiable iff \( \varphi \models s \lor_{i=1}^{k} \psi_i \).

\[ \square \]

**Theorem 4.3.3.** Containment is \( \text{coNP} \)-hard for each of the following classes of queries:

a) for connected Berge-acyclic conjunctive queries with guarded unary negated atoms (or with comparisons),

b) for Berge-acyclic conjunctive queries with guarded unary negated atoms (or with comparisons) and with the requirement that they contain an atom with root as an argument, for a fixed constant root.

c) and for connected \( \alpha \)-acyclic conjunctive queries with guarded unary negation (or with comparisons) and with the requirement that they contain an atom with root as an argument, for a fixed constant root.

Proof. Item a) follows from Lemmas 5.4.2 and 4.3.4, since tree patterns with negated labels (resp. with comparisons) are connected Berge-acyclic conjunctive queries with guarded unary negated atoms (with comparisons).

Item b) follows from a). Indeed, let \( P \subseteq Q \) be the encoding from a). Then for \( P' = R(\text{root}) \land P \) and \( Q' = R(\text{root}) \land Q \), where \( \text{root} \) is a constant and \( R \) a unary relational name, it holds \( P \subseteq Q \) if and only if \( P' \subseteq Q' \).

For item c) we use the encoding from a). Let \( P \subseteq Q \) be the encoding from a). We construct Boolean \( \alpha \)-acyclic conjunctive queries \( P' \) and \( Q' \) as follows. Let \( \{x_1, \ldots, x_n\} \) be the variables of \( P \), \( P \) a fresh \((n+1)\)-ary relational name, \( \text{root} \) a constant, \( G \) a fresh binary relational name, and \( r \) the root (variable) of \( Q \). Then \( P' = P(\text{root}, x_1, \ldots, x_n) \land P \land \lor_{i=1}^{n} G(\text{root}, x_i) \) and \( Q' = G(\text{root}, r) \land Q \). Note that both \( P' \) and \( Q' \) are \( \alpha \)-acyclic queries with guarded negation. In particular, \( P' \) is acyclic because all its hyperedges are contained in the hyperedge \( P \). We show that \( P \subseteq Q \) if \( P' \subseteq Q' \).

\[ 62 \]
4.4 Polynomial-time algorithms for containment

(⇒). Let \( I \) be an instance such that \( I \models \mathcal{P'} \). Thus there exists a satisfying variable assignment \( \theta : \text{Var}(\mathcal{P'}) \to \text{dom}(I) \). In particular, \( \theta \) is satisfying for \( \mathcal{P} \) in \( I \). Let \( I' = I \upharpoonright \theta(\{x_1, \ldots, x_n\}) \). Since \( I' \models \mathcal{P} \), it holds that \( I' \models \mathcal{Q} \). Let \( \theta' \) be a satisfying assignment for \( \mathcal{Q} \) in \( I' \). Then \( r \) is mapped to one of \( \theta(x_j) \). Since \( \text{root} \) must be mapped to \( \text{root} \) and \( G(\text{root}, \theta(x_i)) \) holds in \( I \) for every \( i \), we have that \( \theta' \cup \{\text{root} \rightarrow \text{root}\} \) is a satisfying assignment for \( \mathcal{Q}' \) in \( I' \).

(⇐). Let \( I \) be an instance such that \( I \models \mathcal{P} \). Let \( \theta \) be a satisfying assignment for \( \mathcal{P} \) in \( I \). W.l.o.g. we can assume that \( I = I \upharpoonright \text{Var}(\mathcal{P}) \). We then construct the instance \( I' \) as

\[
I' = I \cup \{P(\text{root}, \theta(x_1), \ldots, \theta(x_n)),
G(\text{root}, \theta(x_1)), \ldots, G(\text{root}, \theta(x_n)).
\]

Clearly, \( \theta \cup \{\text{root} \rightarrow \text{root}\} \) is a satisfying assignment for \( \mathcal{P}' \) in \( I' \). Then it holds that \( I' \models \mathcal{Q}' \). Let \( \theta' \) be a satisfying assignment for \( \mathcal{Q}' \) in \( I' \). In particular, \( \text{Var}(\mathcal{Q}) \) must be mapped to \( \theta(\{x_1, \ldots, x_n\}) \) since \( G \) is fresh and \( \text{root} \) is mapped to \( \text{root} \). Thus, \( \theta' \) is a satisfying assignment for \( \mathcal{Q} \) in \( I \). Thus \( I \models \mathcal{Q} \).

We say that a conjunctive query \( Q \) with guarded negation (resp. with arithmetic comparisons) is **pointed Berge acyclic with guarded negation** (resp. with arithmetic comparisons) if \( Q \) contains at least one binary atom and

(i) is connected,

(ii) contains an atom having \( \text{root} \) as an argument, where \( \text{root} \) is a fixed constant, and

(iii) is Berge-acyclic.

Theorem 4.3.3 shows that containment for the class of conjunctive queries with guarded atomic negation or arithmetic comparisons (with at least one binary atom) that satisfies at most two of the conditions (i)–(iii) is \( \text{coNP}-\text{hard} \).

We leave it as an open question whether containment for pointed Berge acyclic queries is in \( \text{PTIME} \). However, we are able to obtain \( \text{PTIME} \) results for containment of child-only tree patterns with label negation or comparisons, which is a fragment of pointed Berge acyclic queries.

### 4.4 Polynomial-time algorithms for containment

In this section we consider a fragment of pointed Berge-acyclic conjunctive queries with guarded negation – child-only tree patterns with label negation. The additional requirement for tree patterns is that every query must contain a constant \( \text{root} \), which always maps to the designated node in a graph, i.e., we consider **strong** satisfaction. We refer to such tree patterns as **rooted** child-only tree patterns. This root requirement, besides Berge-acyclicity and connectedness, turns out to be crucial for \( \text{PTIME} \) containment, since without this requirement containment becomes \( \text{coNP}-\text{hard} \), by Theorem 4.3.3, (b). Note that containment in this case is the same as strong containment.

We characterize containment via the notion of **homomorphism**. Let \( P = (N, E, r, l_e, l^+, l^-) \) and \( Q = (N', E', r', l'_e, l'^+, l'^-) \) be child-only tree patterns with label negation. A mapping \( h : N' \to N \) is called a **homomorphism** from \( Q \) to \( P \), if the following are satisfied:
4. Containment for ACQ with Atomic Negation and Arithmetic Comparisons

(i) \( h(r') = r \);

(ii) If \((x, y) \in E'\) and \(l'_e(\langle x, y \rangle) = \alpha\), then \((h(x), h(y)) \in E\) and \(l_e(\langle h(x), h(y) \rangle) = \alpha\);

(iii) \( l^+(x) \subseteq l^+(h(x)) \), for every \( x \in N' \);

(iv) \( l^-(x) \subseteq l^-(h(x)) \), for every \( x \in N' \).

Note that the above definition without item (iv) coincides with the usual definition of homomorphism for tree patterns without negation (Miklau and Suciu, 2004).

**Theorem 4.4.1.** Let \( P \) and \( Q \) be consistent child-only tree patterns with label negation. Then \( P \subseteq Q \) if and only if there exists a homomorphism from \( Q \) to \( P \).

**Proof.** Let \( P = (N, E, r, l_e, l^+, l^-) \) and \( Q = (N', E', r', l'_e, l'^+, l'^-) \) be child-only tree patterns with label negation.

\((\Leftarrow)\). Assume \( h : N' \rightarrow N \) is a homomorphism. Let \( G = (\text{Nodes}(G), E'', \rho_e, \rho_n, r'') \) be a graph such that \( G \models P \), i.e., there is an embedding \( e : N \rightarrow \text{Nodes}(G) \) with \( e(r) = r'' \). Then we claim that \( e' = e \circ h \) is an embedding of \( Q \) in \( G \). We check the conditions (0)–(4) from the definition of embedding (except (2)):

\((0)\) \( e'(r') = e \circ h(r') = e(r) = r'' \).

\((1)\) Let \((x, x') \in E'\) and \(l'_e(\langle x, x' \rangle) = \alpha\). Then \((h(x), h(x')) \in E\) and \(l_e(\langle h(x), h(x') \rangle) = \alpha\), which implies \((e(h(x)), e(h(x'))) \in E''\) and \(\alpha \in \rho_e(\langle e(h(x)), e(h(x')) \rangle)\).

\((3)\) Let \( x \in N' \) and \( p \in l'^+(x) \). Then \( p \in l^+(h(x)) \), which implies that \( p \in \rho_n(e(h(x))) \), as needed.

\((4)\) Let \( x \in N' \) and \( p \in l'^-(x) \). Then \( p \in l^-(h(x)) \), which implies that \( p \not\in \rho_n(e(h(x))) \), as needed.

\((\Rightarrow)\). We show the contrapositive. Suppose there is no homomorphism from \( Q \) to \( P \). We then construct a counter-example by taking a graph (tree) with the same structure as \( P \). Let \( P.y \) be the subtree of \( P \) rooted in \( y \) and \( Q.x \) the subtree of \( Q \) rooted in \( x \). By induction on the depth of \( P.y \) we show

\((\text{IH})\) If there is no homomorphism from \( Q.x \) to \( P.y \), then there exists a tree \( T \) such that \( T \models P.y \) and \( T \not\models Q.x \).

**Base of induction:** \( \text{depth}(P.y) = 0 \). Then there is no homomorphism from \( Q.x \) to \( P.y \) if either

- there exists a label \( p \in \Sigma \) such that either (i) \( p \in l'^+(x) \) and \( p \not\in l^+(y) \), or (ii) \( p \in l'^-(x) \) and \( p \not\in l^-(y) \). We define \( T = (\text{Nodes}(T), E'', \rho_e, \rho_n, y) \), where \( \text{Nodes}(T) = \{y\} \), \( E'' = \emptyset \), and \( \rho_n \) is defined according to the above cases: (i) \( \rho_n(y) = l^+(y) \) or (ii) \( \rho_n(y) = l^+(y) \cup \{p\} \). By construction, we have \( T \models P.y \). It also holds that \( T \not\models Q.x \). Indeed, otherwise it would hold that \( l'^+(x) \subseteq \rho_n(y) \) and \( l'^-(x) \cap \rho_n(y) = \emptyset \), which contradicts with the definition of \( \rho_n \).
Or there exists $x'$ such that $(x, x') \in E'$. In this case, we define $T = (\text{Nodes}(T), E'', \rho_e, \rho_n, y)$, where $\text{Nodes}(T) = \{y\}$, $E'' = \emptyset$, and $\rho_n(y) = l^+(y)$. By construction we have that $T \models P.y$. Moreover, $T \not\models Q.x$ since there is no child of the image of $x$ in $T$.

**Induction step:** $\text{depth}(P.y) > 0$ and there is no homomorphism from $Q.x$ to $P.y$. It is because either

- there exists a label $p$ such that either (i) $p \in l^+(x)$ and $p \notin l^-(y)$, or (ii) $p \in l^-(x)$ and $p \notin l^-(y)$. We define $T = (N_T, E_T, \rho_e, \rho_n, y)$, where $N_T = \{n \in N \mid P \models yE^*n\}$, i.e., the nodes below $y$ in $P$, $E_T = E\mid_{N_T^2}$, $\rho_e = l_e$, and the node labeling $\rho$ is defined as follows.

\[
\rho(u) = \begin{cases} 
  l^+(u) & \text{if } u = y \text{ and (i) holds}, \\
  l^+(u) \cup \{p\} & \text{if } u = y \text{ and (ii) holds}, \\
  l^+(u) & \text{if } u \neq y.
\end{cases}
\]

It is easy to see that $T \models P.y$ and $T \not\models Q.x$.

- Or there exists $x'$ such that $(x, x') \in E'$ and for all $y_i$ with $(y, y_i) \in E$ and $l_e((y, y_i)) = l'_e((x, x'))$ it holds that there is no homomorphism from $Q.x'$ to $P.y_i$. Since $\text{depth}(P.y_i) < \text{depth}(P.y)$ for every such $y_i$, by the induction hypothesis, it holds that there exists a tree $T_i = (N_i, E_i, \rho_i^e, \rho_i^r, r_i)$ such that $T_i \models P.y_i$ and $T_i \not\models Q.x'$. Let $T'_j = (N'_j, E'_j, \rho^e_j, \rho^r_j, r'_j)$ be the canonical trees for the subtrees $P.u_j$ such that $yEu_j$ and $l'_e((y, u_j)) \neq l'_e((x, x'))$. We can assume that these trees are pairwise disjoint. We then define the tree $T = (N_T, E_T, \rho_e, \rho_n, y)$ such that $N_T = \{y\} \cup \bigcup_i N_i \cup \bigcup_j N'_j$, $E_T = \bigcup_i (E_i \cup \{(y, y_i)\}) \cup \bigcup_j (E'_j \cup \{(y, u_j)\})$, $\rho_e((u,v)) = \begin{cases} 
  l_e((u,v)) & \text{if } u = y, \\
  \rho^e_i((u,v)) & \text{if } T_i \models uE_i v, \\
  \rho^e_j((u,v)) & \text{if } T'_j \models uE'_j v,
\end{cases}$

\[
\rho(u) = \begin{cases} 
  l^+(y) & \text{if } u = y, \\
  \rho^e_i(u) & \text{if } T_i \models y_iE_i^* u, \\
  \rho^e_j(u) & \text{if } T'_j \models u_jE'_j^* u.
\end{cases}
\]

We claim that $T \models P.y$ and $T \not\models Q.x$. The former is by definition of $T$. For the latter, suppose $e : Q.x \rightarrow T$ is an embedding. In particular, that means that $e$ is an embedding of $Q.x'$ to one of $T_i$, where $y_i$ is a child of $y$. Thus, $T_i \models Q.x'$, which is a contradiction.

Thus, since there is no homomorphism from $Q.r'$ to $P.r$, there exists a tree such that $T \models P$ and $T \not\models Q$. □

**Corollary 4.4.1.** Containment for child-only tree patterns with label negation is in PTIME.

**Proof.** Let $P \subseteq Q$ be a containment problem, where $P$ and $Q$ are child-only tree patterns with label negation. We first check if $P$ is consistent. If not, we output “yes”. If it is consistent, we check if $Q$ is consistent. If not, we output “no”. Otherwise, by Theorem 4.4.1
it is enough to check existence of a homomorphism from $Q$ to $P$. To this purpose, we reduce the problem to checking homomorphism for tree patterns without label negation. The latter can be done e.g., using a bottom-up procedure (Miklau and Suciu, 2004). For each negated label $\neg p$ occurring in $P$ or $Q$, we introduce a new label $\tilde{p}$. For a tree pattern with label negation $Q$, by $\tilde{Q}$ we denote the result of replacing each negated label $\neg p$ with the corresponding label $\tilde{p}$. It is easy to verify that there is a homomorphism from $Q$ to $P$ if and only if there is a homomorphism from $\tilde{Q}$ to $\tilde{P}$.

Interestingly, using a similar homomorphism characterization, we can prove \textsc{P}\textsc{t}\textsc{ime} results for containment of descendant-only tree patterns with label negation and tree patterns with attribute comparisons. For each of the cases we introduce the corresponding notions of homomorphism.

Let $P = (N, E_{/\text{f}}, r, l_e, l^+, l^-)$ and $Q = (N', E'_{/\text{f}}, r', l'_e, l'^+, l'^-)$ be descendant-only tree patterns. A mapping $h : N' \rightarrow N$ is called a d-homomorphism of $Q$ to $P$ if it satisfies the conditions (i), (iii) and (iv) of the definition of a homomorphism above, and, furthermore, the following condition:

$$(ii') \text{ If } (x, y) \in E'_{/\text{f}} \text{ and } l_e(\langle x, y \rangle) = \alpha, \text{ then } (h(x), h(y)) \in E_{/\text{f}}^+ \text{ and every edge on the path from } h(x) \text{ to } h(y) \text{ in } P \text{ is labeled with } \alpha.$$ 

Let $P = (N, E, r, l_e, l)$ and $Q = (N', E', r', l'_e, l')$ be child-only tree patterns with attribute comparisons. Then a mapping $h : N' \rightarrow N$ is called an a-homomorphism if it satisfies the conditions (i), (ii) and (iii') (where (iii') is obtained from (iii) by replacing $l'^+$ and $l^+$ with $l'$ and $l$), and, furthermore, the following condition:

$$(iv') \text{ For every } x \in N', \text{ if } @_a \text{op}c \in l'(x) \text{ then there must exist } @_a \text{op}'c' \in l(h(x)) \text{ for some } \text{op}' \text{ and } c', \text{ and, } C \models @_a \text{op} \text{, where } C \text{ is the set of comparisons of } a\text{-attribute in } l(h(x)).$$

The following theorem is proved similarly to Theorem 4.4.1 and given in Appendix 4.A.

**Theorem 4.4.2.** Let $P$ and $Q$ be consistent descendant-only tree patterns with label negation (resp. child-only tree patterns with attribute comparisons). Then $P \subseteq Q$ if and only if there exists a d-homomorphism (a-homomorphism) of $Q$ to $P$.

Since the existence of d- and a-homomorphism can be checked in \textsc{P}\textsc{t}\textsc{ime}, we obtain the following.

**Corollary 4.4.2.** The containment problem is in \textsc{P}\textsc{t}\textsc{ime} for the following classes of queries.

- Descendant-only tree patterns with label negation,
- Child-only tree patterns with attribute comparisons.

As pointed before, child-only tree patterns with label negation is a fragment of pointed Berge-acyclic conjunctive queries with guarded negation. The precise complexity for the latter fragment is an open question. In the end of this section, we give an example showing that the homomorphism characterization fails for this fragment.
Example 4.4.1. Let $Q_1$ be the Boolean query $R(c, x), R(c, y), Q(y), R(z, x), R(z, w), \neg Q(w)$ and $Q_2$ the Boolean query $R(c, u), Q(u), R(v, u), R(v, t), \neg Q(t)$. Clearly, there is no such homomorphism mapping $c$ to $c$, however the containment holds. Indeed, let $I$ be an instance such that $I \models Q_1$, i.e., there is a satisfying variable assignment $\theta : \text{Var}(Q_1) \rightarrow \text{dom}(I)$. We then define a variable assignment $\theta' : \text{Var}(Q_2) \rightarrow I$ as the composition of $h : \text{Var}(Q_2) \rightarrow \text{Var}(Q_2)$ with $\theta$, where $h$ is defined according to the following cases.

- $I \models Q(\theta(x))$. In this case we define $h = \{c \rightarrow c, u \rightarrow x, v \rightarrow z, t \rightarrow w\}$.
- $I \not\models Q(\theta(x))$. In this case we define $h = \{c \rightarrow c, u \rightarrow y, v \rightarrow c, t \rightarrow x\}$.

It is straightforward to verify that $\theta$ is a satisfying assignment, thus $I \models Q_2$.

4.5 Conclusion and future work

In this chapter we considered the containment problem for conjunctive queries expanded with atomic negation and arithmetic comparisons. In particular, we studied the common acyclicity restriction on conjunctive queries and addressed the following research question:

RQ 2 Does acyclicity make the complexity of containment for conjunctive queries expanded with atomic negation or arithmetic comparison tractable? If not, what additional restrictions can be imposed to make it tractable?

Firstly, we have shown that complexity of containment for acyclic conjunctive queries with atomic negation can be lowered from $\Pi^P_2$ to $\text{coNP}$ if negation is guarded and the arity of negated atoms is bounded by a fixed constant. Secondly, we have shown several $\text{coNP}$ lower bound proofs that indicate that much stronger restrictions than acyclicity need to be imposed to make containment tractable. As a result, we have defined a new fragment of acyclic conjunctive queries with atomic negation–pointed Berge acyclic conjunctive queries for which the complexity of containment is left open. On the positive side, for one particular restricted fragment, namely child-only tree patterns with label negation, containment is in $\text{PTIME}$. We have also shown that containment for child-only tree patterns with attribute comparisons and descendant-only tree patterns with label negation is in $\text{PTIME}$.

The two main remaining open problems are:

- What is the complexity of containment for pointed Berge acyclic conjunctive queries?
- What is the complexity of containment for acyclic conjunctive queries with guarded negation (with no bound on the arity of the negated atoms)?

In Chapter 5 we show that when both child and descendant are allowed in tree patterns with unrestricted label negation, than containment rises to $\text{PSPACE}$. In Chapter 3 we have seen that safe label negation does not increase the complexity of containment when added to tree languages.
4.A Polynomial time algorithms for containment

4.A.1 Descendant-only tree patterns with label negation

In this section we consider descendant-only tree patterns with label negation.

We prove Theorem 4.4.2 for the case of descendant-only tree patterns.

**Proof.** (of Theorem 4.4.2) Let \( P = (N, E_\leftrightarrow, r, l_e, l^+, l^-) \) and \( Q = (N', E'_\leftrightarrow, r', l'_e, l'^+, l'^-) \) be descendant-only tree patterns with label negation.

\((\Leftarrow)\). Assume \( h : N' \rightarrow N \) is a \( d \)-homomorphism.

Let \( G = (\text{Nodes}(G), E'\leftrightarrow, \rho_e, \rho_n, r'\leftrightarrow) \) be a graph such that \( G \models P \), i.e. there is an embedding \( e : N \rightarrow \text{Nodes}(G) \). Then we claim that \( e' = e \circ h \) is an embedding of \( Q \) into \( G \). We check the conditions (0)-(4), except (1):

1. \((0)\) \( e'(r') = e \circ h(r') = e(r) = r'' \)
2. \((2)\) Let \((x, x') \in E_\leftrightarrow' \) and \( l'_e((x, y)) = \alpha \). Then \((h(x), h(x')) \in E_\leftrightarrow'\) and every edge on the path from \( h(x) \) to \( h(x') \) in \( P \) is labeled with \( \alpha \), which implies \((e(h(x)), e(h(x'))) \in E''\leftrightarrow\), and every edge on the path is labeled with \( \alpha \),
3. \((3)\) Let \( x \in N' \) and \( p \in l'^+(x) \). Then \( p \in l^+(h(x)) \), which implies that \( p \in \rho(e(h(x))) \), as needed.
4. \((4)\) Let \( x \in N' \) and \( p \in l'^-(x) \). Then \( p \in l^-(h(x)) \), which implies that \( p \not\in \rho(e(h(x))) \), as needed.

\((\Rightarrow)\). We show the contrapositive. Suppose there is no \( d \)-homomorphism from \( Q \) to \( P \). We then construct a counter-example graph with the same structure as \( P \). Let \( P.y \) be the subtree of \( P \) rooted in \( y \) and \( Q.x \) the subtree of \( Q \) rooted in \( x \). By induction on the depth of \( P.y \) we show

\((\text{IH})\) If there is no \( d \)-homomorphism from \( Q.x \) to \( P.y \), then there exists a tree \( T \) such that \( T \models P.y \) and \( T \not\models Q.x \).

**Base of induction:** \( \text{depth}(P.y) = 0 \). This part is practically the same as for child-only tree patterns. There is no \( d \)-homomorphism from \( Q.x \) to \( P.y \) if either

- there exists a label \( p \) such that either (i) \( p \in l'^+(x) \) and \( p \not\in l^+(y) \), or (ii) \( p \in l'^-(x) \) and \( p \not\in l^-(y) \). We define \( T = (\{y\}, \emptyset, \rho_e, \rho_n, y) \), where the labeling function \( \rho_n \) is defined according to the above cases: (i) \( \rho_n(y) = l^+(y) \) or (ii) \( \rho_n(y) = l^-(y) \cup \{p\} \). By construction, we have \( T \models P.y \). It also holds that \( T \not\models Q.x \). Indeed, otherwise it would hold that \( l'^+(x) \subseteq \rho_n(y) \) and \( l'^-(x) \cap \rho_n(y) = \emptyset \), which contradicts with the definition of \( \rho \).
- Or there exists \( x' \) such that \((x, x') \in E'_\leftrightarrow\). In this case, we define \( T = (\{y\}, \emptyset, \rho_e, \rho_n, y) \), where \( \rho_n(y) = l^+(y) \). By construction we have that \( T \models P.y \). Moreover, \( T \not\models Q.x \) since there is no descendant of the image of \( x \) in \( T \).

**Induction step:** \( \text{depth}(P.y) > 0 \) and there is no \( d \)-homomorphism from \( Q.x \) to \( P.y \). It is because either
4.A. Polynomial time algorithms for containment

• there exists a label \( p \) such that either (i) \( p \in l^+(x) \) and \( p \not\in l^+(y) \), or (ii) \( p \in l^-(x) \) and \( p \not\in l^-(y) \). We define \( T = (N_T, E_T, \rho_e, \rho_n, y) \), where \( N_T = \{ n \in N \mid P \models y E^* n \} \), i.e., the nodes below \( y \) in \( P \), \( E_T = E/f/N_2 \), and the labeling \( \rho_e = l_e \) and \( \rho_n \) is defined as follows.

\[
\rho_n(u) = \begin{cases} 
  l^+(u) & \text{if } u = y \text{ and (i) holds,} \\
  l^+(u) \cup \{p\} & \text{if } u = y \text{ and (ii) holds,} \\
  l^+(u) & \text{if } u \neq y.
\end{cases}
\]

It is easy to see that \( T \models P.y \) and \( T \not\models Q.x \).

• Or there exists \( x' \) such that \( (x, x') \in E'_/ \) and for all \( y' \) with \( (y, y') \in E^+_/ \) it holds that there is no \( d \)-homomorphism from \( Q.x' \) to \( P.y' \). Let \( y_i, i \in \{1, \ldots, k\} \), be the direct successors of \( y' \). Since \( \text{depth}(P,y) < \text{depth}(P,y') \), by the induction hypothesis, it holds that for every \( y_i \) of \( y \) there exists a tree \( T_i = (N_i, E_i, \rho_{i_e}, \rho_{i_n}, r_i) \) such that \( T_i \models P.y_i \) and \( T_i \not\models Q.x' \). Moreover, these trees have the shape of \( P.y_i \). We then define the tree \( T = (N_T, E_T, \rho_e, \rho_n, y) \) with the shape as \( P \), i.e., such that \( N_T = \{y\} \cup \bigcup_i N_i, E_T = \bigcup_i (E_i \cup \{(y, y_i)\}) \) and

\[
\rho_n(u) = \begin{cases} 
  l^+(y) & \text{if } u = y, \\
  \rho_i(u) & \text{if } T_i \models y_i E^* u.
\end{cases}
\]

We claim that \( T \models P.y \) and \( T \not\models Q.x \). The former is by definition of \( T \). For the latter, suppose \( e : Q.x \rightarrow T \) is an embedding. In particular, that means that \( e \) is an embedding of \( Q.x' \) to a subtree \( T_i.y \), where \( y_i \) is a descendant of \( y \). Thus, \( T_i \models Q.x' \), which is a contradiction.

Thus, since there is no homomorphism from \( Q.x' \) to \( P.r \), there exists a tree such that \( T \models P \) and \( T \not\models Q \). \( \square \)

**Corollary 4.A.1.** Containment for descendant-only tree patterns with label negation is solvable in \( \text{PTIME} \).

**Proof.** Let \( P \subseteq Q \), where \( P \) and \( Q \) are (descendant-only) tree patterns with negation, be an instance of the containment problem. We first check if the input tree patterns are consistent. Consistency check can be done in \( \text{PTIME} \) by simple check if no node contains a label \( p \) in both positive and negative labeling. If \( P \) is inconsistent, we output “yes”. Otherwise, if \( Q \) is inconsistent we output “no”. Otherwise, by Theorem 4.4.2 it is enough to check existence of a \( d \)-homomorphism from \( Q \) to \( P \). We reduce this problem to checking a homomorphism from \( \bar{Q} \) to \( \bar{P} \), where \( \bar{P} \) and \( \bar{Q} \) are tree patterns without negated labels obtained from \( P \) and \( Q \) by replacing each \( \neg p \) with \( \bar{p} \). From the definition of a homomorphism, it can be seen that existence of a homomorphism for positive descendant tree patterns amounts to existence of a homomorphism of a descendant-only tree pattern into a tree. The latter problem can be solved in \( \text{PTIME} \) (Götz et al., 2007). \( \square \)

4.A.2 Tree patterns with attribute value comparisons

In this section we prove the second part of Theorem 4.4.2.
4. Containment for ACQ with Atomic Negation and Arithmetic Comparisons

Proof. (of Theorem 4.4.2) For simplicity, we assume all edges have the same label, and thus \( l_e \) is a constant function. Let \( P = (N, E, r, l) \) and \( Q = (N', E', r', l') \) be tree patterns with attribute value comparisons.

\( (\Leftarrow) \). Assume \( h : N' \to N \) is an a-homomorphism. Let \( G = (Nodes(G), E'', \rho_n, r'', att) \) be a graph such that \( G \models P \), i.e., there is an embedding \( e : N \to Nodes(G) \). Then we claim that \( e' = e \circ h \) is an embedding of \( Q \) into \( G \). We check the conditions (1)-(4):

1. \( e'(r') = e \circ h(r') = e(r) = r'' \),
2. Let \( (x, x') \in E' \). Then \( (h(x), h(x')) \in E' \), which implies \( (e(h(x)), e(h(x'))) \in E'' \),
3. Let \( x \in N' \) and \( p \in l'(x) \). Then \( p \in l(h(x)) \), which implies that \( p \in \rho_n(e(h(x))) \), as needed,
4. Let \( x \in N' \) and \( @_a \text{opc} \in l'(x) \). Then there exists \( @_a \text{op} e' \in l(h(x)) \) and, \( C \models @_a \text{op} c \), where \( C \) is the set of constraints of \( a \) in \( l(h(x)) \). Since \( e \) is an embedding, it holds that \( att(e(h(x)), a) \) is defined and \( C \) is satisfied by \( att(e(h(x)), a) \).

\( (\Rightarrow) \). We show the contrapositive. Suppose there is no a-homomorphism from \( Q \) to \( P \). We then construct a counter-example with the same structure as \( P \). Let \( P.y \) be the subtree of \( P \) rooted in \( y \) and \( Q.x \) the subtree of \( Q \) rooted in \( x \). By induction on the depth of \( P.y \) we show

(\textbf{IH}) If there is no homomorphism from \( Q.x \) to \( P.y \), then there exists a tree \( T \) such that \( T \models P.y \) and \( T \nvdash Q.x \).

**Base of induction:** \( \text{depth}(P.y) = 0 \). Then there is no homomorphism from \( Q.x \) to \( P.y \) if either

- there exists a label \( p \) such that either \( p \in l'(x) \) and \( p \not\in l(y) \). We define \( T = (\{y\}, \emptyset, y, \rho) \), where the labeling function \( \rho(y) = l(y) \). By construction, we have \( T \models P.y \). It also holds that \( T \nvdash Q.x \). Indeed, otherwise it would hold that \( l'(x) \subseteq \rho(y) \), which contradicts with the definition of \( \rho \).
- there exists \( @_a \text{opc} \in l'(x) \) such that no \( @_a \text{op} e' \in l(y) \) or \( C \not\models @_a \text{op} c \), where \( C \) is the set of constraints of \( a \)-attribute in \( l(y) \). In the first case we take \( T = (\{y\}, \emptyset, y, \rho, att) \) with \( \rho(y) = l(y) \), \( att(y, a) \) undefined and \( att(y, b) = c_b \) for every \( b \neq a \) such that \( c_b \) satisfies the constraint of \( b \) in \( l(y) \). By construction, \( T \models P.y \) and \( T \nvdash Q.x \). In the second case there is a constant \( c'' \) that satisfies \( C \) but not \( c'' \text{op} c \). Thus, \( T \models P.y \) and \( T \nvdash Q.x \).
- Or there exists \( x' \) such that \( (x, x') \in E' \). In this case, we define \( T = (\{y\}, \emptyset, y, \rho) \), where \( \rho(y) = l(y) \). By construction we have that \( T \models P.y \). Moreover, \( T \nvdash Q.x \) since there is no child of the image of \( x \) in \( T \).

**Induction step:** \( \text{depth}(P.y) > 0 \) and there is no a-homomorphism from \( Q.x \) to \( P.y \). It is because either
there exists a label \( p \) such that \( p \in l'(x) \) and \( p \notin l(y) \). We define \( T = (N_T, E_T, y, \rho, \text{att}) \), where \( N_T = \{ n \in N \mid P \models yE^*n \} \), i.e., the nodes below \( y \) in \( P \), \( E_T = E \big|_{N_T^2} \), the labeling \( \rho \) is defined as \( l \), and \( \text{att} \) is defined canonically to satisfy constraints in \( P \).

It is easy to see that \( T \models P.y \) and \( T \not\models Q.x \).

- there exists \( @_a \text{op} c \in l'(x) \) such that either (i) no \( @_a \text{op} c' \) is in \( l(y) \) or (ii) \( C \not\models @_a \text{op} c \), where \( C \) is the set of constraints of \( a \)-attribute in \( l(y) \). We define \( T = (N_T, E_T, y, \rho, \text{att}) \), where \( N_T = \{ n \in N \mid P \models yE^*n \} \), i.e., the nodes below \( y \) in \( P \), \( E_T = E \big|_{N_T^2} \), the labeling \( \rho \) is defined as \( l \). The attribute function is defined as follows. If \( @_b \text{op} c \), appeared in a node \( z \) in \( P \), then \( \text{att}(z, b) = c_b \) such that \( c_b \) satisfies the constraints of \( b \)-attribute in \( l(z) \). Additionally, we take \( \text{att}(y, a) \) as undefined in case (i) and the constant witnessing \( C \not\models @_a \text{op} c \) in case (ii). It holds that \( T \models P.y \) and \( T \not\models Q.x \).

- Or there exists \( x' \) such that \((x, x') \in E' \) and for all \( y_i \) with \((y, y_i) \in E \) it holds that there is no \( a \)-homomorphism from \( Q.x' \) to \( P.y_i \). Since \( \text{depth}(P, y_i) < \text{depth}(P, y) \), by the induction hypothesis, it holds that for every child \( y_i \) of \( y \) there exists a tree \( T_i = (N_i, E_i, r_i, \rho_i, \text{att}_i) \) such that \( T_i \models P.y_i \) and \( T_i \not\models Q.x' \). We can assume that these trees are pairwise disjoint. We then define the tree \( T = (N_T, E_T, y, \rho, \text{att}) \) such that \( N_T = \{ y \} \cup \bigcup_i N_i \), \( E_T = \bigcup_i (E_i \cup \{ \langle y, y_i \rangle \}) \) and

\[
\rho(u) = \begin{cases} 
  l(y) & \text{if } u = y, \\
  \rho_i(u) & \text{if } T_i \models y_i E^*u.
\end{cases}
\]

and \( \text{att} = \bigcup_i \text{att}_i \). We claim that \( T \models P.y \) and \( T \not\models Q.x \). The former is by definition of \( T \). For the latter, suppose \( e : Q.x \to T \) is an embedding. In particular, that means that \( e \) is an embedding of \( Q.x' \) to one of \( T_i \), where \( y_i \) is a child of \( y \). Thus, \( T_i \models Q.x' \), which is a contradiction.

Thus, since there is no homomorphism from \( Q.r' \) to \( P.r \), there exists a tree such that \( T \models P \) and \( T \not\models Q \).

\textbf{Corollary 4.A.2.} 
\textit{Containment for child-only tree patterns with attribute value comparisons is solvable in PTIME.}

\textbf{Proof.} We first check consistency of the input tree patterns which can be done in PTIME. If one of the tree patterns is inconsistent, the problem is trivial. Otherwise, according to the theorem above, it is enough to check existence of a homomorphism. The latter can be done in PTIME, since \(< \) can be decided in PTIME.

\hfill \Box
We have already seen tree patterns in Chapter 3 and Chapter 4. In this chapter we study an expansion of tree patterns. A Conditional Tree Pattern (CTP) expands a tree pattern with labels attached to the descendant edges. These labels can be XML element names or Boolean CTP’s. The meaning of a descendant edge labelled by \( A \) and ending in a node labelled by \( B \) is a path of child steps ending in a \( B \) node such that all intermediate nodes are \( A \) nodes. In effect this expresses the \textit{until \( B \), \( A \) holds} construction from temporal logic.

This chapter studies the containment problem for CTP. For tree patterns (TP), this problem is known to be \( \text{coNP-complete} \) (Miklau and Suciu, 2004). We show that it is \( \text{PSPACE-complete} \) for CTP. This increase in complexity is due to the fact that CTP is expressive enough to encode an unrestricted form of label negation: \( * \setminus a \), meaning “any node except an \( a \)-node”. Containment of TP expanded with this type of negation is already \( \text{PSPACE-hard} \).

CTP is a positive, forward, first order fragment of Regular XPath. Unlike TP, CTP expanded with disjunction is not equivalent to unions of CTP’s. But like TP, CTP is a natural fragment to consider: CTP is closed under intersections and CTP with disjunction is equally expressive as positive existential first order logic expanded with the until operator.

### 5.1 Introduction

Tree Patterns are one of the most studied languages for XML documents and used in almost all aspects of XML data management. Tree patterns are a natural language: over trees, unions of tree patterns are equally expressive as positive first order logic (Benedikt et al., 2005). Also, like relational conjunctive queries, the semantics of TP’s can be given by embeddings from patterns to tree models (Amer-Yahia et al., 2002). Equivalence and containment of TP’s is decidable in \( \text{PTIME} \) for several fragments (Amer-Yahia et al., 2002), and \( \text{coNP} \) complete in general (Miklau and Suciu, 2004). Tree patterns can be represented as trees, as in Figure 5.1, or be given a natural XPath-like syntax.

In this chapter, we study the expansion of tree patterns with the conditional descendant axis. We call this expansion \textit{Conditional Tree Patterns}, abbreviated as CTP. Where the descendant axis in TP can be written as the transitive reflexive closure of the XPath step \( \text{child:: *} \), the conditional descendant axis is the transitive closure of
5. Containment for Conditional Tree Patterns

Figure 5.1: The tree pattern corresponding to the XPath expression \(/p[t]//s[.//v]\). The node in the square box denotes the output node.

Figure 5.2: Conditional tree pattern corresponding to (5.1).

\[ \text{child} :: p[F_1]|F_2|...|F_n], \text{where } n \geq 0 \text{ and each } F_i \text{ is an XPath expression which might contain the conditional descendant axis itself, followed by a child step. Syntactically, the expansion is straightforward: in the tree representation add labels representing conditional tree patterns themselves to the edges. Figure 5.2 contains an example which is equivalent to the following XPath-like formula in which we use } (\cdot)^* \text{ to denote the reflexive transitive closure of a path formula:} \]

\[
\begin{align*}
\text{self} & :: p[\text{child} :: t]/(\text{child} :: r)^*/\text{child} :: s \\
& \quad [(\text{child} :: a[(\text{child} :: a)^*/\text{child} :: b)]^*/\text{child} :: v] \quad (5.1)
\end{align*}
\]

The edge in Figure 5.2 labeled by \( r \) corresponds to the expression \((\text{child} :: r)^*/\text{child} :: s\), and merely states that all intermediate nodes are labeled by \( r \). The other labeled edge shows a nesting of patterns, corresponding to a nested transitive closure statement: all intermediate nodes have to be labeled by \( a \) and moreover have to start an \( a \)-labeled path ending in a \( b \)-node.

Conditional tree patterns are the forward fragment of Conditional XPath (Marx, 2005) without disjunction and negation. The conditional descendant axis is closely related to the strict until operator from temporal logic (Libkin and Sirangelo, 2010; Marx, 2005).
5.1. Introduction

Main results

Our main results concern the expressivity of CTP and the complexity of the containment problem. We consider two types of models: the standard XML trees in which each node has exactly one label, and trees in which nodes can have an arbitrary number of labels. These latter, called multi-labeled trees, are the models considered in temporal logic. All our results hold for both semantics. Models with multiple labels are a convenient logical abstraction for reasoning about tree patterns expanded with attribute value equalities. These are expressions of the form $@a = c$, where $a$ is an attribute, $c$ a constant, meaning that it holds at a node if and only if the value of the $a$-attribute of the node equals $c$. (With that we can express XPath formulas like //table[@border = '1']).

Containment of tree patterns has been studied in (Amer-Yahia et al., 2002; Miklau and Suciu, 2004; Neven and Schwentick, 2006). The most relevant results for us are that containment of TP’s is coNP-complete in general (Miklau and Suciu, 2004) and PSPACE-complete when the domain of labels is finite (Neven and Schwentick, 2006). We show that containment of CTP’s is PSPACE-complete (with both finite and infinite domains of labels). Interestingly, this increase in complexity is due to the fact that CTP is expressive enough to encode an unrestricted form of label negation: $\ast \setminus a$, meaning “any node except an $a$-node”. We show that containment of TP’s expanded with this form of negation is already PSPACE-hard. The matching upper bound for CTP containment is easily obtained by a translation into Existential CTL (Kupferman and Vardi, 2000). As a contrast we consider the expansion of TP with a safe form of propositional negation $n \setminus a$, which selects nodes with the label containing $n$ and not $a$, instead of $\ast \setminus a$ (Bárány et al., 2011). Note that this construct only makes sense on models with multiple labels. With respect to expressivity, we show that most results for TP can be generalized to CTP. CTP’s can be interpreted in trees by generalizing the TP-embeddings to simulations known from temporal logic. Similarly to the characterization for TP in (Benedikt et al., 2005), we show that CTP’s with disjunction and union are equally expressive as positive first order logic expanded with an until operator. From this we obtain that like TP’s, CTP’s are closed under taking intersections.

Organization

The chapter is organized as follows. This section is continued with a few more comparisons between TP and CTP and a motivating example. Section 5.2 contains preliminaries. Section 5.3 contains the expressivity results and Section 5.4 the results on the complexity of the containment problem. We end with conclusions and open questions.

Comparing logical properties of TP and CTP

A characteristic difference between TP and Relational Conjunctive Queries (CQ) is the disjunction property: if $A \models B \lor C$, then $A \models B$ or $A \models C$. This holds for CQ, but not for TP. A counterexample is $//p \models /p \lor *///p$. The languages TP and CTP differ on the following:

**Unions** TP expanded with disjunction is equally expressive as unions of TP (Benedikt et al., 2005). However, CTP with disjunction is more expressive than unions of CTP.
Countermodels If containment between two TP’s fails, there is a countermodel for it of polynomial size (Miklau and Suciu, 2004). Countermodels for CTP containment may be exponential.

Complexity TP containment is \( \text{coNP}\)-complete (Miklau and Suciu, 2004) and CTP containment is \( \text{PSPACE}\)-complete. For both languages these results remain true if we add disjunction to the language (for TP see (Neven and Schwentick, 2006)).

However, there are a few useful technical results that TP and CTP share.

Monotonicity TP and CTP formulas are preserved under extensions of models at the leaves (i.e. when the original model is a subtree of the extension). This means that if a TP (CTP) formula holds in a tree, then it holds in the extensions of the tree.

Multiple output nodes The containment problem for TP and CTP formulas with multiple output nodes can be reduced to containment of Boolean TP and CTP formulas (i.e., when the formula has a single output node which is the root).

Containment for unions Containment for unions of TPs can be reduced in \( \text{PTIME} \) to checking a set of containments between TP formulas (Miklau and Suciu, 2004). This reduction can be seen as a weak disjunction property. A similar property holds for CTP (see Proposition 5.4.2).

Multi-labeled models There is a \( \text{PTIME} \) reduction from the containment problem over trees in which each node has exactly one label to the containment problem over multi-labeled trees. This holds for both TP and CTP.

For TP, most of these results are in (Miklau and Suciu, 2004). Here we show how their proofs can be generalized to CTP.

Motivation

Tree patterns exhibit a nice tradeoff between expressive power and the complexity of static analysis. However, there are natural scenarios where tree patterns are not powerful enough, e.g. in Example 5.1.1. The conditional axis gives us more querying capabilities while preserving some of the nice properties of tree patterns (see the comparison above).

Example 5.1.1. Conditional tree patterns are used to query tree shaped structures. As an example, take the tree structure of the UNIX file system. In this file system, every file and directory has different access permissions (read, write or execute) for different type of users (the user, the group and others). Thus, the file system can be modeled as a tree where each node corresponds to a directory or a file (labeled by “dir” and “file” respectively) and has a required attribute for each pair \( (\text{user}, \text{access right}) \) which takes values from \( \{0, 1\} \). A file can only be a leaf in the tree.

Assume we want to ask for all the files that are readable by the user. This means that we are looking for precisely those files for which the following permissions hold:

- the file is readable for the user,
• the directory in which the file resides is both readable and executable for the user,
• the same holds recursively for all the directories from the root to the file.

This query can be neatly expressed as a CTP path formula:

\((\text{child :: dir[@(user,read) = 1][@(user,execute) = 1]*/child :: file[@(user,read) = 1]})\)

Additionally, CTP can express non-trivial constraints over the tree representing the file system. For instance, the formula

\((//\text{self :: file[@(other,read) = 1]} \rightarrow //\text{child :: dir[@(other,read) = 1][@(other,execute) = 1]})*/*)\)

imposes the constraint that for all files that are readable it holds that every directory on the path from the root to this file must be both readable and executable by others.

It is known that the conditional axis cannot be expressed by tree patterns or in Core XPath (Marx, 2005). On the other hand, the queries from Example 5.1.1 can be expressed in the positive forward fragment of Regular XPath, which is more expressive than CTP. However, we believe this additional expressive power leads to an increase in the complexity (of containment) than for conditional tree patterns.

5.1.1 Related work

The complexity of tree patterns is studied in a number of papers and since (Neven and Schwentick, 2006) a virtually complete picture exists for the complexity of the containment problem for positive fragments of XPath. Miklau and Suciu (2004) show that the complexity of the containment problem for TP with filters, wildcard and descendant is \(\text{coNP-complete}\). Containment and equivalence for fragments of TP were studied before. The most interesting result is that containment for TP without the wildcard is in \(\text{PTIME}\) (Amer-Yahia et al., 2002).

Our conditional tree patterns are a first order fragment of conjunctive regular path queries. Calvanese et al. (2000) show that containment of these queries is \(\text{ExpSPACE-complete}\), but these are interpreted on general graph models.

Conditional XPath (Marx, 2005) and conditional tree patterns are closely related to branching time temporal logic \(\text{CTL}\) (Clarke et al., 1986). The conditional child axis and the strict until connective are interdefinable. Kupferman and Vardi (2000) show that the containment problem for \(\exists\text{CTL}\), which is the restriction of \(\text{CTL}\) to formulas having only the \(\exists\) path quantifier in front of them, is a \(\text{PSPACE-complete}\) problem. The positive \(\exists\text{CTL}\)-fragment without until was also studied by Miklau and Suciu (2004). They show that the containment problem for this fragment is equivalent to the TP-containment problem and thus also \(\text{coNP-complete}\).

This chapter studies the containment problem without presence of schema information. A number of complexity results for containment in TP w.r.t DTDs are given in (Neven and Schwentick, 2006). In particular, containment for TP with filters, the wildcard and descendant w.r.t. DTD is \(\text{ExpTIME-complete}\). This hardness result together with an \(\text{ExpTIME}\) upper bound for Conditional XPath (Marx, 2005), which contains CTP, gives us \(\text{ExpTIME-completeness}\) of containment for CTP in the presence of DTDs.
5.2 Preliminaries

We briefly review the basic definitions of XML trees, Regular XPath and its semantics. Then we present Tree Patterns and Conditional Tree Patterns as sublanguages of Regular XPath. Tree patterns have an alternative semantics in terms of embeddings (Miklau and Suciu, 2004). We give such an “embedding semantics” for Conditional Tree Patterns using “until-simulations” in Section 5.3.

5.2.1 Trees

We work with node-labeled unranked finite trees, where the node labels are elements of an infinite set \( \Sigma \). Formally, a tree over \( \Sigma \) is a tuple \((N, E, r, \rho)\), where \( N \), the set of nodes of the tree, is a prefix closed set of finite sequences of natural numbers, \( E = \{\langle n_1, \ldots, n_k \rangle, \langle n_1, \ldots, n_k, n_{k+1} \rangle \mid \langle n_1, \ldots, n_{k+1} \rangle \in N\} \) is the edge or child relation, \( r \) is the root of the tree, that is the empty sequence, and \( \rho \) is the function assigning to each node in \( N \) a finite subset of \( \Sigma \). We refer to a tree over \( \Sigma \) just as a tree if \( \Sigma \) is clear from the context.

Trees in which \( \rho(\cdot) \) is always a singleton are called single-labeled or XML trees. Trees without this restriction are called multi-labeled trees.

We denote by \( E^+ \) the descendant relation, which is the transitive closure of the edge relation \( E \), and by \( E^* \) the reflexive and transitive closure of \( E \), and by \( E(x) \) the set of all children of the node \( x \). A node \( n \) is a leaf if \( E(n) \) is empty. A path from a node \( n \) to a node \( m \) is a sequence of nodes \( n = n_0, \ldots, n_k = m \), with \( k > 0 \), such that for each \( i \leq k, n_{i+1} \in E(n_i) \). We call a branch any maximal path starting from the root. If \( mE^+n, m \) is called an ancestor of \( n \), and if \( mEn, m \) is called the parent of \( n \).

If \( n \) is in \( N \), by \( T.n \) we denote the subtree of \( T \) rooted at \( n \). A pointed tree is a pair \( T, n \) where \( T \) is a tree and \( n \) is a node of \( T \). The height of a pointed tree \( T, n \) is the length of the longest path in \( T.n \).

Given two trees \( T_1 = (N_1, E_1, r_1, \rho_1) \) and \( T_2 = (N_2, E_2, r_2, \rho_2) \) such that \( N_1 \) and \( N_2 \) are disjoint, we define the result of fusion of \( T_1 \) and \( T_2 \), denoted as \( T_1 \oplus T_2 \), as the tree obtained by joining the trees \( T_1 \) and \( T_2 \) without the roots under a new common root labeled by the union of the labels of the roots of \( T_1 \) and \( T_2 \). Formally, \( T_1 \oplus T_2 \) is the tree \( T = (N, E, r, \rho) \), where \( N = (N_1 \setminus \{r_1\}) \cup (N_2 \setminus \{r_2\}) \cup \{r\}, E = (E_1 \setminus \{(r_1, n) \mid n \in N_1\}) \cup (E_2 \setminus \{(r_2, n) \mid n \in N_2\}) \cup \{(r, n) \mid (r_1, n) \in E_1 \lor (r_2, n) \in E_2\} \) and

\[
\rho(n) = \begin{cases} 
\rho_1(r_1) \cup \rho_2(r_2) & \text{if } n = r, \\
\rho_1(n) & \text{if } n \in N_1 \setminus \{r_1\}, \\
\rho_2(n) & \text{if } n \in N_2 \setminus \{r_2\}.
\end{cases}
\]

5.2.2 XPath and Tree Patterns

We define Tree Patterns and Conditional Tree Patterns as sublanguages of Regular XPath (ten Cate, 2006).

**Definition 5.2.1** (Forward Regular XPath). Let \( \Sigma \) be an infinite domain of labels. Forward Regular XPath, RXPath for short, consists of node formulas \( \varphi \) and path formulas \( \alpha \) which are defined by the following grammar
5.2. Preliminaries

\[ \varphi ::= p \mid \top \mid \neg \varphi \mid \varphi \lor \varphi \mid \varphi \land \varphi \mid \langle \alpha \rangle \varphi \]

\[ \alpha ::= \downarrow \mid \, ?\varphi \mid \alpha ; \alpha \mid \alpha \cup \alpha \mid \alpha^* , \]

where \( p \in \Sigma \).

We will use \( \alpha^+ \) as an abbreviation of \( \alpha ; \alpha^* \).

For the semantics of RXPath, given a tree \( T = (N, E, r, \rho) \) over \( \Sigma \), the relation \( [\alpha]_T \subseteq N \times N \) for a path expression \( \alpha \) and the satisfaction relation \( \models \) between pointed trees and node formulas are inductively defined as follows:

- \( [\downarrow]_T = E \),
- \( [\, ?\varphi]_T = \{(n, n) \in N \times N \mid T, n \models \varphi\} \),
- \( [\alpha; \beta]_T = [\alpha]_T \circ [\beta]_T \),
- \( [\alpha \cup \beta]_T = [\alpha]_T \cup [\beta]_T \),
- \( [\alpha^*]_T = ([\alpha]_T)^* \),

and

- \( T, n \models \top \),
- \( T, n \models p \) iff \( p \in \rho(n) \),
- \( T, n \models \neg \varphi \) iff \( T, n \not\models \varphi \),
- \( T, n \models \varphi \land \psi \) iff \( T, n \models \varphi \) and \( T, n \models \psi \),
- \( T, n \models \varphi \lor \psi \) iff \( T, n \models \varphi \) or \( T, n \models \psi \),
- \( T, n \models \langle \alpha \rangle \varphi \) iff there is a node \( m \) with \((n, m) \in [\alpha]_T\) and \( T, m \models \varphi \).

Sometimes we will write \( T \models \varphi \) to denote \( T, r \models \varphi \). If the latter holds, we say that \( T \) is a model of \( \varphi \).

(Conditional) Tree Patterns

Tree patterns are the conjunctive fragment of RXPath without unions of paths and with a strongly restricted Kleene star operation. Node formulas correspond to Boolean tree patterns, and path formulas to tree patterns with one output node.

In the following definitions we again let \( \Sigma \) be an infinite domain of labels. We define Tree Patterns by restricting the syntax of RXPath as follows:

Definition 5.2.2 (Tree Pattern). Tree Patterns (TP) consist of node formulas \( \varphi \) and path formulas \( \alpha \) defined by the following grammar:

\[ \varphi ::= p \mid \top \mid \varphi \land \varphi \mid \langle \alpha \rangle \varphi \]

\[ \alpha ::= \downarrow \mid \, ?\varphi \mid \alpha ; \alpha \mid \alpha \cup \alpha \mid \alpha^* , \]

where \( p \in \Sigma \).
For example, the tree pattern from Figure 5.1 can be written as the path formula 
\( \alpha = ?(p \land (\downarrow t); \downarrow +; ?(s \land (\downarrow v)). \) Conditional Tree Patterns can also be defined by restricting the syntax of XPath, where we allow conditional descendant paths.

**Definition 5.2.3** (Conditional Tree Pattern). Conditional Tree Patterns (CTP) consist of node formulas \( \varphi \) and path formulas defined by the following grammar:

\[
\begin{align*}
\varphi & ::= p | \top | \varphi \land \varphi | \alpha \varphi \\
\alpha & ::= \downarrow | ?\varphi | \alpha | (\downarrow; ?\varphi)^*; \downarrow,
\end{align*}
\]

where \( p \in \Sigma \).

The tree from Figure 5.2 can be written as the path formula

\[
?(p \land (\downarrow t); (\downarrow; ?r)^*; \downarrow; ?(s \land ((\downarrow; ?a)^*; (\downarrow; b))^*; \downarrow) v).
\]

Note that the node formula \((\downarrow; ?\varphi)^*; \downarrow) \psi\) is exactly the strict until \( \exists U(\psi, \varphi)\) from branching time temporal logic CTL (Kupferman and Vardi, 2000). We will abbreviate this formula simply as \( \langle \varphi^+ \rangle \psi \). Because of the equivalences \( \langle \alpha; \beta \rangle \varphi \equiv \langle \alpha \rangle \langle \beta \rangle \varphi \) and \( \langle ?\varphi \rangle \psi \equiv \varphi \land \psi \), CTP node formulas can be given the following equivalent definition:

\[
\varphi ::= p | \top | \varphi \land \varphi | (\downarrow) \varphi | (\downarrow^+) \varphi | (\varphi^+) \varphi.
\]

Even though the syntax is slightly different, CTP is the conjunctive forward only fragment of Conditional XPath (Marx, 2005).

**Expansions**

We consider two expansions of TP and CTP, with negated labels and with disjunction in node formulas together with union in paths. Negated labels is a restricted type of negation where only the construct \( \neg p \) is allowed in the node formulas. We denote expansions of the language \( L \) with one or two of these features by \( L^S \) for \( S \subseteq \{\neg, \lor\} \).

**Query evaluation**

In (Gottlob et al., 2005a) it was shown that the query evaluation problem for Core XPath is \( PTIME \)-complete in the combined complexity. As noted in (Marx, 2005), using results on model checking for Propositional Dynamic Logic, this can be extended to Regular XPath, and thus to all our defined fragments.

**Fact 1** (Marx (2005)). Let \( T \) be a tree, \( n_1, n_2 \) nodes in \( T \), and \( \alpha \) a Regular XPath path formula. The problem whether \( (n_1, n_2) \in [\alpha]_T \) is decidable in time \( O(|T| \times |\alpha|) \) with \( |T| \) the size of the tree and \( |\alpha| \) the size of the formula.

**5.2.3 Containment**

As we are considering two kinds of expressions, path and node expressions, we have different notions of containment.

**Definition 5.2.4.** Let \( \varphi \) and \( \psi \) be two XPath-node formulas. We say that \( \varphi \) is contained in \( \psi \), notation \( \varphi \subseteq \psi \), if for every \( T, n, T, n \models \varphi \) implies \( T, n \models \psi \). Let \( \alpha \) and \( \beta \) be two XPath-path formulas. We say that
5.2. Preliminaries

- \( \alpha \) is contained as a binary query in \( \beta \), denoted \( \alpha \subseteq^2 \beta \), if for any tree \( T \), \( \llbracket \alpha \rrbracket_T \subseteq \llbracket \beta \rrbracket_T \).

- \( \alpha \) is contained as a unary query in \( \beta \), denoted \( \alpha \subseteq^1 \beta \), if for any tree \( T \) with root \( r \), and any node \( n \), \( (r, n) \in \llbracket \alpha \rrbracket_T \) implies \( (r, n) \in \llbracket \beta \rrbracket_T \).

Containment over single-labeled trees is denoted by \( \subseteq \), and containment over multi-labeled models by \( \subseteq_{ML} \).

Luckily, these three notions are closely related, and containment of path formulas can be reduced to containment of node formulas and vice versa (cf. also (Miklau and Suciu, 2004; Neven and Schwentick, 2006)).

**Proposition 5.2.1.** Let \( \alpha \) and \( \beta \) be two RXPath-path formulas, \( \varphi \) and \( \psi \) RXPath-node formulas, in which negation is restricted to labels only.

(i) \( \alpha \subseteq^2 \beta \) iff \( \alpha \subseteq^1 \beta \),

(ii) Let \( p \) be a label not occurring in \( \alpha \) or in \( \beta \). Then, \( \alpha \subseteq^2 \beta \) iff \( \llbracket \alpha \rrbracket \updownarrow p \subseteq \llbracket \beta \rrbracket \updownarrow p \),

(iii) \( \varphi \subseteq \psi \) iff \( \varphi \subseteq^2 \psi \).

All the above items also hold for the case of multi-labeled trees.

**Proof.**

(i) \((\Rightarrow)\) Let \( T = (N, E, r, \rho) \) be a tree such that \( (r, n) \in \llbracket \alpha \rrbracket_T \). By the assumption, we have \( \llbracket \alpha \rrbracket_T \subseteq \llbracket \beta \rrbracket_T \). This implies that \( (r, n) \in \llbracket \beta \rrbracket_T \), which was required to show.

\((\Leftarrow)\) Let \( T = (N, E, r, \rho) \) be a tree, \( n_1 \) and \( n_2 \) in \( N \) such that \( (n_1, n_2) \in \llbracket \alpha \rrbracket_T \). Since \( \alpha \) is from the forward fragment of Regular XPath, we have that \( (n_1, n_2) \in \llbracket \alpha \rrbracket_{T,n_1} \). Using the assumption, we have \( (n_1, n_2) \in \llbracket \beta \rrbracket_{T,n_1} \). Then by monotonicity, we obtain \( (n_1, n_2) \in \llbracket \beta \rrbracket_T \), which was desired.

(ii) \((\Rightarrow)\) Suppose \( \alpha \subseteq^2 \beta \), and let \( T, n \models \llbracket \alpha \rrbracket \updownarrow p \). Thus there is a descendant \( m \) of \( n \) in \( T \) such that \( (n, m) \in \llbracket \alpha \rrbracket_T \) and \( T, m \models \llbracket \downarrow \rrbracket p \). By the hypothesis we therefore have \( (n, m) \in \llbracket \beta \rrbracket_T \) and thus \( T, n \models \llbracket \downarrow \rrbracket p \).

\((\Leftarrow)\) Assume \( \llbracket \alpha \rrbracket \updownarrow p \subseteq \llbracket \beta \rrbracket \updownarrow p \). Consider a tree \( T = (N, E, r, \rho) \) and a pair \( (n, m) \in \llbracket \alpha \rrbracket_T \). Since \( p \) does not occur in \( \alpha \), we may assume that \( T, n \not\models \downarrow p \) for every node \( n \in N \). We then define the tree \( T' = (N', E', r, \rho') \), where

- \( N' := N \cup \{x\} \),
- \( E' := E' \cup \{(m, x)\} \),
- \( \rho'(y) := \begin{cases} p & \text{if } y = x, \\ \rho(y) & \text{otherwise}. \end{cases} \)

By definition of \( T' \), we have \( T', m \models \downarrow p \) and \( (n, m) \in \llbracket \alpha \rrbracket_{T'} \). Hence, \( T', n \models \llbracket \alpha \rrbracket \downarrow p \). By assumption, this implies that \( T', n \models \llbracket \beta \rrbracket \downarrow p \). Since \( p \) holds at \( x \) only, and \( x \) is a child of \( m \), we have that \( (n, m) \in \llbracket \beta \rrbracket_{T'} \). By definition of \( T' \), the path between \( n \) and \( m \) is also in \( T \). Thus, \( (n, m) \in \llbracket \beta \rrbracket_T \), as desired.

Item (iii) easily follows from the definitions.

In light of Proposition 5.2.1, from now on we consider the containment problem of node formulas only. We now give an interesting example of CTP containment.
Example 5.2.1. Let us consider the CTP node formulas

\[
\varphi = \langle (\langle b^- \rangle d^+) \rangle \langle a^+ \rangle b \text{ and } \psi = \langle (\langle c^+ \rangle d^+) \rangle \langle a^+ \rangle b.
\]

Although it is hard to see from a first glance, \( \varphi \subseteq \psi \) holds. Indeed, in every model \( T \) of \( \varphi \) either there is a direct child of the root where \( \langle a^+ \rangle b \) holds, or there is a path \( r = v_1, \ldots, v_n \) in \( T \) to the node \( v_n \) where \( \langle a^+ \rangle b \) holds and \( \langle b^+ \rangle d \) holds in every node \( v_i \) (\( 1 < i < n \)) on the path. In the first case, \( \psi \) holds at the root since \( \langle a^+ \rangle b \) holds at the direct child.

Now let’s consider the second case. Let \( j \in \{2, \ldots, n-1\} \) be the least number with the property that \( v_j \) has a non-empty \( b \)-path to the \( d \)-descendant. If there is no such number, then \( \langle c^+ \rangle d \) holds at every \( v_i \), \( 1 < i < n \) (as each of them has a direct \( d \)-child) and, thus, \( T, r \models \psi \).

Assume there is such a \( j \). Since \( v_j \) has a \( b \)-node as a child, we have that \( T, v_j \models \langle a^+ \rangle b \). Moreover, \( \langle c^+ \rangle d \) holds at each \( v_i \) for \( i < j \) since \( v_i \) has a \( d \)-node as a child. Thus in this case we obtain that \( T, r \models \psi \) holds too.

5.3 Expressivity

We extend the semantics of TP given by embeddings of queries into trees to CTP. Instead of embeddings we need a simulation known from temporal logic.

5.3.1 Interpreting Conditional Tree Patterns by simulations

The semantics of conditional tree patterns can be defined using simulations developed for LTL (Blackburn et al., 2001). These simulations generalize the embeddings for tree patterns from (Amer-Yahia et al., 2002; Miklau and Suciu, 2004) with an additional clause for checking the labels on the edges.

We start by defining the tree pattern analogues of CTP node and path expressions.

Definition 5.3.1. A conditional tree pattern is a node and edge labeled finite tree \((N, E, r, \bar{o}, \rho_N, \rho_E)\), where \( N \) is the set of nodes of the tree, \( E \subseteq N \times N \) is the set of edges, \( r \) is the root of the tree, \( \bar{o} \) is a \( k \)-tuple \((k > 0)\) of output nodes, \( \rho_N \) is the function assigning to each node in \( N \) a finite set of labels from \( \Sigma \) and \( \rho_E \) is the function assigning to each pair in \( E \) either \( \downarrow \) or a Boolean conditional tree pattern. A Boolean conditional tree pattern is a conditional tree pattern with a single output node which equals the root.

A conditional tree pattern is said to have multiple output nodes if the number \( k = |\bar{o}| \) is greater than 1.

A tree pattern is a conditional tree pattern whose edges are only labeled by \( \downarrow \) or \( \top \).

To be consistent with the pictorial representation of TP, in CTP an edge labeled with \( \downarrow \) is drawn as a single line, while an edge labeled with a CTP node formula is drawn as a double line with a CTP as the label (e.g. as in Figure 5.2). The output nodes have the square shape.
5.3. Expressivity

CTP node and path expressions can be translated into (Boolean) conditional tree patterns with one output node and vice-versa. The translations are given in Appendix 5.A. We denote the equivalent (Boolean) conditional tree pattern of a CTP path or node expression \( \alpha \) or \( \varphi \) by \( c(\alpha) \) and \( c(\varphi) \), respectively.

Next we generalize the notion of TP-embeddings (Miklau and Suciu, 2004) to CTP-simulations.

**Definition 5.3.2.** Let \( T = (N, E, r, \bar{o}, \rho_N, \rho_E) \) be a conditional tree pattern as in the previous definition and \( T' = (N', E', r', \rho') \) a tree. A total function \( f : N \rightarrow N' \) is called a simulation from the pattern \( T \) into the pointed tree \( T', r' \) if it satisfies the following properties:

- **root preserving** \( f(r) = r' \);
- **label preserving** if \( p \in \rho_N(n) \), then \( p \in \rho'(f(n)) \);
- **child edge preserving** if \( n E n' \) and \( \rho_E(n, n') = \downarrow \), then \( f(n) E f(n') \);
- **conditional edge simulation** if \( n E n' \) and \( \rho_E(n, n') \) is not equal to \( \downarrow \), then \( f(n) E^+ f(n') \) and for every \( x \) such that \( f(n) E^+ x E^+ f(n') \) there is a simulation from the Boolean conditional tree pattern \( \rho_E(n, n') \) into \( T'.x \) (the subtree of \( T' \) rooted at \( x \)).

When a pattern is a tree pattern, \( \downarrow \) and \( \top \) are the only labels on edges. For the label \( \top \), the “conditional edge simulation” clause trivializes to checking that \( f \) is an embedding for the descendant edges. Simulations for tree patterns are thus equivalent to tree pattern embeddings (Amer-Yahia et al., 2002; Miklau and Suciu, 2004).

The next theorem states that simulations can be used to evaluate conditional tree patterns.

**Theorem 5.3.3.** Let \( \varphi \) and \( \alpha \) be a CTP node and path expression, respectively. Let \( T \) be a tree and \( n \) a node in \( T \).

1. \( T, n \models \varphi \) if and only if there is a simulation from \( c(\varphi) \) into \( T.n \).
2. \( (n, n') \in \llbracket \alpha \rrbracket_T \) if and only if there is a simulation from \( c(\alpha) \) into \( T.n \) which relates the output node of \( c(\alpha) \) to node \( n' \).
3. Items (i) and (ii) also hold when \( T \) is an infinite tree.

The proof is by mutual induction on the node and path expressions.

**Remark 5.3.1.** The notions of (conditional) tree pattern and embedding for tree patterns and simulation for conditional tree patterns are easily extended to work for expansions of these languages with negated labels (denoted by TP\(^-\) and CTP\(^-\), respectively).

For (conditional) tree patterns, add a second node labelling function \( \rho_N^- (\cdot) \) that also assigns each node a finite set of labels. These are interpreted as the labels that are false at the node.

For the embeddings and simulations, in Definition 5.3.2 we add a clause stating that also negated labels are preserved:

- **negated label preserving** If \( p \in \rho_N^-(n) \), then \( p \notin \rho'(f(n)) \).

With these modifications, Theorem 5.3.3 also holds for TP\(^-\) and CTP\(^-\).
5. Containment for Conditional Tree Patterns

5.3.2 Expressivity characterization

In this section we give an expressivity characterization for CTP similar to the one for various fragments of XPath in (Benedikt et al., 2005). The exact logical characterization allows one to compare different fragments of (Regular) XPath and derive non-trivial closure properties such as closure under intersection. We show that CTP path formulas correspond to a natural fragment of first order logic (FO) and are closed under intersections.

For \( \varphi \) a formula, let \( \text{desc}_\varphi(x, y) \) be an abbreviation of the “until” formula \( \text{desc}(x, y) \land \forall z (\text{desc}(x, z) \land \text{desc}(z, y) \rightarrow \varphi(z)) \). Let \( \exists^+(\text{child}, \text{desc}_\varphi) \) be the fragment of first order logic built up from the binary relations \( \text{child} \) and \( \text{desc} \), label predicates \( p(x) \) for each label \( p \in \Sigma \) and equality ‘\( '=' \)’, by closing under \( \land \), \( \lor \) and \( \exists \) as well as under the rule:

\[
\text{if } \varphi(x) \in \exists^+(\text{child}, \text{desc}_\varphi), \text{ then } \text{desc}_\varphi(x, y) \in \exists^+(\text{child}, \text{desc}_\varphi). \tag{5.2}
\]

We use \( \exists^+(\text{child}, \text{desc}_\varphi)(c, s) \) to denote \( \exists^+(\text{child}, \text{desc}_\varphi) \) formulas with exactly two variables \( c \) and \( s \) free. Following Benedikt et al. (2005), we restrict the FO fragment to its downward fragment \( \exists^+(\text{child}, \text{desc}_\varphi)[\text{down}](c, s) \) by requiring that every bound variable as well as \( s \) is syntactically restricted to be a descendant of \( c \) or equal to \( c \).

Note that \( \exists^+(\text{child}, \text{desc}_\varphi)[\text{down}](c, s) \) without the rule (5.2) is the logic \( \exists^+(\text{child}, \text{desc})[\text{down}](c, s) \) from Benedikt et al. (2005), and shown there to be equivalent to unions of tree patterns. Even though \( \exists^+(\text{child}, \text{desc}_\varphi)[\text{down}](c, s) \) does not contain negation, not every formula is satisfiable (e.g. \( \text{desc}(x, x) \)).

We can now characterize conditional tree patterns in terms of \( \exists^+(\text{child}, \text{desc}_\varphi)[\text{down}](c, s) \).

**Theorem 5.3.4.** The following languages are equivalent in expressible power:

- unions of the false symbol and CTP paths which can have disjunctions in the node formulas
- \( \exists^+(\text{child}, \text{desc}_\varphi)[\text{down}](c, s) \).

**Proof.** Translating a CTP path formula \( \alpha \) into an equivalent formula in \( \exists^+(\text{child}, \text{desc}_\varphi)[\text{down}](c, s) \) can be done via a standard translation \( TR_{xy}(\cdot) \). The translation is essentially the semantics of path and node formulas written in the first order language.

\[
\begin{align*}
TR_{xy}(\emptyset) &= \text{child}(x, y) \land x = y \\
TR_{xy}(\downarrow) &= \text{child}(x, y) \\
TR_{xy}(\downarrow; \varphi) &= x = y \land TR_x(\varphi) \\
TR_{xy}(\alpha_1; \alpha_2) &= \exists z. (TR_{xz}(\alpha_1) \land TR_{zy}(\alpha_2)), \text{ where } z \text{ is a fresh variable} \\
TR_{xy}(\downarrow; \varphi)^*; \downarrow &= \text{desc}_{TR_x(\varphi)}(x, y) \\
TR_{xy}(\alpha_1 \cup \alpha_2) &= TR_{xy}(\alpha_1) \lor TR_{xy}(\alpha_2) \\
TR_x(p) &= p(x) \\
TR_x(T) &= x = x \\
TR_x(\varphi_1 \land \varphi_2) &= TR_x(\varphi_1) \land TR_x(\varphi_2) \\
TR_x(\varphi_1 \lor \varphi_2) &= TR_x(\varphi_1) \lor TR_x(\varphi_2) \\
TR_x(\langle \alpha \rangle \varphi) &= \exists y. (TR_{xy}(\alpha) \land TR_y(\varphi)), \text{ where } y \text{ is a fresh variable.}
\end{align*}
\]
5.3. Expressivity

By definition, \( TR_{cs}(\alpha) \) is a formula in \( \exists^+(\text{child}, \text{desc}_\varphi)[\text{down}](c, s) \) and equivalent to \( \alpha \).

For the other direction, let \( \theta \in \exists^+(\text{child}, \text{desc}_\varphi)[\text{down}](c, s) \). We use our earlier notation \( \text{desc}_\psi(x, y) \) for the “until” formulas. First we introduce two special formulas \( \top(x) \) and \( \bot(x) \) which stand for \( x = x \) and \( \text{desc}(x, x) \), respectively. We will modify \( \theta \) in several steps. First we replace \( \text{child}(x, y) \) and \( \text{desc}(x, y) \) by the equivalent \( \text{desc}_\bot(x, y) \) and \( \text{desc}_\top(x, y) \), respectively. Then eliminate all equalities by renaming variables. Bring all existential quantifiers inside \( \theta \) to the front, bring the body into disjunctive normal form and distribute the disjunctions over the quantifiers. We then end up with a disjunction of formulas of the form \( \exists \bar{x} \varphi(c, s) \), with \( \varphi \) a conjunction of \( \text{desc}_\psi(x, y), \text{p}(x), \top(x) \) and \( \bot(x) \). If \( \varphi \) contains \( \bot \) replace \( \exists \bar{x} \varphi(c, s) \) with \( \bot \).

As our target language is closed under unions and \( \bot \), we only need to translate the “conjunctive queries” \( \exists \bar{x} \varphi(c, s) \). Consider the graph of the variables in \( \varphi \) in which two variables \( x, y \) are related if \( \varphi \) contains an atom \( \text{desc}_\psi(x, y) \). If the graph is cyclic, it cannot be satisfied on a tree and \( \exists \bar{x} \varphi(c, s) \) is equivalent to \( \bot \). If it is a tree, \( c \) will be the root. Assuming that we can rewrite all \( \psi \) in the atoms \( \text{desc}_\psi(x, y) \), we can rewrite it as a conditional tree pattern. If \( \psi \) is a boolean combination of \( \text{p}(z), \top(z) \) and \( \bot(z) \) atoms, this is not hard: Simply bring it into disjunctive normal form, and remove each conjunct containing \( \bot \). If the result is not empty, then translate to a union of (trivial) conditional tree patterns. If it is empty, translate \( \text{desc}_\psi(x, y) \) to a child step. If \( \psi \) contains subformulas of the form \( \text{desc}_\psi(x, y) \), we apply the current procedure to it.

Thus assume that the variable graph is a directed acyclic graph. We eliminate undirected cycles step by step. The length of a cycle equals the number of variables in it. Consider that the graph contains two paths \( \pi_1 \) and \( \pi_2 \) both going from \( x \) to \( y \) and without other common variables. We show that this subgraph is equivalent to a union of subgraphs with no or smaller cycles.

In the simplest case, both paths are of length 1 and thus consist of a \( \text{desc}_\psi(x, y) \) atom. But then we can use the following equivalence to remove the cycle:

\[
desc_\varphi(x, y) \land \desc_\psi(x, y) \equiv \desc_\psi \land \psi(x, y)
\]  

(5.3)

So assume the cycle looks like Figure 5.3.

![Figure 5.3: Undirected cycle in \( \varphi \).](image)

If this is satisfied on a tree \((N, E, r, \rho)\) with assignment \( g \), there are three possibilities: \( g(z_1) = g(z_2), g(z_1)E^+g(z_2) \) or \( g(z_2)E^+g(z_1) \). In each case our original formula is equivalent to one with a smaller cycle. The three possibilities are...
when $g(z_1) = g(z_2)$ desc $\varphi \land \psi(x, z_1) \land z_1\pi'_1 y \land z_1\pi'_2 y$

when $g(z_1) E^+ g(z_2)$ desc $\varphi \land \psi(x, z_1) \land \psi(z_1) \land z_1\pi'_1 y \land desc \psi(z_1, z_2) \land z_2\pi'_2 y$

when $g(z_2) E^+ g(z_1)$ desc $\varphi \land \psi(x, z_2) \land \varphi(z_2) \land z_2\pi'_2 y \land desc \varphi(z_2, z_1) \land z_1\pi'_1 y$.

In the first case the length of the cycle decreased by two, in the two other cases by one.

Thus their disjunction is equivalent to the formula of Figure 5.3. We replace that formula by this disjunction, bring the result in disjunctive normal form and distribute the disjuncts out. We again have a disjunction of “conjunctive queries”. As the new cycles are smaller, this procedure will terminate, and results in a (big) disjunction of trees. □

An important consequence of this result is that CTP patterns are closed under intersection:

**Theorem 5.3.5.** The intersection of two CTP paths is equivalent to $\bot$ or a union of CTP paths.

Theorem 5.3.4 together with the translation of Regular XPath into $\text{FO}^*(c,s)$ from ten Cate (2006) implies that every union of CTP patterns with disjunctions is in the intersection of first order logic and positive downward $\text{FO}^*(c,s)$. It is an intriguing open problem whether the converse also holds.

## 5.4 Containment

Before we determine the exact complexity of the containment problem for CTP and expansions we prove a number of reductions. Most are generalizations from TP to CTP. The key new result is the encoding of negated labels in CTP.

### 5.4.1 Containment preliminaries

The following reductions will be used later in our upper and lower bound proofs.

**Multiple output nodes**

The main difference between tree patterns and their XPath formulation is that tree patterns can have multiple output nodes. Kimelfeld and Sagiv (2008) (Proposition 5.2) show that for the TP containment problem the number of output nodes is not important: the problem can be PTIME reduced to a containment problem of Boolean TPs. This is achieved, given $\varphi, \psi \in \text{TP}$, by adding a child labeled with a new label $a_i$ to every output node $X_i$ in both $\varphi$ and $\psi$. Second, to every leaf that is not an output node or a newly added node, we add a child labeled with $\top$. The same result, using the same argument, holds for CTP.

**Proposition 5.4.1.** Let $S \subseteq \{\lor, \neg\}$. For CTP$^S$ patterns with multiple output nodes $\varphi, \psi$ there are PTIME computable Boolean CTP$^S$, $\varphi', \psi'$ such that $\varphi \subseteq \psi$ iff $\varphi' \subseteq \psi'$. The same holds for multi-labeled trees.
5.4. Containment

![Diagram of pattern \( \varphi' \)](image1)

![Diagram of pattern \( \psi \)](image2)

Figure 5.4: Patterns \( \varphi' \) and \( \psi \) from Proposition 5.4.2.

![Diagram of model for pattern \( \varphi' \)](image3)

Figure 5.5: Model for pattern \( \varphi' \) from Proposition 5.4.2.

**Disjunctions in the consequent**

We now show that the containment problem for both unions of \( \text{CTP}^\neg \) and unions of \( \text{TP}^\neg \) can be reduced to containments without unions. This is useful in lower bound proofs, as we can use a union in the consequent to express multiple constraints.

The proof of the following proposition is a slight modification of the proof for \( \text{TP} \) in (Miklau and Suciu, 2004).
Proposition 5.4.2. Let $\varphi$ be a CTP$^-$ (TP$^-$) formula and $\Delta$ a finite set of CTP$^-$ (resp. TP$^-$) formulas. Then there are PTIME computable CTP$^-$ (TP$^-$) formulas $\varphi'$ and $\psi$ such that $\varphi \subseteq \bigvee \Delta$ iff $\varphi' \subseteq \psi$.

If $\varphi$ and $\Delta$ are in CTP (TP), $\varphi'$ and $\psi$ are in CTP (TP) as well.

The same holds for containment over multi-labeled trees.

Proof. First, for the case of TP$^-$, the proof from Miklau and Suciu (2004) can be readily applied here (using embeddings which also preserve negated labels, cf Remark 5.3.1).

Now we prove the proposition for CTP$^-$. For simplicity, we use the same letter to denote a CTP$^-$ formula and its corresponding tree pattern representation. Assume $\Delta$ is $\{\delta_1, \ldots, \delta_k\}$. If $\iota$ is a CTP$^-$ pattern, by $\iota^a$ we denote the CTP$^-$ pattern defined as having the root labeled by $a$, whose unique child is the root of $\iota$. Consider new labels $a$ and $b$ occurring neither in $\varphi$ nor $\Delta$. Let $\gamma = \bigwedge_{0 < \ell \leq k} \delta^b_\ell$. Note that $\gamma$ is consistent if every $\delta_\ell$ is consistent. Now define $\varphi'$ as the CTP$^-$ tree pattern in Figure 5.4(a), and $\psi$ as the CTP$^-$ tree pattern in Figure 5.4(b).

We verify that $\varphi \subseteq \bigvee \Delta$ iff $\varphi' \subseteq \psi$. Without loss of generality, we assume that each of $\varphi, \delta_1, \ldots, \delta_k$ is consistent.

For the direction from left to right, assume $\varphi \subseteq \bigvee \Delta$ and $T, n \models \varphi'$ for an arbitrary $T, n$. This means that there is a path $n = m_0 \ldots m_{2k-1}$ of nodes in $T$ that are labeled with $a$ and such that:

- for every $0 < \ell \leq k$: $T, m_i \models (\delta^b_\ell)^a$, with $i \in \{1, \ldots, k-1\} \cup \{k+1, \ldots, 2k-1\}$,

- $T, m_k \models (\delta^b_1)^a$.

By the assumption, it follows that there is an index $j$ such that $T, m_k \models (\delta^b_j)^a$. Then, by Theorem 5.3.3, there is a simulation $f'$ from $(\delta^b_j)^a$ into $T, m_k$. The simulation $f'$ can be extended to a simulation $f$ from $\psi$ into $T, n$ in the obvious way such that $f$ is a simulation from $(\delta^b_1)^a$ into $T, m_{k-j+i}$ and the $a$-descendant edge in $\psi$ is simulated on the path $m_0, \ldots, m_{k-j+1}$. Thus, $T, n \models \psi$.

For the other direction, assume $\varphi' \subseteq \psi$ and $T, n \models \varphi$ for an arbitrary $T$ rooted at $n$. As all $\delta_\ell$ are consistent, there are trees $T_\ell, n_\ell \models \delta_\ell$, for each $\ell \in \{1, \ldots, k\}$. Let $T'$ be the tree created from $T, n$ and the $T_\ell$’s depicted in Figure 5.5 with root $r$. Then $T', r \models \varphi'$. Because we assumed $\varphi' \subseteq \psi$, then also $T', r \models \psi$, which by Theorem 5.3.3 implies the existence of a simulation $g$ from $\psi$ into $T', r$. In particular, the span of $k$ a-nodes in $\psi$ has to be simulated on an $a$-path of length $k$ in $T'$. This means that for some $j \in \{1, \ldots, k\}$, $g$ is a simulation from $\delta_j$ into $T, n$. By Theorem 5.3.3 again, $T, n \models \delta_j$, and thus $T, n \models \bigvee \Delta$.

Note that if $\varphi$ and $\Delta$ are in CTP, then the constructed $\varphi'$ and $\psi$ are in CTP too. □

From single-labeled to multi-labeled trees

We now show that the containment problem over single-labeled trees can be reduced to a containment problem over multi-labeled trees.

Proposition 5.4.3. Let $S \subseteq \{\neg, \lor\}$. Given CTP$^S$ (TP$^S$) patterns $\varphi, \psi$, there are PTIME computable CTP$^S$ (TP$^S$) patterns $\varphi', \psi'$ such that $\varphi \subseteq \psi$ iff $\varphi' \subseteq_{\text{ML}} \psi'$.
Proof. Let \( p_1, \ldots, p_n \) be the labels from \( \Sigma \) occurring in \( \varphi \) or \( \psi \). We take \( \varphi'' \) as \( \varphi \), and \( \psi'' := \psi \lor \bigvee_{1 \leq i < j \leq n} (p_i \land p_j) \lor \bigvee_{1 \leq i < j \leq n} (\nabla i) (p_i \land p_j) \). The disjuncts added to \( \psi \) ensure that every node of a counterexample is labeled with at most one label. Now we show that \( \varphi \subseteq \psi \) iff \( \varphi'' \subseteq \psi'' \).

\((\Rightarrow)\) We show the contraposition. Let \( T \) be a multi-labeled tree such that \( T \models \varphi'' \) and \( T \not\models \psi'' \). Then let \( T' \) be the tree obtained from \( T \) by restricting the labels \( \rho'(v) := \rho(v) \cap \{p_1, \ldots, p_n\} \) for every node \( v \). Since \( T \) does not satisfy \( \psi'' \), the label of every node in \( T' \) contains at most one symbol. Because we did not change the valuation of the labels \( p_1, \ldots, p_n \), for each formula \( \theta \) constructed from these tags, it holds that \( T, v \models \theta \) iff \( T', v \models \theta \). From this and the fact that the label of each node of \( T' \) is of size at most one, it follows that \( T' \models \varphi'' \) and \( T' \not\models \psi'' \). In order to make a single-labeled tree out of \( T' \), we add a dummy symbol \( q \) in the label of a node if its label in \( T' \) is empty. For the resulting tree \( T'' \) it holds \( T'' \models \varphi \) and \( T'' \not\models \psi \).

\((\Leftarrow)\) Let \( T' \) be a single-labeled tree such that \( T \models \varphi \) and \( T \not\models \psi \). Then this tree can be considered as a multi-labeled tree. Moreover, \( T \models \varphi'' \) and \( T \not\models \psi'' \) since \( T \) does not satisfy any of the disjuncts in \( \psi'' \).

Our transformation does not introduce negations, but only disjunctions in \( \psi'' \). Thus the proposition is proven for the cases when \( S \) contains disjunction, where we take \( \varphi' := \varphi'' \) and \( \psi' := \psi'' \). For the remaining cases (\( S \subseteq \{\neg\} \)), although \( \psi'' \) contains disjunctions, by Proposition 5.4.2, there exist two PTIME computable CTP\(^S\) (TP\(^S\)) patterns \( \varphi' \) and \( \psi' \) such that \( \varphi'' \subseteq \psi'' \) iff \( \varphi' \subseteq \psi' \). This concludes the proof. \( \square \)

Negated labels

We now show that CTP is expressive enough to encode label negation, as far as the containment problem is concerned.

The trick of the encoding lies in the fact that two nodes connected by a descendent edge are in either child or descendant of a child relation. Additionally, if we require that neither of these relations occur at the same time, we can faithfully encode label negation.

**Proposition 5.4.4.** Let \( \varphi \) and \( \psi \) be CTP\(^\sim\) patterns. There are PTIME computable CTP patterns \( \varphi' \) and \( \psi' \) such that

\[
\varphi \subseteq \psi \iff \varphi' \subseteq \psi'.
\]

This also holds for containment over multi-labeled trees.

**Proof.** Given a containment problem \( \varphi \subseteq \psi \) in CTP\(^\sim\), we construct an equivalent containment problem \( \varphi^* \subseteq \psi^\circ \) with \( \varphi^* \) in CTP and \( \psi^\circ \) a union of CTP patterns. Applying Proposition 5.4.2 then yields the desired result.

Let \( p_1, \neg p_1, \ldots, p_n, \neg p_n \) be the labels appearing in \( \varphi \) and \( \psi \) and their negations. Let \( s \) be a new label and let \( \zeta \) be the formula \( \langle s \rangle \langle \bigwedge_i \langle \nabla i \rangle p_i \rangle \). We define the translation
5. Containment for Conditional Tree Patterns

\( (\cdot)^* \) inductively:

\[
\begin{align*}
\top^* &= \zeta \\
(p_i)^* &= \zeta \land \langle \downarrow \rangle (s \land \langle \downarrow \rangle p_i) \\
(\neg p_i)^* &= \zeta \land \langle \downarrow \rangle (s \land \langle \downarrow \rangle p_i^+) \\
(\theta \land \sigma)^* &= \theta^* \land \sigma^* \\
(\langle \downarrow \rangle \varphi)^* &= \zeta \land \langle \downarrow \rangle \varphi^* \\
(\langle \varphi^+ \rangle \psi)^* &= \zeta \land \langle \varphi^* + \rangle \psi^*.
\end{align*}
\]

The translation is defined in such a way that for any \( \varphi, \varphi^* \) implies \( \zeta \). Obviously \( (\cdot)^* \) is a \text{PTIME} translation. Let \( \langle \downarrow^* \rangle \varphi \) denote \( \varphi \lor \langle \downarrow^+ \rangle \varphi \). Let \( \text{AX} \) be the disjunction of the following formulas:

\[
\begin{align*}
\langle \downarrow^* \rangle (s \land \langle \downarrow^* \rangle \zeta) &= \langle \downarrow^* \rangle (s \land \langle \downarrow^* \rangle \zeta) \\
\bigvee_{i} \langle \downarrow^* \rangle (p_i^* \land (\neg p_i)^*) &= \langle \downarrow^* \rangle (p_i^* \land (\neg p_i)^*) \\
\bigvee_{i \neq j} \langle \downarrow^* \rangle (p_i^* \land p_j^*). &= \langle \downarrow^* \rangle (p_i^* \land p_j^*).
\end{align*}
\]

In our intended models, none of these disjuncts are true at the root. The disjunct (5.4) is technical, (5.5) states that no node makes the encodings of both \( p \) and \( \neg p \) true, and (5.6) ensures that no node makes the encoding of two different labels true. We define \( \psi^o = \psi^* \lor \text{AX} \). In the case of multi-labeled trees the translation is the same, except that we do not include the disjunction (5.6) in the definition of \( \psi^o \). Note that although in \( \psi^o \) we have disjunctions within the scope of a modality, we can (in \text{PTIME}) rewrite the formula into an equivalent union of disjunction free formulas.

We now show that \( \varphi \subseteq \psi \) iff \( \varphi^* \subseteq \psi^* \).

\((\Leftarrow)\) We show the contrapositive. Given a single-labeled tree \( T = (N, E, r, l) \) such that \( T, r \models \varphi \) and \( T, r \not\models \psi \), we build a single-labeled tree \( T' = (N', E', r', l') \) as follows. The set of nodes \( N' \) is the maximal \( E' \)-connected subset of \( N \times \{0, 1, 2, 3\} \times \{p_1, \ldots, p_n, \#\} \) that contains the root \( r' = (r, 0, \#) \). The relation \( E' \) is defined as follows:

\[
\begin{align*}
(n', 0, \#) &\text{ is the parent of } (n, 0, \#) \text{ when } n' \text{ is the parent of } n \text{ in } T; \\
(n, 1, \#) &\text{ is the parent of } (n, 2, p_i), i = 1, \ldots, n; \\
(n, 3, p_i) &\text{ is the parent of } (n, 3, p_i), i = 1, \ldots, n. \text{ The labeling } l' \text{ is defined as follows: } s \text{ only labels nodes of the form } (n, 1, \#). \text{ Then, } p_i \text{ labels } (n, 2, p_i) \text{ if } T, n \models p_i \text{ and } p_i \text{ labels } (n, 3, p_i) \text{ if } T, n \not\models p_i. \text{ No other nodes are labeled by } p_i. \text{ In all other cases, we label a node by a fresh label } z.
\end{align*}
\]

It is clear from the definition that \( T' \) is a single-labeled tree. Note that \( T' \not\models \text{AX} \) and that \( \zeta \) is true at all nodes of type \( (n, 0, \#) \), and only at these nodes. Let \( \theta \) be a formula in variables \( \{p_1, \ldots, p_n\} \), and \( n \in N \). By induction on \( \theta \), we show \( T, n \models \theta \iff T', (n, 0, \#) \models \theta^* \).

- \( \theta = \top \). This holds because by construction \( \zeta \) is true at all nodes of type \( (n, 0, \#) \).
- \( \theta = p \). We have \( T, n \models p \iff l(n) = p \iff l'(n, 2, p) = p \iff (\text{since } (n, 2, p) \text{ is the only child of } (n, 1, \#) \text{ labeled with } p \text{ and } (n, 1, \#) \text{ is labeled by } s) \)
5.4. Containment

\( T', (n, 1, \varepsilon) \models s \wedge \langle \downarrow \rangle p \iff (\text{since } (n, 1, \varepsilon) \text{ is the only child of } (n, 0, \varepsilon) \text{ and } \varepsilon \text{ is always true at } (n, 0, \varepsilon)) T', (n, 0, \varepsilon) \models \zeta \wedge \langle \downarrow \rangle (s \wedge \langle \downarrow \rangle p) \iff T', (n, 0, \varepsilon) \models p^* \).

\( \theta = \neg p \). We have \( T, n \models \neg p \iff l(n) \neq p \iff l'(n, 3, p) = p \iff (\text{since } (n, 3, p) \text{ is the only descendant of } (n, 1, \varepsilon) \text{ labeled with } p \text{ and } (n, 1, \varepsilon) \text{ is labeled by } s) T', (n, 1, \varepsilon) \models s \wedge \langle \downarrow \rangle \langle \downarrow \rangle p \iff (\text{since } (n, 1, \varepsilon) \text{ is the only child of } (n, 0, \varepsilon) \text{ and } \zeta \text{ is always true at } (n, 0, \varepsilon)) T', (n, 0, \varepsilon) \models \zeta \wedge \langle \downarrow \rangle (s \wedge \langle \downarrow \rangle \langle \downarrow \rangle p) \iff T', (n, 0, \varepsilon) \models (\neg p)^* \).

\( \theta = \varphi_1 \wedge \varphi_2 \). We have \( T, n \models \varphi_1 \wedge \varphi_2 \iff T, n \models \varphi_1 \text{ and } T, n \models \varphi_2 \iff (\text{by the induction hypothesis}) T', (n, 0, \varepsilon) \models \varphi_1^* \text{ and } T', (n, 0, \varepsilon) \models \varphi_2^* \iff T', (n, 0, \varepsilon) \models \varphi_1^* \wedge \varphi_2^* \iff T', (n, 0, \varepsilon) \models (\varphi_1 \wedge \varphi_2)^* \).

\( \theta = \langle \downarrow \rangle \varphi \). We only show the right to left direction. \( T', (n, 0, \varepsilon) \models (\langle \downarrow \rangle \varphi)^* \iff T', (n, 0, \varepsilon) \models \zeta \wedge \langle \downarrow \rangle \varphi^* \iff \exists m \in N' \text{ such that } (n, 0, \varepsilon)E^m \text{ and } T', m \models \varphi^* \). But then \( T', m \models \zeta \text{ because } \varphi^* \text{ implies } \zeta \). Thus \( m \text{ must be of the form } (n', 0, \varepsilon) \) as only these make \( \zeta \) true. But then \( n' \in N \) and \( nE n' \) and we may apply the inductive hypothesis to get \( T, n' \models \varphi \), and thus \( T, n \models \langle \downarrow \rangle \varphi \).

\( \theta = \langle \varphi^+ \rangle \psi \). We only show the right to left direction. \( T', (n, 0, \varepsilon) \models (\langle \varphi^+ \rangle \psi)^* \iff T', (n, 0, \varepsilon) \models \zeta \wedge \langle \varphi^+ \rangle \psi^* \iff \exists m \in N' \text{ such that } (n, 0, \varepsilon)E^+m \text{ and } T', m \models \psi^* \text{ and } \forall m'. (n, 0, \varepsilon)E^+m'E^+m \text{ it holds } T', m' \models \varphi^* \). Now, because \( \varphi^* \) implies \( \zeta \) for all \( \varphi \), the node \( m \) and all the nodes \( m' \) are of the form \( (n', 0, \varepsilon) \) such that \( n' \) is in the original set \( N \). Moreover they stand in the same way in the \( E \) relation. Thus we can apply the inductive hypothesis and obtain \( T, n \models \langle \varphi^+ \rangle \psi \).

As a special case, \( T', (r, 0, \varepsilon) \) satisfies \( \varphi^* \) but not \( \psi^* \). Recall that \( T', (r, 0, \varepsilon) \) does not satisfy the other disjuncts \( AX \) of \( \psi^0 \) either and thus, \( T', (r, 0, \varepsilon) \models \varphi^* \text{ and } T', (r, 0, \varepsilon) \not\models \psi^0 \), as desired.

\((\Rightarrow)\) Again we show the contrapositive. Suppose there is a model \( T = (N, E, r, l) \) satisfying \( \varphi^* \), but not \( \psi^0 \) at the root \( r \). Then in particular \( T, r \not\models AX \). Without loss of generality, we can assume that the simulation from (the conditional tree pattern corresponding to) \( \varphi^* \) into \( T \) is surjective. (Otherwise the image of \( \varphi^* \) is a subtree of \( T \) and thus by monotonicity \( \psi^0 \) cannot be satisfied at the root of this subtree.) In this model, as a consequence of the fact that \( \varphi^* \) implies \( \zeta \), every branch has an initial segment satisfying \( \zeta \), immediately followed by a node labeled by \( s \), which is followed by a segment where \( \zeta \) is never satisfied because of the first disjunct \((5.4)\) of \( AX \).

We define a tree \( T' = (N', E', r', l') \) whose set of nodes \( N' \) consists of the nodes of \( T \) where \( \zeta \) is satisfied, i.e. \( N' = \{ n \in N \mid T, n \models \zeta \} \); \( E' \) is simply the restriction of \( E \) to \( N' \) and \( r' = r \). We define \( l'(n) = p_i \) iff \( T, n \models p^*_i \), and if \( T, n \not\models p^*_i \) for any \( i \), then we label \( n \) with a fresh variable \( z \). This definition of \( l' \) is well-defined because the falsity of the disjunction \((5.6)\) in \( AX \) ensures that each node makes at most one \( p^*_i \) true in \( T \).

Let \( \theta \) be a formula in variables \( \{p_1, \ldots, p_n\} \), and \( n \in N \). By induction on \( \theta \), we show that

\[ T, n \models \theta^* \text{ iff } T', n \models \theta. \quad (5.7) \]

\( \theta = \top \). Then \( T, n \models \top^* \iff (\text{by definition of } (\cdot)^* Mit) T, n \models \zeta \iff (\text{by definition of } N') T', n \models \top. \)
5. Containment for Conditional Tree Patterns

- $\theta = p$. Then $T, n \models p^* \iff \text{(by definition of the labeling $l' \cdot l'(n) = p \iff T', n \models p$.}

- $\theta = \neg p$. If $T, n \not\models \neg p^*$, then by the falsity of $AX$, $T, n \not\models p^*$, and thus $l'(n) \neq p$ and $T', n \not\models p$. Conversely, $T', n \models \neg p \iff l'(n) \neq p \iff T, n \not\models p^*$. But $T, n \models \zeta$ and thus either $p^*$ or $(\neg p)^*$ must hold at $T, n$. Thus $T, n \models \neg p^*$.

- $\theta = \varphi_1 \land \varphi_2$. Then $T, n \models (\varphi_1 \land \varphi_2)^* \iff T, n \models \varphi_1^*$ and $T, n \models \varphi_2^* \iff (n \in N'$ because $\varphi^*$ implies $\zeta$ and thus by the inductive hypothesis) $T', n \models \varphi_1$ and $T', n \models \varphi_2 \iff T', n \models \varphi_1 \land \varphi_2$.

- $\theta = \langle \downarrow \rangle \varphi$. Then $T, n \models (\langle \downarrow \rangle \varphi)^* \iff T, n \models \zeta$ and $T, n \models \langle \downarrow \rangle \varphi^* \iff$ there exists $n' \in N$ such that $nEn'$ and $T, n' \models \varphi^* \iff \text{(by the fact $T, n' \models \zeta$ and, thus, $n' \in N'$ and the inductive hypothesis) there exists $n' \in N'$ such that $nE'n'$ and $T', n' \models \varphi \iff T', n \models \langle \downarrow \rangle \varphi$, as desired.}

- $\theta = \langle \theta^+ \rangle \tau$. Assume $T, n \models (\langle \theta^+ \rangle \tau)^*$. Then, by definition of $(\cdot)^*$, $T, n \models \zeta \land (\langle \theta^+ \rangle \tau)^*$. That means there exists $n'$ in $T$ with $nE^+n'$ such that $T, n' \models \tau^*$ and for all $n''$ with $nE^nE^+n'$ it holds $T, n'' \models \theta^*$. By definition of $(\cdot)^*$, the nodes $n, n'$ and all the nodes between $n$ and $n'$ satisfy $\zeta$ and thus belong to $T'$. By inductive hypothesis, $T', n' \models \tau$ and $T', n'' \models \theta$ for all $nE^nE^+n'$, which means $T', n \models (\theta^+)^* \tau$ holds. Conversely, assume $T', n \models (\theta^+)^* \tau$. By definition of $T'$, we have that $T, n \models \zeta$, which is the first conjunct of $(\langle \theta^+ \rangle \tau)^*$. The second conjunct follows by the inductive hypothesis.

As $T$ is a counterexample for $\varphi^* \subseteq \psi^*$, (5.7) implies that $T'$ is a counterexample of $\varphi \subseteq \psi$, as desired.

The same argument applies for multi-labeled trees. The only change is to remove the last disjunction (5.6) from $AX$. \qed

5.4.2 Lower bounds

In this section we show that the containment for TP$^-$ is PSPACE hard. This lower bound will carry over to the containment problem for CTP.

**Theorem 5.4.1.**

(i) The containment problem for CTP is PSPACE-hard.

(ii) The containment problem for TP$^-$ is PSPACE-hard,

(iii) Both results also hold for multi-labeled trees.

**Proof.** (i) follows from (ii) by Proposition 5.4.4. (iii) follows from (i) and (ii) by Proposition 5.4.3. For proving (ii), we reduce the corridor tiling problem, which is known to be hard for PSPACE (Chlebus, 1986; van Emde Boas, 1997), to the containment problem for TP$^-$.

We use the construction from the PSPACE-hardness proof for the containment problem of TP with disjunction over a finite alphabet in (Neven and Schwentick, 2006).

The corridor tiling problem is formalized as follows. Let $\mathcal{T}_l = (D, H, V, \bar{b}, \bar{t}, n)$ be a tiling system, where $D = \{d_1, \ldots, d_m\}$ is a finite set of tiles, $H, V \subseteq D^2$ are horizontal and vertical constraints, $n$ is a natural number given in unary notation, $\bar{b}$ and $\bar{t}$ are tuples
over $D$ of length $n$. Intuitively, given a corridor of width $n$, the goal is to construct a tiling of the corridor using the tiles from $D$ so that the horizontal and vertical constraints are satisfied and the bottom and top rows are tiled by $\bar{b}$ and $\bar{t}$, respectively. We say that a tiling satisfies the horizontal constraints $H$ (respectively the vertical constraints $V$) if for every $1 \leq i \leq n, j \in \mathbb{N}$ it holds that if $d_1$ and $d_2$ are the tiles on the positions $(i, j)$ and $(i + 1, j)$ of the corridor (respectively $(i, j)$ and $(i, j + 1)$), then $(d_1, d_2) \in H$ (($(d_1, d_2) \in V$).

Now we construct in $\text{PTIME}$ in the length of $\text{Til}$, two $\text{TP}^\neg$ expressions $\varphi$ and $\psi$ such that the following holds:

$$\varphi \nsubseteq \psi \text{ iff there exists a tiling for Til.}$$

(5.8)

By Proposition 5.4.2, we may without loss of generality construct $\psi$ as a disjunction of $\text{TP}^\neg$ expressions. To this purpose, we use the string representation of a tiling. Each row of the considered tiling is represented by the tiles it consists of. If the tiling of a corridor of width $n$ has $k$ rows, it is represented by its rows separated by the special symbol $\#$. The top row is followed by the symbol $\$$. Thus, a tiling is a word of the form $u_1\#u_2\#\cdots\#u_k\$, where each $u_i$ is the word of length $n$ corresponding to the $i$-th row in the tiling. In particular $u_1 = \bar{b}$ and $u_k = \bar{t}$. For the sake of readability, for expression $r$, $r^i$ denotes the path formula $?r_1; \downarrow; \ldots; r_i; \downarrow; \ldots; ?r$ with $i$ occurrences of $r$. Let $\varphi$ be

$$\langle ?b_1; \downarrow; ?b_2; \ldots; \downarrow; ?b_n; \downarrow; ?\#; \downarrow^+; ?t_1; \downarrow; \ldots; \downarrow; \downarrow; ?t_n; \downarrow \rangle \$$. Intuitively, this expression enforces a tiling to start with a path starting with $\bar{b}$ and finishing with $\bar{t}$ and the final symbol $\$$. Now the formula $\psi$ defines all incorrect tilings and additional constraints. It is the disjunction of the following $\text{TP}^\neg$ formulas.

(0) $\langle \downarrow^+; (?d_1 \wedge \ldots \wedge \neg d_m \wedge \neg \#); \downarrow^+ \rangle \$. There is a position that is labeled neither by a tile nor a delimiter.

(1) Incorrect length of a row.

(1a) $\bigvee_{i=0}^{n-1} \langle \downarrow^+; ?\#; \top^i; \downarrow \# \rangle$, a row is too short;

(1b) $\langle \downarrow^+; (?\#)^{n+1} \rangle \top$, a row is too long;

(2) $\bigvee_{(d_1, d_2) \not\in H} \langle \downarrow^+; ?d_1; \downarrow; ?d_2 \rangle \top$, some horizontal constraints are violated;

(3) $\bigvee_{(d_1, d_2) \not\in V} \langle \downarrow^+; ?d_1; \downarrow; \top^n; \downarrow; ?d_2 \rangle \top$, some vertical constraints are violated.

Note that negated labels are used in (0) and (1b). Also note that the size of $\varphi$ and $\psi$ is bounded by a polynomial in the size of $\text{Til}$.

We now show (5.8).

($\Leftarrow$). Assume that there exists a tiling of the corridor. Let $s$ be the string representation of it. Then, $s = u_1\#u_2\#\ldots\#u_k\$, where $|u_i| = n$, $u_i \in D^n$, $u_1 = \bar{b}$ and $u_k = \bar{t}$. Moreover, on the one hand if $x \cdot y$, is an infix of some $u_i$, then $(x, y) \in H$, and on the other hand for every infix $x \cdot u' \cdot y$ of length $n + 1$ of $u_i\#u_{i+1}$, it holds that $(x, y) \in V$. Let $T_s$ be the corresponding tree, i.e. a single path of $|s|$ nodes $\{v_1, \ldots, v_{|s|}\}$ where the
5. Containment for Conditional Tree Patterns

labeling is set in accordance with \( s \), i.e. \( l(v_i) = s_i \). Clearly, \( T_s \) is a model of \( \varphi \) and not of \( \psi \).

\((\Rightarrow)\). Let \( T \) be a tree such that \( T, r \models \varphi \) and \( T, r \not\models \psi \). Since \( T, r \models \varphi \), there must exist a path \( r = v_1, \ldots, v_m \) in \( T \) which starts with \( \bar{b} \) and finishes with \( \bar{t} \). Moreover, either \( \sharp \) or a symbol from \( D \) is the label of every node \( v_i \), \( 1 \leq i < m \), according to (0).

We define a tiling function \( g : \{0, \ldots, n-1\} \times \mathbb{N} \rightarrow D \) assigning a tile to every position in the corridor as follows: \( g(i, j) = l(v_{(n+1) \times j+i+1}), 1 \leq i \leq n \), where \( l \) is the labeling function of \( T \). Indeed, this function is well defined, as (1) ensures the correct counting. By formulas (2) and (3) the tiling defined by \( g \) satisfies the horizontal and vertical constraints.

The difference between CTP patterns and TP patterns is that CTP descendent edges can be labeled by patterns. One might ask whether a bound on the degree of such a labeling nesting can lead to a lower complexity of the containment problem. Define the until nesting depth \( un : CTP \rightarrow \mathbb{N} \) as follows.

- \( un(p) = un(T) = 0 \),
- \( un(\langle \downarrow \rangle \varphi) = un(\langle \downarrow + \rangle \varphi) = 1 \),
- \( un(\varphi_1 \land \varphi_2) = \max\{un(\varphi_1), un(\varphi_2)\} \),
- \( un(\langle \varphi^+ \rangle \psi) = un(\varphi) + 1 \).

Unfortunately, a close examination of the encoding in the lower bound proof and the encodings in Propositions 5.4.2 and 5.4.4 gives a negative answer to the question. Thus we obtain

Theorem 5.4.2. The CTP containment problem for formulas of until nesting depth one is PSPACE-hard.

5.4.3 Upper bounds

In this section, we show a matching PSPACE upper bound for CTP containment.

The complexity of CTP\(\neg,\lor\) containment follows from a translation into existential CTL (\(\exists\)CTL), whose containment problem is known to be PSPACE-complete (Kupferman and Vardi, 2000). The only small technical issue is that \(\exists\)CTL formulas are interpreted over infinite finitely branching trees. We solve that by relativizing formulas with a new propositional variable \( s \), whose interpretation will provide the desired finite tree.

Theorem 5.4.3. The containment problem for CTP\(\neg,\lor\) is decidable in PSPACE. This also holds for multi-labeled trees.

Proof. We prove the upper bound for the case of multi-labeled trees. The upper bound for single-labeled trees then follows by Proposition 5.4.3.

We recall from Kupferman and Vardi (2000) the definition of \(\exists\)CTL. Let Prop be a set of propositional variables. \(\exists\)CTL node formulas \( \varphi \) and path formulas \( \alpha \) are defined by:

\[
\varphi ::= T \mid \bot \mid p \mid \neg p \mid \varphi \land \varphi \mid \varphi \lor \varphi \mid \exists \alpha \\
\alpha ::= \varphi \mid \alpha \land \alpha \mid \alpha \lor \alpha \mid X \alpha \mid (\alpha U \alpha) \mid (\alpha \hat{U} \alpha)
\]
where \( p \in \text{Prop} \), and asking that in node formulas, the operators \( X(\text{“next”}), U(\text{“until”}) \) and \( \overline{U}(\text{“dual of until”}) \) are always immediately preceded by \( \exists \).

The semantics for \( \exists \text{CTL} \) is given by \textit{infinite finitely branching trees}. \( \exists \text{CTL} \) path formulas are interpreted at a (possibly infinite) paths of the tree and \( \exists \text{CTL} \) node formulas are interpreted at nodes of the tree. Our reduction will translate \( \overline{\text{CP}} \) formulas to \( \exists \text{CTL} \) node formulas, with occurrences of formulas of the form \( \exists X \varphi \) and \( \exists \psi U \varphi \). Semantics of such formulas is defined as follows, given an infinite tree \( T = (N, E, r, \rho) \) and a node \( n \in N \).

\[
T, n \models \exists X \varphi \text{ iff there exists a node } m \in N \text{ such that } nEm \text{ and } T, m \models \varphi,
\]

\[
T, n \models \exists \psi U \varphi \text{ iff there exists a node } m \in N \text{ such that } nE^*m \text{ and } T, m \models \varphi,
\]

and for all \( n' \in N \) with \( nE^nE^*m \) it holds \( T, n' \models \psi \).

The \( \overline{\text{CP}} \) node formula \( \langle \varphi^+ \rangle \psi \) corresponds to the strict until operator, which is expressible in \( \exists \text{CTL} \) as \( \exists X \exists \psi U \varphi \).

We denote by \( \subseteq_{\infty} \) the containment relation for \( \exists \text{CTL} \) node formulas over finitely branching trees where each branch is infinite.

Let \( \varphi, \psi \) be in \( \overline{\text{CP}} \) and let \( s \) be a new propositional variable not in \( \varphi, \psi \). The translation \( (\cdot)^s \) from \( \overline{\text{CP}} \) to \( \exists \text{CTL} \) node formulas relativizes every subformula with \( s \) and adjusts the syntax.

\[
(\top)^s = s \land \top
\]

\[
(p)^s = s \land p
\]

\[
(\neg p)^s = s \land \neg p
\]

\[
(\varphi_1 \land \varphi_2)^s = \varphi_1^s \land \varphi_2^s
\]

\[
(\varphi_1 \lor \varphi_2)^s = \varphi_1^s \lor \varphi_2^s
\]

\[
((\downarrow) \varphi)^s = s \land \exists X \varphi^s
\]

\[
((\psi^+) \varphi)^s = s \land \exists \exists \psi U \varphi^s
\]

We claim that \( \varphi \subseteq \psi \text{ iff } \varphi^s \subseteq_{\infty} \psi^s \).

The proof is by contraposition. First assume that for some finite tree \( T = (N, E, r, \rho) \) and node \( n \in N \) it holds \( T, n \models \varphi \) and \( T, n \not\models \psi \). We then construct an infinite tree which is a counterexample. Let \( s \) be a propositional variable not occurring in \( \varphi \) or \( \psi \). Let \( T^s_{\infty} \) be the infinite tree obtained from \( T \) by adding to each leaf in \( T \) an infinite path. The labeling is changed as follows: all new nodes have the empty label set and we add the label \( s \) to the label set of all old nodes. Formally, \( T^s_{\infty} = (N_{\infty}, E_{\infty}, r, \rho_{\infty}) \), where \( N_{\infty} = N \cup \{n^m_1, n^m_2, \ldots \mid m \text{ is a leaf in } T\} \) is the set of nodes, \( E_{\infty} = E \cup \{(m,n^m_1) \mid n^m_1 \in N_{\infty}\} \cup \{(n^m_i,n^m_{i+1}) \mid n^m_i, n^m_{i+1} \in N_{\infty}, i \geq 1\} \) is the set of edges, \( r \) is the root and \( \rho_{\infty} \) is the labeling function defined as follows.

\[
\rho_{\infty}(n) = \begin{cases} 
\rho(n) \cup \{s\} & \text{if } n \in N, \\
\emptyset & \text{if } n \in N_{\infty} \setminus N.
\end{cases}
\]

We show by induction on the structure of the formula that for every node \( n \in N \) and every \( \overline{\text{CP}} \) formula \( \theta, T, n \models \theta \) iff \( T^s_{\infty}, n \models \theta^s \).
To show this we will use the following two facts which are easy consequences of the definitions of $T^s_\infty$ and the translation $(\cdot)^s$:

$$T^s_\infty, n \models s \iff n \in N,$$

and

$$T^s_\infty, n \models \varphi^s \Rightarrow T^s_\infty, n \models s.$$  (***)

- $\theta = \top$. We have $T, n \models \top$ iff $n \in N$ iff $n \in N_\infty$ and $s \in \rho_\infty(n)$ iff $T^s_\infty, n \models s \wedge \top$ iff $T^s_\infty, n \models (\top)^s$.

- $\theta = p, p \in \Sigma$. We have $T, n \models p$ iff $p \in \rho(n)$ iff (since $n \in N$) $\{p, s\} \subseteq \rho_\infty(n)$ iff $T^s_\infty, n \models s \wedge p$ iff $T^s_\infty, n \models (p)^s$.

- $\theta = \neg p, p \in \Sigma$. We have $T, n \models \neg p$ iff $p \notin \rho(n)$ iff (since $n \in N$ and, thus, $s \in \rho_\infty(n)$) $p \notin \rho_\infty(n)$ and $s \in \rho_\infty(n)$ iff $T^s_\infty, n \models s \wedge \neg p$ iff $T^s_\infty, n \models (\neg p)^s$.

- $\theta = \varphi_1 \land \varphi_2$. We have $T, n \models \varphi_1 \land \varphi_2$ iff $T, n \models \varphi_1$ and $T, n \models \varphi_2$ iff (by the induction hypothesis, (*) and (**)) $T^s_\infty, n \models \varphi_1^s$ and $T^s_\infty, n \models \varphi_2^s$ iff $T^s_\infty, n \models \varphi_1^s \land \varphi_2^s$.

- $\theta = \phi_1 \lor \varphi_2$. By the same argument as for $\varphi_1 \land \varphi_2$.

- $\theta = (\downarrow)\varphi$. We have $T, n \models (\downarrow)\varphi$ iff there exists $m \in N$ such that $nEm$ and $T, m \models \varphi$ (by the induction hypothesis, (*) and (**) and the fact that $n \in N$) $T^s_\infty, n \models s$ and there exists $m \in N_\infty$ such that $nE_\infty m$ and $T^s_\infty, m \models \varphi^s$ iff $T^s_\infty, n \models s \wedge \exists X \varphi^s$ iff $T^s_\infty \models (\downarrow)\varphi^s$.

- $\theta = (\psi^+)\varphi$. We have $T, n \models (\psi^+)\varphi$ iff there exists $m \in N$ such that $T, m \models \varphi$ and for all $n' \in N$ with $nE^+ n' E^+ m$ it holds $T, n' \models \psi$. Then by the induction hypothesis, (*) and (**), the latter is equivalent to existence of $m \in N_\infty$ such that $T^s_\infty, m \models \varphi^s$ and for all $n' \in N_\infty$ with $nE^+_\infty n' E^+_\infty m$ it holds $T^s_\infty \models \psi^s$. The latter implication holds because for every node $n'$ with $nE^+_\infty n' E^+_\infty m$ it holds $n' \in N$ and $nE^+ n' E^+ m$. Equivalently, there exists $n_1 \in N_\infty$ and $m \in N_\infty$ such that $nE_\infty n_1 E^+_\infty m$, $T^s_\infty, m \models \varphi^s$ and for all $n'$ with $n_1 E^+_\infty n' E^+_\infty m$ it holds $T^s_\infty, n' \models \psi^s$. This is equivalent to $T^s_\infty, n \models s \wedge \exists X \exists \psi^s \psi \varphi^s$ as desired.

Thus, we obtain both $T^s_\infty, n \models \varphi^s$ and $T^s_\infty, n \not\models \psi^s$.

For the other direction, let $T_\infty, n = (N_\infty, E_\infty, r, \rho_\infty)$ be some infinite tree over $\Sigma$ such that $T_\infty, r \models \varphi^s$ and $T_\infty, r \not\models \psi^s$. We then remove from the model all nodes without $s$ and their descendants. Formally, $T = (N, E, r, \rho)$, where $N = N_\infty \setminus \{n \mid \exists n' \in N_\infty, s \notin \rho_\infty(n') \wedge n' E^+_\infty n\}$ is the set of nodes, $E = E_\infty \setminus N \times N$ is the set of edges, $r$ is the root, and $\rho(n) = \rho_\infty(n)$ is the labeling function.

By induction we can show that for every CTP formula $\theta$ and node $n \in N$, it holds $T_\infty, n \models \theta^s$ if and only if $T, n \models \theta^s$. The two non-trivial cases are the following.

- $\theta = (\downarrow)\varphi$. We have $T_\infty, n \models s \wedge \exists X \varphi^s$ iff $T_\infty, n \models s$ and there exists $m \in N_\infty$ such that $nE_\infty m$ and $T_\infty, m \models \varphi^s$ iff $T, n \models s$ and there exists $m \in N$ such that $nEm$ and $T, m \models \varphi^s$. The direction from right to left is obvious, while
the direction from left to right because of the following. Since $T_\infty, m \models \varphi^s$, it follows that $T_\infty, m \models s$, i.e. $s \in \rho_\infty(m)$. Then since $n \in N$, we have that $m \in N$ too by the definition. The latter also implies that $nEm$ holds in $T$ and thus that $T, n \models s \land \exists X \varphi^s$.

- $\theta = (\psi^+)\varphi$. We have $T_\infty, n \models s \land \exists X \exists \psi^sU \varphi^s$ iff $T_\infty, n \models s$ and there exists $m \in N_\infty$ such that $T_\infty, m \models \varphi^s, nE^\infty_\infty m$ and for all $n' \in N_\infty$ with $nE^\infty_\infty n'E^\infty_\infty m$ it holds $T_\infty, n' \models \psi^s$. This is equivalent to $T, n \models s$ and there exists $m \in N$ such that $T, m \models \varphi^s$ and for all $n'$ with $nE^+ n'E^+ m$ it holds $T, m \models \psi^s$, which means $T, n \models s \land \exists X \exists \psi^sU \varphi^s$ as desired. The direction from left to write is trivial since $T$ is a substructure of $T_\infty$. The direction from right to left follows from the fact that $m \in N$ and all the nodes $n'$ such that $nE^+ n'E^+ m$ belong to $N$ as well and, moreover, it holds $nE^+ n'E^+ m$.

Thus, we obtain that $T, r \models \varphi^s$ and $T, r \nvdash \psi^s$. Because all nodes of $T$ now make $s$ true, we can discard the relativization with $s$ in the formulas. Thus obtaining $T, r \models \varphi$ and $T, r \nvdash \psi$. The only problem is that $T$ is infinite. But using the simulations from Theorem 5.3.3 it is easy to see that we can turn $T$ into a finite counterexample.

Thus, we have shown that $\varphi \subseteq \psi$ if and only if $\varphi^s \subseteq_\infty \psi^s$. The latter containment problem in $\exists$CTL is known to be decidable in PS

**Corollary 5.4.1.** The containment problem for $TP^\neg$ is PSPACE complete.

However, restricting negation to a safe negation $p \land \neg q_1 \land \ldots \land \neg q_n$ keeps the complexity of the containment problem for tree patterns in $\text{CONP}$. Note that $p \land \neg q_1 \land \ldots \land \neg q_n$ only adds expressive power over multi-labeled models, because on single labeled models $p \equiv p \land \neg q_1 \land \ldots \land \neg q_n$. The proof of the following result can be found in Chapter 3 and (Marx and Sherkhonov, 2015). Here $TP^{\forall \land \neg^s}$ is tree patterns expanded with disjunction and the safe negation construct.

**Theorem 5.4.4.** The containment problem for $TP^{\forall \land \neg^s}$ over multi-labeled trees is in $\text{CONP}$.

### 5.5 Conclusion

We have shown that adding conditions on the edges of tree patterns gives a boost in expressive power which comes with the price of a higher – PSPACE – complexity for the containment problem than for tree patterns. We located the source of the extra complexity in the fact that unrestricted negations of labels can be coded in Conditional Tree Patterns. Adding negations of labels to tree patterns causes an increase in complexity of the containment problem from $\text{CONP}$ to PSPACE. In Chapter 3 we showed that if negation is restricted to be safe, then containment for PosXPath and CQ stays in $\text{CONP}$ and $\Pi_2^P$, respectively. In Chapter 4 we show that containment for child-only tree patterns with label negation is solvable in PTIME.

This work is a first step in exploring “Regular Tree Patterns” and fragments of it. We mention some directions for future work.
Miklau and Suciu (2004) mention that the existence of a homomorphism between tree patterns is a necessary but not sufficient condition for containment in TP. Can we extend the simulations between conditional tree patterns and trees to simulations between queries, partly capturing containment as for tree patterns?

What is the complexity of containment of regular tree patterns, i.e., the positive fragment of Regular XPath without disjunction and union? As the satisfiability (and thus also the containment) problem for Regular XPath is known to be ExpTime-complete, it must lie in between PSPACE and ExpTime.

There are also interesting characterization questions: what is the exact FO fragment corresponding to CTP or CTP with disjunction and union? ten Cate (2006) showed that full Regular XPath (with all four axis relations) expanded with path equalities is equally expressive as binary FO* (First-order logic extended with a transitive closure operator that can be applied to formulas with exactly two free variables). Is every positive forward binary FO* formula expressible as a Regular Tree Pattern? Is CTP with disjunction and union equally expressive as FO intersected with positive FO*? Are unions of CTP equivalent to unions of the first order fragment of conjunctive regular path queries (Calvanese et al., 2000)?

5. A Translations between CTP and ctp

The following constructions are similar to the tree and graph representations for tree patterns and conjunctive queries over trees (Björklund et al., 2011; Miklau and Suciu, 2004)

We define the translation function \( c(\cdot) \) which assigns an equivalent conditional tree pattern with one output node to every CTP formula. The output node of \( c(\varphi) \), where \( \varphi \) is a node formula, equals the root.

Let \( \alpha \) and \( \varphi \) be path and node CTP formulas. We define \( c(\alpha) \) and \( c(\varphi) \) by mutual induction on the complexity of the path and node formulas. We take \( c(\alpha) \) or \( c(\varphi) \) to be the tree \( (N, E, r, o, \rho_N, \rho_E) \), where the components are defined according to the cases.

- \( \alpha = \downarrow. \) Then \( N \) consists of two nodes \( r \) and \( n \). The edge relation \( E \) is defined as \( \{ \langle r, n \rangle \} \). Moreover, \( o := n \), \( \rho_N(v) = \emptyset \) for \( v \in \{ r, n \} \) and \( \rho_E(\langle r, n \rangle) = \downarrow \).
- \( \alpha = ?\varphi. \) Then \( c(\alpha) := c(\varphi) \).
- \( \alpha = \alpha_1; \alpha_2. \) Let \( c(\alpha_1) \) and \( c(\alpha_2) \) be the conditional tree patterns for \( \alpha_1 \) and \( \alpha_2 \). Then \( c(\alpha) \) is the tree obtained as follows. We fuse the root of \( c(\alpha_2) \) with the output node of \( c(\alpha_1) \) and declare the output node of \( c(\alpha_2) \) as the output node of \( c(\alpha) \). The label of the fusion node is the union of the labels of the output node of \( c(\alpha_1) \) and the root of \( c(\alpha_2) \). Labels of other nodes and the edges remain the same as in \( c(\alpha_1) \) and \( c(\alpha_2) \).
- \( \alpha = (\downarrow; ?\varphi)^*; \downarrow. \) Then \( N \) consist of two nodes \( r \) and \( n \). The edge relation \( E \) is defined as \( \{ \langle r, n \rangle \} \). Moreover, \( o := n \), \( \rho_N(v) = \emptyset \) for \( v \in \{ r, n \} \) and \( \rho_E(\langle r, n \rangle) = c(\varphi) \).

For node formulas, the output node of the translation result is always defined as the root \( r \).
• \( \varphi = p \). Then \( N \) consists of a single node \( r \), \( E \) is empty, the labeling \( \rho_N(r) = \{ p \} \).

• \( \varphi = \top \). Similar to the previous case, with the exception that \( \rho_N(r) = \emptyset \)

• \( \varphi = \varphi_1 \land \varphi_2 \). Then \( c(\varphi) := c(\varphi_1) \oplus c(\varphi_2) \), i.e. the fusion of the conditional tree patterns \( c(\varphi_1) \) and \( c(\varphi_2) \).

• \( \varphi = (\alpha)\varphi_1 \). Let \( c(\alpha) \) and \( c(\varphi_1) \) be the corresponding conditional tree patterns. Then \( c(\varphi) \) is obtained by fusing the output node of \( c(\alpha) \) with the root of \( c(\varphi) \). The labeling of the fusion node is defined as the union of the labels of the root of \( c(\varphi) \) and the output node of \( c(\alpha) \). Labels of the other nodes and edges remain the same as in \( c(\alpha) \) and \( c(\varphi) \).

Translation \( f(\cdot) \) works the other way around. Let \( t = (N, E, r, o, \rho_N, \rho_E) \) be a conditional tree pattern with one output node. We define \( f(t) \) by induction on the nesting depth and the depth of the tree. We first define a mapping \( \varphi \) from nodes \( v \in N \) to CTP node formulas. The mapping is defined inductively starting from the leaves as follows. Here, for a finite set \( S = \{p_1, \ldots, p_n\} \), by \( \bigwedge S \) we denote the finite conjunction \( p_1 \land \ldots \land p_n \). We take \( \bigwedge \emptyset \) to be \( \top \). For a conditional tree pattern \( t \), by \( r_t \) we denote the root of \( t \). For \( v \) a node in pattern \( t \):

\[
\varphi(v) = \land \rho_N(v) \land \\
\land_{\langle v, v' \rangle \in E, \rho_E(v, v') = t'} \langle ?\varphi(r_{v'}) \rangle \varphi(v') \land \\
\land_{\langle v, v' \rangle \in E, \rho_E(v, v') = \downarrow} \langle \downarrow \rangle \varphi(v')
\]

Now let \( r = v_1, \ldots, v_n = o \) be the path from the root \( r \) to the output node \( o \) in \( t \). Let the expression \( d_i, 1 \leq i \leq n - 1 \) be defined by: \( d_i = \downarrow \) if \( \rho_E(v_i, v_{i+1}) = \downarrow \) and \( d_i = (\downarrow \langle ?\varphi(r_{v'}) \rangle)^*; \downarrow \) if \( \rho_E(v_i, v_{i+1}) = t' \). Then the result of the translation \( f(t) \) of the conditional tree pattern \( t \) is the CTP path formula:

\[\langle ?\varphi(v_1); d_1; ?\varphi(v_2); d_2; \ldots; ?\varphi(v_{n-1}); d_{n-1}; ?\varphi(v_n) \rangle.\]

For the next proposition we need the definition of equivalence between conditional tree patterns. Let \( t \) be a conditional tree pattern with output nodes \( \bar{o}, |\bar{o}| = k \), and \( T \) a tree. Then the answer set of \( t \) over \( T \) is the set \( Out(t, T) = \{ \langle g(o_1), \ldots, g(o_k) \rangle \mid g \text{ is a simulation of } t \text{ in } T \} \). We say that two conditional tree patterns \( t_1 \) and \( t_2 \) are equivalent, denoted as \( t_1 \simeq t_2 \), if \( Out(t_1, T) = Out(t_2, T) \) for every tree \( T \).

**Proposition 5.A.1.** Let \( \varphi \) and \( \alpha \) be CTP node and path formulas, \( t \) a conditional tree pattern. Then it holds that

(i) \( f(c(\varphi)) \equiv \varphi \) and \( f(c(\alpha)) \equiv \alpha \),

(ii) \( c(f(t)) \simeq t \).

The proof of (i) is by mutual induction on \( \alpha \) and \( \varphi \), and the proof of (ii) is by induction on nesting depth and depth of \( t \).
Part II

Application: Why-not Explanations
In this chapter we propose a foundational framework for *why-not explanations*, that is, explanations for why a tuple is missing from a query result. Our why-not explanations leverage concepts from an ontology to provide high-level and meaningful reasons for why a tuple is missing from the result of a query.

A key algorithmic problem in our framework is that of *computing a most-general explanation* for a why-not question, relative to an ontology, which can either be provided by the user, or it may be automatically derived from the data and/or schema. We study the complexity of this problem and associated problems, and present concrete algorithms for computing why-not explanations, thus addressing RQ 4. In the case where an external ontology is provided, we first show that the problem of deciding the existence of an explanation to a why-not question is NP-complete in general. However, the problem is solvable in polynomial time for queries of bounded arity, provided that the ontology is specified in a suitable language, such as a member of the DL-Lite family of description logics, which allows for efficient concept subsumption checking. Furthermore, we show that a most-general explanation can be computed in polynomial time in this case. In addition, we address RQ 3 by proposing a method for deriving a suitable (virtual) ontology from a database and/or a schema. We will show that this is the same as solving the containment problem. Thus, the framework proposed here can be seen as a use case for the containment problem.

We also present an algorithm for computing a most-general explanation to a why-not question, relative to such derived ontologies. This algorithm runs in polynomial-time in the case when concepts are defined in a selection-free language or if the underlying schema is fixed. Finally, we also study the problem of computing short most-general explanations, and we briefly discuss alternative definitions of what it means to be an explanation, and to be most general.

### 6.1 Introduction and results

An increasing number of databases are derived, extracted, or curated from disparate data sources. Consequently, it becomes more and more important to provide data consumers with mechanisms that will allow them to gain an understanding of the data that they are
confronted with. An essential functionality towards this goal is the capability to provide
meaningful explanations about why data is present or missing from the result of a query.
Explanations help data consumers gauge how much trust one can place on the result.
Perhaps more importantly, they provide useful information for debugging the query or
data that led to incorrect results.

This is particularly the case in scenarios where complex data analysis tasks are speci-
fied through large collections of nested views (i.e., views that may be defined in terms of
other views). For example, schemas with nested view definitions and integrity constraints
capture the core of LogiQL (Green, 2015; Green et al., 2012; Halpin and Rugaber, 2014)
(where view definitions may, in general, involve not only relational operations, but also
aggregation, machine learning and mathematical optimization tasks). LogiQL is a lan-
guage developed and used at LogicBlox (Aref et al., 2015) for developing data-intensive
“self service” applications involving complex data analytics workflows. Similar recent
industrial systems include Datomic\(^1\) and Google’s Yedalog (Chin et al., 2015). In each
of these systems, nested view definitions (or, Datalog programs) are used to specify com-
plex workflows to drive data-analytics tasks. Explanations for unexpected query results
(such as an unexpected tuple or a missing tuple) are very useful in such settings, since
the source of an error can be particularly hard to track.

There has been considerable research on the topic of deriving explanations for why
a tuple belongs to the output of a query. Early systems were developed in (Arora et al.,
1993; Shmueli and Tsur, 1990) to provide explanations for answers to logic programs in
the context of a deductive database. The presence of a tuple in the output is explained by
enumerating all possible derivations, that is, instantiations of the logic rules that derive
the answer tuple. In (Shmueli and Tsur, 1990), the system also explains missing answers,
by providing a partially instantiated rule, based on the missing tuple, and leaving the user
to figure out how the rest of the rule would have to be instantiated. In the last decade or
so, there have been significant efforts to characterize different notions of provenance (or
lineage) of query answers (see, e.g., (Cheney et al., 2009; Green et al., 2007b)) which
can also be applied to understand why an answer is in the query result. More details on
this can be found in Chapter 2.

There have also been extensive studies on the why-not problem (e.g., more recent
studies include (Baid et al., 2015; Chapman and Jagadish, 2009; Herschel et al., 2009;
Huang et al., 2008a; Meliou et al., 2010; Tran and Chan, 2010)). The why-not problem
is the problem of explaining why an answer is missing from the output. Since (Shmueli
and Tsur, 1990), the why-not problem was also studied in (Herschel et al., 2009; Huang
et al., 2008a) in the context of debugging results of data extracted via select-project-join
queries, and, subsequently, a larger class of queries that also includes union and aggre-
gation operators. Unlike (Shmueli and Tsur, 1990) which is geared towards providing
explanations for answers and missing answers, the goal in (Huang et al., 2008a) is to
propose modifications to underlying database \( I \), yielding another database \( I' \) based on
the provenance of the missing tuple, constraints, and trust specification at hand, so that
the missing tuple appears in the result of the same query \( q \) over the updated database
\( I' \). In contrast to the data-centric approach of updating the database to derive the miss-
ing answer, another line of research (Bidoit et al., 2014a; Chapman and Jagadish, 2009;
Tran and Chan, 2010) follows a query-centric approach whereby the query \( q \) at hand is

\(^1\)www.datomic.com
modified to \( q' \) (without modifying the underlying database) so that the missing answer appears in the output of \( q'(I) \). More details can be found in Chapter 2.

**A new take on why-not questions**

In this chapter, we develop a novel foundational framework for why-not explanations that is principally different from prior approaches. Our approach is neither data-centric nor query-centric. Instead, we derive high-level explanations via an ontology that is either provided, or is derived from the data or schema. Our immediate goal is not to compute repairs of the underlying database or query so that the missing answer would appear in the result. Rather, as in (Shmueli and Tsur, 1990), our primary goal is to provide understandable explanations for why an answer is missing from the query result. As we will illustrate, explanations that are based on an ontology have the potential to be high-level and provide meaningful insight to why a tuple is missing from the result. This is because an ontology abstracts a domain in terms of concepts and relationships amongst concepts. Hence, explanations that are based on concepts and relationships from an ontology will embody such high-level abstractions. As we shall describe, our work considers two cases. The first is when an ontology is provided externally, in which case explanations will embody external knowledge about the domain. The second is when an ontology is not provided. For the latter, we allow an ontology to be derived from the schema, and hence explanations will embody knowledge about the domain through concepts and relationships that are defined over the schema.

Formally, an explanation for why a tuple \( \bar{\sigma} \) is not among the results of a query \( q(I) \), in our framework, is a tuple of concepts from the ontology whose extension includes the missing tuple \( \bar{\alpha} \) and, at the same time, does not include any tuples from \( q(I) \). For example, a query may ask for all products that each store has in stock, in the form of \((\text{product ID}, \text{store ID})\) pairs, from the database of a large retail company. A user may then ask why is the pair \((P0034, S012)\) not among the result of the query. Suppose \( P0034 \) refers to a bluetooth headset product and \( S012 \) refers to a particular store in San Francisco. If \( P0034 \) is an instance of a concept \text{bluetooth headsets} and \( S012 \) is an instance of a concept \text{stores in San Francisco}, and suppose that no pair \((x,y)\), where \( x \) is an instance of \text{bluetooth headset} and \( y \) is an instance of \text{stores in San Francisco}, belongs to the query result. Then the pair of concepts \((\text{bluetooth headset, stores in San Francisco})\) is an explanation for the given why-not question. Intuitively, it signifies the fact that “none of the stores in San Francisco has any bluetooth headsets on stock”.

There may be multiple explanations for a given why-not question. In the above example, this would be the case if, for instance, \( S012 \) belongs also to a more general concept \text{stores in California}, and that none of the stores in California have bluetooth headsets on stock. Our goal is to compute a most-general explanation, that is, an explanation that is not strictly subsumed by any other explanation. We study the complexity of computing a most-general explanation to a why-not question. Formally, we define a why-not instance (or, why-not question) to be a quintuple \((S, I, q, Ans, \bar{\alpha})\) where \( S \) is a schema, which may include integrity constraints; \( I \) is an instance of \( S \); \( q \) is a query over \( S \); \( Ans = q(I) \); and \( \bar{\alpha} \not\in q(I) \).

As mentioned earlier, a particular scenario where why-not questions easily arise is when querying schemas that include a large collection of views, and where each view
may be nested, that is, defined in terms of other views. Our framework captures this setting, since view definitions can be expressed by means of constraints.

Our framework supports a very general notion of an ontology, which we call S-ontologies. For a given relational schema S, an S-ontology is a triple \((C, \sqsubseteq, \text{ext})\) that defines the set of concepts, the subsumption relationship between concepts, and respectively, the extension of each concept w.r.t. an instance of the schema S. We use this general notion of an S-ontology to formalize the key notions of explanation and most-general explanation, and we show that S-ontologies capture two different types of ontologies.

The first type of ontologies we consider are those that are defined externally, provided that there is a way to associate the concepts in the externally defined ontology to the instance at hand. For example, the ontology may be represented in the form of an Ontology-Based Data Access (OBDA) specification (Poggi et al., 2008). More precisely, an OBDA specification consists of a set of concepts and subsumption relation specified by means of a description logic terminology, and a set of mapping assertions that relates the concepts to a relational database schema at hand. Every OBDA specification induces a corresponding S-ontology. If the concepts and subsumption relation are defined by a TBox in a tractable description logic such as DL-Lite\(R_x\), and the mapping assertions are Global-As-View (GAV) assertions, the induced S-ontology can in fact be computed from the OBDA specification in polynomial time. We present an algorithm for computing most-general explanations to a why-not question, given an external S-ontology. The algorithm runs in polynomial time when the arity of the query is bounded, and it executes in exponential time in general. We show that the exponential running time is unavoidable, unless \(P=NP\), because the problem of deciding whether or not there exists an explanation to a why-not question given an external S-ontology is NP-complete in general.

The second type of ontologies that we consider are ontologies that are derived either (a) from a schema S, or (b) from an instance of the schema. In both cases, the concepts of the ontology are defined through concept expressions in a suitable language \(L_S\) that we develop. Specifically, our concepts are obtained from the relations in the schema, through selections, projections, and intersections. The difference between the two cases (a) and (b) lies in the way the subsumption relation \(\sqsubseteq\) is defined. In the former, a concept \(C\) is considered to be subsumed by another concept \(C'\) if the extension of \(C\) is contained in the extension of \(C'\) over all instances of the schema. For the latter, subsumption is considered to hold if the extension of \(C\) is contained in the extension of \(C'\) with respect to the given instance of the schema. The S-ontology induced by a schema S, or instance I, denoted \(O_S\) or \(O_I\), respectively, is typically infinite, and is not intended to be materialized. Instead, we present an algorithm for directly computing a most-general explanation with respect to \(O_I\). The algorithm runs in exponential time in general. However, if the schema is of bounded arity, the algorithm runs in polynomial time. As for computing most-general explanations with respect to \(O_S\), we identify restrictions on the integrity constraints under which the problem is decidable, and we present complexity upper bounds for these cases.
6.2 Preliminaries

More related work

The use of ontologies to facilitate access to databases is not new. A prominent example is OBDA, where queries are either posed directly against an ontology, or an ontology is used to enrich a data schema against which queries are posed with additional relations (namely, the concepts from the ontology) (Bienvenu et al., 2013; Poggi et al., 2008). Answers are computed based on an open-world assumption and using the mapping assertions and ontology provided by the OBDA specification. As we described above, we make use of OBDA specifications as a means to specify an external ontology and with a database instance through mapping assertions. However, unlike in OBDA, we consider queries posed against a database instance under the traditional closed-world semantics, and the ontology is used only to derive why-not explanations.

The problems of providing why explanations and why-not explanations have also been investigated in the context of OBDA in (Borgida et al., 2008) and (Calvanese et al., 2013), respectively. The why-not explanations of (Calvanese et al., 2013) follow the data-centric approach to why-not provenance as we discussed earlier where their goal is to modify the assertions that describe the extensions of concepts in the ontology so that the missing tuple will appear in the query result.

There has also been prior work on extracting ontologies from data. For example, in (Lubyte and Tessaris, 2009), the authors considered heuristics to automatically generate an ontology from a relational database by defining project-join queries over the data. Other examples on ontology extraction from data include publishing relational data as RDF graphs or statements (e.g., D2RQ (Bizer and Seaborne, 2004), Triplify (Auer et al., 2009)). We emphasize that our goal is not to extract and materialize ontologies, but rather, to use an ontology that is derived from data to compute why-not explanations.

Organization

After the preliminaries, in Section 6.3 we present our framework for why-not explanations. In Section 6.4 we discuss in detail the two ways of obtaining an S-ontology. In Section 6.5 we present our main algorithmic results. Finally, in Section 6.6, we study variations of our framework, including the problem of producing short most-general explanations, and alternative notions of explanation, and of what it means to be most general.

6.2 Preliminaries

A schema is a pair \((S, \Sigma)\), where \(S\) is a set \(\{R_1, \ldots, R_n\}\) of relation names, where each relation name has an associated arity, and \(\Sigma\) is a set of first-order sentences over \(S\), which we will refer to as integrity constraints. Abusing the notation, we will write \(S\) for the schema \((S, \Sigma)\). A fact is an expression of the form \(R(b_1, \ldots, b_k)\), where \(R \in S\) is a relation of arity \(k\), and for \(1 \leq i \leq k\), we have \(b_i \in \text{Const}\), where \(\text{Const}\) is a countably infinite set of constants. We assume a dense linear order \(<\) on \(\text{Const}\). An attribute \(A\) of an \(k\)-ary relation name \(R \in S\) is a number \(i\) such that \(1 \leq i \leq k\). For a fact \(R(\bar{b})\) where \(\bar{b} = b_1, \ldots, b_k\), we sometimes write \(\pi_{A_1, \ldots, A_k}(\bar{b})\) to mean the tuple \((b_{A_1}, \ldots, b_{A_k})\). An
atom over $S$ is an expression $R(x_1, \ldots, x_n)$, where $R \in S$ and every $x_i, i \in \{1, \ldots, n\}$ is a variable or a constant.

A database instance, or simply an instance, $I$ over $S$ is a set of facts over $S$ satisfying the integrity constraints $\Sigma$. Equivalently, an instance $I$ is a map that assigns to each $k$-ary relation name $R \in S$ a finite set of $k$-tuples over $\text{Const}$ such that the integrity constraints are satisfied. By $R^I$ we denote the set of these tuples. We write $\text{Inst}(S)$ to denote the set of all database instances over $S$, and $\text{adom}(I)$ to denote the active domain of $I$, i.e., the set of all constants occurring in facts of $I$.

Queries A conjunctive query (CQ) over $S$ is a query of the form $\exists y. \varphi(x, y)$ where $\varphi$ is a conjunction of atoms over $S$. Given an instance $I$ and a CQ $q$, we write $q(I)$ to denote the set of answers of $q$ over $I$. We allow conjunctive queries containing comparisons to constants, that is, comparisons of the form $x \text{ op } c$, where $\text{op} \in \{=, <, >, \leq, \geq\}$ and $c \in \text{Const}$. We show that all upper bounds hold for the case of CQs with such comparisons, and all lower bounds hold without the use of comparisons (unless explicitly specified otherwise). We do not allow comparisons between variables.

Integrity constraints We consider different classes of integrity constraints, including functional dependencies and inclusion dependencies. We also consider UCQ-view definitions and nested UCQ-view definitions, which can be expressed using integrity constraints as well.

A functional dependency (FD) on a relation $R \in S$ is an expression of the form $R : X \rightarrow Y$ where $X$ and $Y$ are subsets of the set of attributes of $R$. We say that an instance $I$ over $S$ satisfies the FD if for every $\bar{a}_1$ and $\bar{a}_2$ from $R^I$ if $\pi_A(\bar{a}_1) = \pi_A(\bar{a}_2)$ for every $A \in X$, then $\pi_B(\bar{a}_1) = \pi_B(\bar{a}_2)$ for every $B \in Y$.

An inclusion dependency (ID) is an expression of the form

$$R[A_1, \ldots, A_n] \subseteq S[B_1, \ldots, B_n],$$

where $R, S \in S$, each $A_i$ and $B_j$ is an attribute of $R$ and $S$ respectively. We say that an instance $I$ over $S$ satisfies the ID if

$$\{\pi_{A_1, \ldots, A_n}(\bar{a}) \mid \bar{a} \in R^I\} \subseteq \{\pi_{B_1, \ldots, B_n}(\bar{b}) \mid \bar{b} \in S^I\}.$$

Note that functional and integrity constraints can equivalently be written as first-order sentences (Abiteboul et al., 1995).

View Definitions To simplify our presentation, we treat view definitions as a special case of integrity constraints.

A set of integrity constraints $\Sigma$ over $S$ is said to be a collection of UCQ-view definitions if there exists a partition $S = D \cup V$ such that for every $P \in V$, $\Sigma$ contains exactly one first-order sentence of the form:

$$P(\bar{x}) \leftrightarrow \bigvee_{i=1}^{k} \varphi_i(\bar{x}),$$

where each $\varphi_i$ is a conjunctive query (with comparisons to constants) over $D$.

Similarly, a set of integrity constraints $\Sigma$ over $S$ is said to be a collection of nested UCQ-view definitions if there exists a partition $S = D \cup V$ such that for every $P \in V$, $\Sigma$
6.3. Why-not explanations

Data schema $D$ :

\{ Cities(name, population, country, continent),
    Train-Connections(city_from, city_to) \}

View schema $V$ :

\{ BigCity(name), EuropeanCountry(name),
    Reachable(city_from, city_to) \}

UCQ-view definitions:

BigCity($x$) $\leftrightarrow$ Cities($x$, $y$, $z$, $w$) $\land$ $y \geq 5000000$
EuclideanCountry($z$) $\leftrightarrow$ Cities($x$, $y$, $z$, $w$) $\land$ $w = \text{Europe}$
Reachable($x$, $y$) $\leftrightarrow$ Train-Connections($x$, $y$) $\lor$
    (Train-Connections($x$, $z$) $\land$ Train-Connections($z$, $y$))

Functional and inclusion dependencies:

country $\rightarrow$ continent
BigCity[name] $\subseteq$ Train-Connections[city_from]
Train-Connections[city_from] $\subseteq$ Cities[name]
Train-Connections[city_to] $\subseteq$ Cities[name]

Figure 6.1: Example of a schema $S$.

contains exactly one first-order sentence of the form (*), where each $\varphi_i$ is now allowed

to be a conjunctive query over $D \cup V$, but subject to the following acyclicity condition.

Let us say that $P \in V$ depends on $R \in V$, if $R$ occurs in the view definition of $P$, that

is, in the sentence of $\Sigma$ that is of the form (*) for $P$. We require that the “depends on”

relation is acyclic. If, in the view definition of every $P \in V$, each disjunct $\varphi_i$ contains at

most one atom over $V$, then we say that $\Sigma$ is a collection of linearly nested UCQ-view

definitions.

Note that a collection of nested UCQ-view definitions (in the absence of comparisons)

can be equivalently viewed as a non-recursive Datalog program and vice versa (Benedikt

and Gottlob, 2010). In particular, a collection of linearly nested UCQ-view definitions

corresponds to a linear non-recursive Datalog program.

Example 6.2.1. As an example of a schema, consider $S = D \cup V$ with the integrity

constraints in Figure 6.1. An instance $I$ of the schema $S$ is given in Figure 6.2.  

6.3 Why-not explanations

Next, we introduce our ontology-based framework for explaining why a tuple is not in

the output of a query. Our framework is based on a general notion of an ontology. As we

shall describe in Section 6.4, the ontology that is used may be an external ontology (for

example, an existing ontology specified in a description logic), or it may be an ontology

that is derived from a schema. Both are a special case of our general definition of an

$S$-ontology.

Definition 6.3.1 ($S$-ontology). An $S$-ontology over a relational schema $S$ is a triple

$O = (C, \sqsubseteq, ext)$, where

- $C$ is a possibly infinite set, whose elements are called concepts,
• $\sqsubseteq$ is a pre-order (i.e., a reflexive and transitive binary relation) on $C$, called the subsumption relation, and

• $\text{ext} : C \times \text{Inst}(S) \rightarrow \wp(\text{Const})$ is a polynomial-time computable function that will be used to identify instances of a concept in a given database instance ($\wp(\text{Const})$ denotes the powerset of $\text{Const}$).

More precisely, we assume that $\text{ext}$ is specified by a Turing machine that, given $C \in C$, $I \in \text{Inst}(S)$ and $c \in \text{Const}$, decides in polynomial time if $c \in \text{ext}(C, I)$.

A database instance $I \in \text{Inst}(S)$ is consistent with $\mathcal{O}$ if, for all $C_1, C_2 \in C$ with $C_1 \sqsubseteq C_2$, we have $\text{ext}(C_1, I) \subseteq \text{ext}(C_2, I)$.

An example of an S-ontology $\mathcal{O} = (C, \sqsubseteq, \text{ext})$ is shown in Figure 6.3, where the concept subsumption relation $\sqsubseteq$ is depicted by means of a Hasse diagram. Note that, in this example, $\text{ext}(C, I)$ is independent of the database instance $I$ (and, as a consequence, every S-instance is consistent with $\mathcal{O}$). In general, this is not the case (for example, the extension of a concept may be determined through mapping assertions, cf. Section 6.4.1).

We define our notion of an ontology-based explanation next.

**Definition 6.3.2 (Explanation).** Let $\mathcal{O} = (C, \sqsubseteq, \text{ext})$ be an S-ontology, $I$ an S-instance consistent with $\mathcal{O}$. Let $q$ be an $m$-ary query over $S$, and $\overline{a} = \langle a_1, \ldots, a_m \rangle$ a tuple of constants such that $\overline{a} \not\in q(I)$. Then a tuple of concepts $(C_1, \ldots, C_m)$ from $C^m$ is called an explanation for $\overline{a} \not\in q(I)$ with respect to $\mathcal{O}$ (or an explanation in short) if:

• for every $1 \leq i \leq m$, $a_i \in \text{ext}(C_i, I)$, and

• $(\text{ext}(C_1, I) \times \ldots \times \text{ext}(C_m, I)) \cap q(I) = \emptyset$.

6.3. Why-not explanations

In other words, an explanation is a tuple of concepts whose extension includes the missing tuple \( \bar{a} \) (and thus explains \( \bar{a} \)) but, at the same time, it does not include any tuple in \( q(I) \) (and thus does not explain any tuple in \( q(I) \)). Intuitively, the tuple of concepts is an explanation that is orthogonal to existing tuples in \( q(I) \) but relevant for the missing tuple \( \bar{a} \), and thus forms an explanation for why \( \bar{a} \) is not in \( q(I) \). There can be multiple explanations in general and the “best” explanations are the ones that are the most general.

**Definition 6.3.3 (Most-general explanation).** Let \( O = (C, \sqsubseteq, ext) \) be an S-ontology, and let \( E = (C_1, \ldots, C_m) \) and \( E' = (C'_1, \ldots, C'_m) \) be two tuples of concepts from \( C^m \).

- We say that \( E \) is less general than \( E' \) with respect to \( O \), denoted as \( E \leq_O E' \), if \( C_i \sqsubseteq C'_i \) for every \( i, 1 \leq i \leq m \).
- We say that \( E \) is strictly less general than \( E' \) with respect to \( O \), denoted as \( E <_O E' \), if \( E \leq_O E' \), and \( E' \not\leq_O E \).
- We say that \( E \) is a most-general explanation for \( \bar{a} \not\in q(I) \) if \( E \) is an explanation for \( \bar{a} \not\in q(I) \), and there is no explanation \( E' \) for \( \bar{a} \not\in q(I) \) such that \( E' >_O E \).

As we will formally define in Section 6.5, a why-not problem asks the question: “why is the tuple \( \langle a_1, \ldots, a_m \rangle \) not in the output of a query \( q \) over an instance \( I \) of schema \( S \)?” The following example illustrates the notions of explanations and most-general explanations in the context of a why-not problem.

**Example 6.3.1.** Consider the instance \( I_D \) of the relational schema \( S = \{ \text{Cities}(\text{name, population, country, continent}), \text{Train-Connections}(\text{city_from, city_to}) \} \) shown in Figure 6.2.

Suppose \( q \) is the query \( \exists z. \text{Train-Connections}(x, z) \land \text{Train-Connections}(z, y) \). That is, the query asks for all pairs of cities that are connected via a city. Then \( q(I) \) returns tuples

\[
\{ \langle \text{Amsterdam, Rome} \rangle, \langle \text{Amsterdam, Amsterdam} \rangle, \\
\langle \text{Berlin, Berlin} \rangle, \langle \text{New York, Santa Cruz} \rangle \}.
\]

A user may ask why is the tuple \( \langle \text{Amsterdam, New York} \rangle \) not in the result of \( q(I) \) (i.e., why is \( \langle \text{Amsterdam, New York} \rangle \not\in q(I) \) ?). Based on the S-ontology defined in Figure 6.3, we can derive the following explanations for \( \langle \text{Amsterdam, New York} \rangle \not\in q(I) \):

\[
E_1 = \langle \text{Dutch-City, East-Coast-City} \rangle \\
E_2 = \langle \text{Dutch-City, US-City} \rangle \\
E_3 = \langle \text{European-City, East-Coast-City} \rangle \\
E_4 = \langle \text{European-City, US-City} \rangle
\]

\( E_1 \) is the simplest explanation, i.e., the one we can build by looking at the lower level of the hierarchy in our S-ontology. Each subsequent explanation is more general than at least one of the prior explanations w.r.t. the S-ontology. In particular, we have \( E_4 >_O E_2 >_O E_1 \), and \( E_4 >_O E_3 >_O E_1 \). Thus, the most-general explanation for why \( \langle \text{Amsterdam, New York} \rangle \not\in q(I) \) w.r.t. our S-ontology is \( E_4 \), which intuitively informs that the reason is because Amsterdam is a city in Europe while New York is a city in the US (and hence, they are not connected by train). Note that all the other possible combinations of concepts are not explanations because they intersect with \( q(I) \).
As we will see in Example 6.4.3, there may be more than one most-general explanations in general.

Generalizing the above example, we can informally define the problem of explaining why-not questions via ontologies as follows: given an instance $I$ of schema $S$, a query $q$ over $S$, an $S$-ontology $O$ (consistent with $I$) and a tuple $\overline{a} \notin q(I)$, compute a most-general explanation for $\overline{a} \notin q(I)$, if one exists, w.r.t. $O$. As we shall describe in Section 6.5, in addition to the above problem of computing one most-general explanation, we will also investigate the corresponding decision problem that asks whether or not an explanation for a why-not problem exists, and whether or not a given tuple of concepts is a most-general explanation for a why-not problem. In our framework, the $S$-ontology $O$ may be given explicitly as part of the input, or it may be derived from a given database instance or a given schema. We will introduce the different scenarios by which an ontology may be obtained in the next section, before we describe our algorithms for computing most-general explanations in Section 6.5.

6.4 Obtaining ontologies

In this section we discuss two approaches by which $S$-ontologies may be obtained. The first approach allows one to leverage an external ontology, provided that there is a way to relate a concept in the ontology to a database instance. In this case, the set $C$ of concepts is specified through a description logic such as $ALC$ or $DL-Lite$; $\sqsubseteq$ is a partial order on the concepts defined in the ontology, and the function $ext$ may be given through mapping assertions. The second approach considers an $S$-ontology that is derived from a specific database instance, or from a schema. This approach is useful as it allows one to define an ontology to be used for explaining why-not questions in the absence of an external ontology.

In either case, we study the complexity of deriving such $S$-ontologies based on the language on which concepts are defined, the subsumption between concepts, and the
function $ext$, which is defined according to the semantics of the concept language.

### 6.4.1 Leveraging an external ontology

We first consider the case where we are given an external ontology that models the domain of the database instance, and a relationship between the ontology and the instance. We will illustrate in particular how description logic ontologies are captured as a special case of our framework.

In what follows, our exposition borrows notions from the Ontology-Based Data Access (OBDA) framework. Specifically, we will make crucial use of the notion of an OBDA specification (Di Pinto et al., 2013), which consists of a description logic ontology, a relational schema, and a collection of mapping assertions. To keep the exposition simple, we restrict our discussion to one particular description logic, called DL-Lite$_R$, which is a representative member of the DL-Lite family of description logics (Calvanese et al., 2007). DL-Lite$_R$ is the basis for the OWL 2 QL$^2$ profile of OWL 2, which is a standard ontology language for Semantic Web adopted by W3C. As the other languages in the DL-Lite family, DL-Lite$_R$ exhibits a good trade off between expressivity and complexity bounds for important reasoning tasks such as subsumption checking, instance checking and query answering.

**TBox and Mapping Assertions.** In the description logic literature, an ontology is typically formalized as a TBox (Terminology Box), which consists of finitely many TBox axioms, where each TBox axiom expresses a relationship between concepts. Alongside TBoxes, ABoxes (Assertion Boxes) are sometimes used to describe the extension of concepts. To simplify the presentation, we do not consider ABoxes here.

**Definition 6.4.1 (DL-Lite$_R$).** Fix a finite set $\Phi_C$ of “atomic concepts” and a finite set $\Phi_R$ of “atomic roles”.

- The concept expressions and role expressions of DL-Lite$_R$ are defined as follows:

  \[
  \begin{align*}
  \text{Basic concept expression:} & \quad B ::= A \mid \exists R \\
  \text{Basic role expression:} & \quad R ::= P \mid P^- \\
  \text{Concept expressions:} & \quad C ::= B \mid \neg B \\
  \text{Role expressions} & \quad E ::= R \mid \neg R
  \end{align*}
  \]

  where $A \in \Phi_C$ and $P \in \Phi_R$. Formally, a $(\Phi_C, \Phi_R)$-interpretation $\mathcal{I}$ is a map that assigns to every atomic concept in $\Phi_C$ a unary relation over $\text{Const}$ and to every atomic role in $\Phi_R$ a binary relation over $\text{Const}$. The map $\mathcal{I}$ naturally extends to arbitrary concept expressions and role expressions:

  \[
  \begin{align*}
  \mathcal{I}(P^-) &= \{(x, y) \mid (y, x) \in \mathcal{I}(P)\} \\
  \mathcal{I}(-P) &= \text{Const}^2 \setminus \mathcal{I}(P) \\
  \mathcal{I}(\exists P) &= \pi_1(\mathcal{I}(P)) \\
  \mathcal{I}(\neg A) &= \text{Const} \setminus \mathcal{I}(A)
  \end{align*}
  \]

  Observe that $\mathcal{I}(\exists P^-) = \pi_2(\mathcal{I}(P))$.

\[\text{http://www.w3.org/TR/owl2-profiles/#OWL_2_QL}\]
In general, mapping assertions are first-order sentences over the schema, which is similar to how mappings are used in OBDA (Poggi et al., 2008). Thus, for each TBox axiom, its equivalent semantics in first-order notation.

GAV mapping assertions (universal quantifiers omitted for readability):

<table>

</tbody>
</table>

Train-Connection(x, y), Cities(x, y, w, “Europe”), Cities(x, y, w, “N.America”), Cities(x, y, w, “Netherlands”), Cities(x, y, w, “Europe”) → connected(x, y)

Figure 6.4: Example DL-Lite ontology with mapping assertions.

- A TBox (Terminology Box) is a finite set of TBox axioms where each TBox axiom is an inclusion assertion of the form B ⊆ C or R ⊆ E, where B is a basic concept expression, C is a concept expression, R is a basic role expression and E is a role expression. An (Φ_C, Φ_R)-interpretation I satisfies a TBox if for each axiom X ⊆ Y, it holds I(X) ⊆ I(Y).

- For concept expressions C₁, C₂ and a TBox T, we say that C₁ is subsumed by C₂ relative to T (notation: T ⊢ C₁ ⊆ C₂) if, for all interpretations I satisfying T, we have that I(C₁) ⊆ I(C₂).

An example of a DL-Lite TBox is given at the top of Figure 6.4. For convenience, we have listed next to each TBox axiom, its equivalent semantics in first-order notation.

Next we describe what mapping assertions are. Given an ontology and a relational schema, we can specify mapping assertions to relate the ontology language to the relational schema, which is similar to how mappings are used in OBDA (Poggi et al., 2008). In general, mapping assertions are first order sentences over the schema S ⊆ Φ_C ⊆ Φ_R that express relationships between the symbols in S and those in Φ_C and Φ_R. Among the different schema mapping languages that can be used, we restrict our attention, for simplicity, to the class of Global-As-View (GAV) mapping assertions (GAV mapping assertions or GAV constraints or GAV source-to-target tgds).

**Definition 6.4.2 (GAV mapping assertions).** A GAV mapping assertion over (S, (Φ_C ⊆ Φ_R)) is a first-order sentence ψ of the form

\[ \forall \vec{x} \ (\varphi_1(x_1), \ldots, \varphi_n(x_n)) \rightarrow \psi(\vec{x}), \]

where \( \vec{x} \subseteq x_1 \cup \ldots \cup x_n \), \( \varphi_1, \ldots, \varphi_n \) are atoms over S and ψ is an atomic formula of the form \( A(x_i) \) (for \( A \in \Phi_C \)) or \( P(x_i, x_j) \) (for \( P \in \Phi_R \)). Let I be an S-instance and \( I \) an
6.4. Obtaining ontologies

(Φ_C, Φ_R)-interpretation. We say that the pair (I, I) satisfies the GAV mapping assertion (notation: (I, I) |= ψ) if it holds that for any tuple of elements a from adom(I), with $a = \bigcup_{1 \leq k \leq n} a_k$, if $I |= \varphi_1(a_1), \ldots, \varphi_n(a_n)$, then $a_i \in I(A)$, with $a_i \in a$ (if $ψ = A(x_i)$) or $(a_i, a_j) \in I(P)$, with $a_i, a_j \in a$ (if $ψ = P(x_i, x_j)$).

Intuitively, a GAV mapping assertion associates a conjunctive query over S to an element (concept or atomic role) of the ontology. A set of GAV mapping assertions associates, in general, a union of conjunctive queries to an element of the ontology. Examples of GAV mapping assertions are given at the bottom of Figure 6.4.

**OBDA induced ontologies**

**Definition 6.4.3 (OBDA specification).** Let $T$ be a TBox, $S$ a relational schema, and $M$ a set of mapping assertions from $S$ to the concepts of $T$. We call the triple $B = (T, S, M)$ an OBDA specification.

An (Φ_C, Φ_R)-interpretation $I$ is said to be a solution for an $S$-instance $I$ with respect to the OBDA specification $B$ if the pair $(I, I)$ satisfies all mapping assertions in $M$ and $I$ satisfies $T$.

Note that our notion of an OBDA specification is a special case of the one given in (Di Pinto et al., 2013), where we do not consider view inclusion dependencies. Also, as mentioned earlier, our OBDA specifications assume that $T$ is a DL-Lite_R TBox and $M$ is a set of GAV mappings. These restrictions allow us to achieve good complexity bounds for explaining why-not questions with ontologies. In particular, it is not hard to see that, for the OBDA specifications we consider, every $S$-instance $I$ has a solution.

**Theorem 6.4.1.** ([Calvanese et al. (2007); Poggi et al. (2008)]) Let $T$ be a DL-Lite_R TBox.

(i) There is a PTIME-algorithm for deciding subsumption. That is, given $T$ and two concepts $C_1, C_2$, decide if $T |= C_1 \sqsubseteq C_2$.

(ii) There is an algorithm that, given an OBDA specification $B$, an instance $I$ over $S$ and a concept $C$, computes certain($C, I, B$) = $\bigcap \{I(C) \mid I$ is a solution for $I$ w.r.t. $B\}$. For a fixed OBDA specification, the algorithm runs in PTIME ($AC^0$ in data complexity).

Every OBDA specification induces an $S$-ontology as follows.

**Definition 6.4.4.** Every OBDA specification $B = (T, S, M)$, where $T$ is a DL-Lite_R TBox and $M$ is a set of GAV mappings gives rise to an $S$-ontology where:

- $C_{O_B}$ is the set of all basic concept expressions occurring in $T$;
- $\sqsubseteq_{O_B} = \{(C_1, C_2) \mid T |= C_1 \sqsubseteq C_2\}$;
- $ext_{O_B}$ is the polynomial-time computable function given by $ext_{O_B}(C, I) = \bigcap \{I(C) \mid I$ is a solution for $I$ w.r.t. $B\}$.

Note that the fact that $ext_{O_B}$ is polynomial-time computable follows from Theorem 6.4.1.

We remarked earlier that, for the ODBA specifications $B$ that we consider, it holds that every input instance has a solution. It follows that every input instance $I$ is consistent with the corresponding $S$-ontology $O_B$.
Theorem 6.4.2. The S-ontology $\mathcal{O}_B = (C_{O_B}, \sqsubseteq_{O_B}, ext_{O_B})$ can be computed from a given OBDA specification $\mathcal{B} = (T, S, \mathcal{M})$ in PTIME if $T$ is a DL-Lite$_R$ TBox and $\mathcal{M}$ is a set of GAV mappings.

We are now ready to illustrate an example where a why-not question is explained via an external ontology.

Example 6.4.1. Consider the OBDA specification $\mathcal{B} = (T, S, \mathcal{M})$ where $T$ is the TBox consisting of the DL-Lite$_R$ axioms given in Figure 6.4, $S$ is the schema from Example 6.3.1, and $\mathcal{M}$ is the set of mapping assertions given in Figure 6.4. These together induce an S-ontology $\mathcal{O}_B = (C_{O_B}, \sqsubseteq_{O_B}, ext_{O_B})$. The set $C_{O_B}$ consists of the following basic concept expressions:

- City, EU-City, N.A.-City, Dutch-City, US-City, Country, Continent,
- $\exists$ hasCountry, $\exists$ hasCountry$^-$, $\exists$ hasContinent,
- $\exists$ hasContinent$^-$, $\exists$ connected, $\exists$ connected$^-$.

The set $\sqsubseteq_{O_B}$ includes the pairs of concepts of the TBox $T$ given in Figure 6.4. We use the mappings to compute the extension of each concept in $C_{O_B}$ using the instance $I$ on the left of Figure 6.2. We list a few extensions here:

- $ext_{O_B}(\text{City}, I) = \{\text{Amsterdam, Berlin, Rome, New York, San Francisco, Santa Cruz, Tokyo, Kyoto}\}$
- $ext_{O_B}(\text{EU-City}, I) = \{\text{Amsterdam, Berlin, Rome}\}$
- $ext_{O_B}(\text{N.A.-City}, I) = \{\text{New York, San Francisco, Santa Cruz}\}$
- $ext_{O_B}(\exists\text{hasCountry}, I) = \{\text{Netherlands, Germany, Italy, USA, Japan}\}$
- $ext_{O_B}(\exists\text{connected}, I) = \{\text{Amsterdam, Berlin, New York}\}$

Now consider the query $q(x, y) = \exists z. \text{Train-Connections}(x, z) \land \text{Train-Connections}(z, y)$, and $q(I)$ as in Example 6.3.1. As before, we would like to explain why is $\langle \text{Amsterdam, New York}\rangle \not\in q(I)$. This time, we use the induced S-ontology $\mathcal{O}_B$ described above to derive explanations for $\langle \text{Amsterdam, New York}\rangle \not\in q(I)$:

- $E_1 = \langle \text{EU-City, N.A.-City}\rangle$
- $E_2 = \langle \text{Dutch-City, N.A.-City}\rangle$
- $E_3 = \langle \text{EU-City, US-City}\rangle$
- $E_4 = \langle \text{Dutch-City, US-City}\rangle$.

Among the four explanations above, $E_1$ is a most general one.

6.4.2 Ontologies derived from a schema

We now move to the second approach where an ontology is derived from an instance or a schema. The ability to derive an ontology through an instance or a schema is useful in the context where an external ontology is unavailable. To this purpose we first introduce a simple but suitable concept language that can be defined over the schema $S$.

Specifically, our concept language, denoted as $L_S$, makes use of two relational algebra operations, projection ($\pi$) and selection ($\sigma$). We first introduce and motivate the language. We will then describe our complexity results for testing whether one concept is subsumed by another, and for obtaining an ontology from a given instance or a schema. We will make use of these results later on in Sections 6.5.2 and 6.5.3.

Definition 6.4.5 (The Concept Language $L_S$). Let $S$ be a schema. A concept in $L_S$ is an expression $C$ defined by the following grammar.

---

116
6.4. Obtaining ontologies

\[ D := R \mid \sigma_{A_1 \op c_1, \ldots, A_n \op c_n}(R) \]
\[ C := \top \mid \{c\} \mid \pi_A(D) \mid C \sqcap C \]

In the above, \( R \) is a predicate name from \( S \), \( A, A_1, \ldots, A_n \) are attributes in \( R \), not necessarily distinct, \( c, c_1, \ldots, c_n \in \text{Const} \), and each occurrence of \( \op \) is a comparison operator belonging to \( \{=, <, >, \leq, \geq\} \). For \( C = \{C_1, \ldots, C_k\} \) a finite set of concepts, we denote by \( \sqcap C \) the conjunction \( C_1 \sqcap \ldots \sqcap C_k \). If \( C \) is empty, we take \( \sqcap C \) to be \( \top \).

Given a finite set of constants \( K \subset \text{Const} \), we define \( L_S[K] \) as the concept language \( L_S \) whose concept expressions only use constants from \( K \). By selection-free \( L_S \), we mean the language \( L_S \) where \( \sigma \) is not allowed. Similarly, by intersection-free \( L_S \), we mean the language \( L_S \) where \( \sqcap \) is not allowed, and by \( L_S^{\text{min}} \), we mean the minimal concept language \( L_S \) where both \( \sigma \) and \( \sqcap \) are not allowed.

Observe that the \( L_S \) grammar defines a concept in the form \( C_1 \sqcap \ldots \sqcap C_n \) where each \( C_i \) is \( \top \) or \( \{c\} \) or \( \pi_A(R) \) or \( \pi_A(\sigma_{A_1 \op c_1, \ldots, A_n \op c_n}(R)) \). A concept of the form \( \{c\} \) is called a nominal. A nominal \( \{c\} \) is the “most specific” concept for the constant \( c \). Given a tuple \( \bar{\pi} \) that is not in the output, the corresponding tuple of nominal concepts forms a default, albeit trivial, explanation for why not \( \bar{\pi} \).

As our next example illustrates, even though our concept language \( L_S \) appears simple, it is able to naturally capture many intuitive concepts over the domain of the database.

**Example 6.4.2.** We refer back to our schema \( S \) in Figure 6.1. Suppose we do not have access to an external ontology such as the one given in Example 6.3.1. We show that even so, we can still construct meaningful concepts directly from the database schema using the concept language described above. We list a few semantic concepts that can be specified with \( L_S \) in Figure 6.5, where we also show the corresponding SELECT-FROM-WHERE style expressions and intuitive meaning.

Example 6.4.2 shows that, even though \( L_S \) is a simple language where concepts are essentially intersections of unary projections of relations and nominals, it is already sufficiently expressive to capture natural concepts that can be used to build meaningful explanations. It is worth noting that, for minor extensions of the language \( L_S \), such as with \( \neq \)-comparisons and disjunction, the notion of a most-general explanation becomes trivial, in the sense that, for each why-not question, there is a most-general explanation that essentially enumerates all tuples in the query answer.

By using \( L_S \), we are able to define an ontology whose atomic concepts are derived from the schema itself. This approach allows us to provide explanations using a vocabulary that is already familiar to the user. We believe that this leads to intuitive and useful why-not explanations.

If we view each expression \( \pi_A(D) \) as an atomic concept, then the language \( L_S \) corresponds to a very simple concept language, whose concepts are built from atomic concepts and nominals using only intersection. In this sense, \( L_S \) can be considered to be a fragment of \( DL\text{-Lite}_{\text{core}, \sqcap} \) with nominals (also known as \( DL\text{-Lite}_{\text{horn}} \) (Artale et al., 2009)), i.e., the description logic obtained by enriching \( DL\text{-Lite}_{\text{core}} \) (the simplest language in the DL-Lite family) with conjunction.

The precise semantics of \( L_S \) is as follows. Given a concept \( C \) that is defined in \( L_S \) and an instance \( I \) over \( S \), the extension of \( C \) in \( I \), denoted by \([C]^I\), is inductively defined
### 6. High-Level Why-Not Explanations using Ontologies

</table>

Below. Intuitively, the extension of $C$ in $I$ is the result of evaluating the query associated with $C$ over $I$.

$$\begin{align*}
[R]^I & = R^I \\
\{\{c\}\}^I & = \{c\} \\
\{A_1 \circ \ldots \circ A_n (R)\}^I & = \{b \in R^I | π_{A_i}(b) \circ op_i c_i, 1 \leq i \leq n\} \\
\prod^I & = \text{Const} \\
π_A(D)^I & = π_A([D]^I) \\
[C_1 \cap C_2]^I & = [C_1]^I \cap [C_2]^I
\end{align*}$$

The notion of when one concept is subsumed by another is defined according to the extensions of the concepts. There are two notions, corresponding to concept subsumption w.r.t. an instance or subsumption w.r.t. a schema. More precisely, given two concepts $C_1, C_2$,

- we say that $C_2$ subsumes $C_1$ w.r.t. an instance $I$ (notation: $C_1 \sqsubseteq_I C_2$) if $[C_1]^I \subseteq [C_2]^I$.
- we say that $C_2$ subsumes $C_1$ w.r.t. a schema $S$ (notation: $C_1 \sqsubseteq_S C_2$), if for every instance $I$ of $S$, we have that $C_1 \sqsubseteq_I C_2$.

Note that the latter item is precisely the definition of containment of the query corresponding to $C_1$ in the query corresponding to $C_2$.

We are now ready to define the two types of ontologies, which are based on the two notions of concept subsumption described above, that can be derived from an instance or a schema.

**Definition 6.4.6** (Ontologies derived from a schema). Let $S$ be a schema, and let $I$ be an instance of $S$. Then the ontologies derived from $S$ and $I$ are defined respectively as

- $O_S = (L_S, \sqsubseteq_S, \text{ext})$ and
- $O_I = (L_S, \sqsubseteq_I, \text{ext})$,

where $\text{ext}$ is the function given by $\text{ext}(C, I') = [C]^I'$ for all instances $I'$ over $S$. By $O_S[K]$ we denote the ontology $(L_S[K], \sqsubseteq_S, \text{ext})$, and by $O_I[K]$ we denote the ontology $(L_S[K], \sqsubseteq_I, \text{ext})$.

It is easy to verify that the subsumption relations $\sqsubseteq_S$ and $\sqsubseteq_I$ are indeed pre-orders (i.e., reflexive and transitive relations), and that, for every fixed schemas $S$, the function $[C]^I'$ is polynomial-time computable. Hence, the above definition is well-defined even
6.4. Obtaining ontologies

All stated lower bounds already hold for $L_S^\text{min}$ concept expressions.

Table 6.1: Complexity of concept subsumption.

Though the ontologies obtained in this way are typically infinite. From the definition, it is easy to verify that if $C_1 \sqsubseteq_S C_2$, then $C_1 \sqsubseteq_I C_2$.

The following result about deciding $\sqsubseteq_I$ is immediate, as one can always execute the queries that are associated with the concepts and then test for subsumption, which can be done in polynomial time.

**Proposition 6.4.1.** The problem of deciding, given an instance $I$ of a schema $S$ and given two $L_S$ concept expressions $C_1$, $C_2$, whether $C_1 \sqsubseteq_I C_2$, is in PTIME.

On the other hand, the complexity of deciding $\sqsubseteq_S$ depends on the type of integrity constraints that are used in the specification of $S$. Table 6.1 provides a summary of relevant complexity results.

**Theorem 6.4.3.** Let $W$ be one of the different classes of schemas with integrity constraints listed in Table 6.1. The complexity of the problem to decide, given a schema $S$ in $W$ and two $L_S$ concept expressions $C_1$, $C_2$, whether $C_1 \sqsubseteq_S C_2$, is as indicated in the second column of the corresponding row in Table 6.1.

For example, given two concepts $C_1$, $C_2$, and a schema $(S, \Sigma)$ where $\Sigma$ is a collection of nested UCQ-view definitions, the complexity of deciding $C_1 \sqsubseteq_S C_2$ is CO\text{NEXP}\text{TIME}-complete. The lower bound already holds for concepts specified in $L_S^\text{min}$. We conclude this section with an analysis of the number of distinct concepts that can be formulated in a given concept language and an example that illustrates explanations that can be computed from such derived ontologies.

**Proposition 6.4.2.** Given a schema $S$ and a finite set of constants $K \subseteq \text{Const}$, the number of unique concepts (modulo logical equivalence)

- in $L_S^\text{min}[K]$ is polynomial in the size of $S$ and $K$,
- in selection-free or intersection-free $L_S[K]$ is single exponential in the size of $S$ and $K$.
- in $L_S[K]$ is double exponential in the size of $S$ and $K$.

**Example 6.4.3.** Let $S$ and $I$ be the schema and instance from Figure 6.1 and Figure 6.2. Suppose the concept language $L_S$ is used to define among others the concepts from Figure 6.5. The following concept subsumptions can be derived from $S$. Note that sub-
The first and second subsumptions follow from definitions. The third one holds because according to II, a BigCity is a city with population more than 5 million. The fourth subsumption follows from the inclusion dependency that each BigCity must have a train departing from it. There are subsumptions that hold in $\mathcal{O}_I$ but not in $\mathcal{O}_S$. For instance,

$$\pi_{\text{city-to}}(\sigma_{\text{city-from} = \text{Amsterdam}}(\text{Reachable})) \subseteq I$$
$$\pi_{\text{city-to}}(\sigma_{\text{city-from} = \text{Berlin}}(\text{Reachable})),$$

holds w.r.t. $\mathcal{O}_I$, where $I$ is the instance given in Figure 6.2, but does not hold w.r.t. $\mathcal{O}_S$, since one can construct an instance where not all cities that are reachable from Amsterdam are reachable from Berlin.

We now give examples of most-general explanations w.r.t. $\mathcal{O}_S$ and $\mathcal{O}_I$. As before, let $q(x, y) = \exists z. \text{Train-Connections}(x, z) \land \text{Train-Connections}(z, y)$ be a query with $q(I) = \{\langle \text{Amsterdam}, \text{Rome} \rangle, \langle \text{Amsterdam}, \text{Amsterdam} \rangle, \langle \text{Berlin}, \text{Berlin} \rangle, \langle \text{New York}, \text{Santa Cruz} \rangle\}$. We would like to explain why $\langle \text{Amsterdam}, \text{New York} \rangle \notin q(I)$ using the derived ontologies $\mathcal{O}_S$ and $\mathcal{O}_I$. Note that if $E$ is an explanation w.r.t. $\mathcal{O}_S$, then it is also an explanation w.r.t. $\mathcal{O}_I$ and vice versa. Some possible explanations are:

$$E_1 = \{\pi_{\text{name}}(\sigma_{\text{continent}=\text{Europe}}(\text{Cities})), \pi_{\text{city-from}}(\sigma_{\text{city-to} = \text{San Francisco}}(\text{Train-Connections}))\}$$
$$E_2 = \{\pi_{\text{name}}(\sigma_{\text{continent}=\text{Europe}}(\text{Cities})), \pi_{\text{name}}(\sigma_{\text{population}>7000000}(\text{Cities}))\}$$
$$E_3 = \{\pi_{\text{city-to}}(\sigma_{\text{city-from} = \text{Berlin}}(\text{Reachable})), \pi_{\text{name}}(\sigma_{\text{continent}=\text{N.America}}(\text{Cities}))\}$$
$$E_4 = \{\langle \text{Amsterdam} \rangle, \pi_{\text{name}}(\sigma_{\text{population}>7000000}(\text{Cities}))\}$$
$$E_5 = \{\pi_{\text{name}}(\sigma_{\text{country}=\text{Netherlands}}(\text{Cities})), \pi_{\text{name}}(\text{BigCity}) \land \pi_{\text{name}}(\sigma_{\text{continent}=\text{N.America}}(\text{Cities}))\}$$
$$E_6 = \{\langle \text{Amsterdam} \rangle, \langle \text{New York} \rangle\}$$
$$E_7 = \{\pi_{\text{name}}(\sigma_{\text{continent}=\text{Europe}}(\text{Cities})), \pi_{\text{name}}(\text{BigCity})\}$$
$$E_8 = \{\pi_{\text{name}}(\sigma_{\text{continent}=\text{Europe}}(\text{Cities})), \pi_{\text{name}}(\sigma_{\text{population}>7000000}(\text{Cities}))\}$$

For example, $E_1$ states the reason is that Amsterdam is a European city and New York is a city that has a train connection to San Francisco, and there is no train connection between such cities via a city. The trivial explanation $E_6$ is less general than any other explanation w.r.t. $\mathcal{O}_S$ (and $\mathcal{O}_I$ too). It can be verified that $E_2$ and $E_7$ are most-general explanations w.r.t. both $\mathcal{O}_S$ and $\mathcal{O}_I$. In particular, $E_2 >_{\mathcal{O}_I} E_5$ and $E_2 >_{\mathcal{O}_I} E_3$, but $E_2 >_{\mathcal{O}_S} E_5$ and $E_2 >_{\mathcal{O}_S} E_3$ since there might be an instance of $\mathcal{S}$ where Netherlands is not in Europe or where Berlin is reachable from a non-European city.

In general, if $E$ is an explanation w.r.t. $\mathcal{O}_I$ then $E$ is also an explanation w.r.t. $\mathcal{O}_S$, and vice versa. The following proposition also describes the relationship between most-general explanations w.r.t $\mathcal{O}_S$ and $\mathcal{O}_I$. 

120
Proposition 6.4.3. Let $S$ be a schema, and let $I$ be an instance of $S$.

(i) Every explanation w.r.t. $O_S$ is an explanation w.r.t. $O_I$ and vice versa.

(ii) A most-general explanation w.r.t $O_S$ is not necessarily a most-general explanation w.r.t. $O_I$, and likewise vice versa.

Proof. Statement (i) follows from Definition 6.3.2 and the definition of $ext$ for $O_S$ and $O_I$. That is, $ext$ is the same on the input instance $I$ for both $O_S$ and $O_I$, and the conditions of Definition 6.3.2 use only the value of $ext$ on $I$. Going back to Example 6.4.3, $E_1$ is a most-general explanation w.r.t. $O_S$, but it is not a most-general explanation w.r.t. $O_I$ (since $E_3$ is a strictly more general explanation than $E_1$ w.r.t. $O_I$). Thus, the first direction of (ii) holds. For the other direction of (ii), consider $E_8$ which is a most-general explanation w.r.t. $O_I$. But it holds that $E_7 > O_S E_8$ and $E_7$ is an explanation. Note that $E_7$ and $E_8$ are equivalent w.r.t. $O_I$.

6.5 Algorithms for computing most-general explanations

Next, we formally introduce the ontology-based why-not problem, which was informally described in Section 6.3, and we define algorithms for computing most-general explanations. We start by defining the notion of a why-not instance (or why-not question).

Definition 6.5.1 (Why-not instance). Let $S$ be a schema, $I$ an instance of $S$, $q$ an $m$-ary query over $I$ and $\bar{a} = \langle a_1, \ldots, a_m \rangle$ a tuple of constants such that $\bar{a} \notin q(I)$. We call the quintuple $(S, I, q, Ans, \bar{a})$, where $Ans = q(I)$, a why-not instance or a why-not question.

In a why-not instance, the answer set $Ans$ of $q$ over $I$ is assumed to have been computed already. This corresponds closely to the scenario under which why-not questions are posed where the user requests explanations for why a certain tuple is missing in the output of a query, which is computed a priori. Note that since $Ans = q(I)$ is part of a why-not instance, the complexity of evaluating $q$ over $I$ does not affect the complexity analysis of the problems we study in this chapter. In addition, observe that although a query $q$ is part of a why-not instance, the query is not directly used in our derivation of explanations for why-not questions with ontologies. However, the general setup accommodates the possibility to consider $q$ directly in the derivation of explanations and this is part of our future work.

We will study the following algorithmic problems concerning most-general explanations for a why-not instance.

Definition 6.5.2. The EXISTENCE-OF-EXPLANATION problem is the following decision problem: given a why-not instance $(S, I, q, Ans, \bar{a})$ and an $S$-ontology $O$ consistent with $I$, does there exist an explanation for $\bar{a} \notin Ans$ w.r.t. $O$?

Definition 6.5.3. The CHECK-MGE problem is the following decision problem: given a why-not instance $(S, I, q, Ans, \bar{a})$, an $S$-ontology $O$ consistent with $I$, and a tuple of concepts $\langle C_1, \ldots, C_n \rangle$, is the given tuple of concepts a most-general explanation w.r.t. $O$ for $\bar{a} \notin Ans$?
Definition 6.5.4. The Compute-one-MGE problem is the following computational problem: given a why-not instance \((S, I, q, Ans, \bar{a})\) and an S-ontology \(O\) consistent with \(I\), find a most-general explanation w.r.t. \(O\) for \(\bar{a} \not\in Ans\), if one exists.

Note that deciding the existence of an explanation w.r.t. a finite S-ontology is equivalent to deciding existence of a most-general explanation w.r.t. the same S-ontology.

Thus, our approach to the why-not problem makes use of S-ontologies. In particular, our notion of a “best explanation” is a most-general explanation, which is defined with respect to an S-ontology. We study the problem in three flavors: one in which the S-ontology is obtained from an external source (Section 6.5.1), and thus it is part of the input, and two in which the S-ontology is not part of the input, and is derived, respectively, from the instance \(I\) (Section 6.5.2), or from the schema \(S\) (Section 6.5.3).

6.5.1 Case 1: External ontology

We start by studying the case of computing ontology-based why-not explanations w.r.t. an external S-ontology. We first study the complexity of deciding whether or not there exists an explanation w.r.t. an external S-ontology.

Theorem 6.5.1.

(i) The problem Check-MGE is solvable in PTIME.

(ii) The problem Existence-of-explanation is NP-complete. It remains NP-complete even for bounded schema arity.

Intuitively, to check if a tuple of concepts is a most-general explanation, we can first check in PTIME if it is an explanation. Then, for each concept in the explanation, we can check in PTIME if it is subsumed by some other concept in \(O\) such that by replacing it with this more general concept, the tuple of concepts remains an explanation. The membership in NP is due to the fact that we can guess a tuple of concepts of polynomial size and verify in PTIME that it is an explanation. The lower bound is by a reduction from the Set Cover problem. Our reduction uses a query of unbounded arity and a schema of bounded arity. As we will show in Theorem 6.5.2, the problem is in PTIME if the arity of the query is fixed.

In light of the above result, we define an algorithm, called the Exhaustive Search Algorithm, which is an ExpTIME algorithm for solving the Compute-one-MGE problem.

This algorithm first generates the set of all possible explanations, and then iteratively reduces the set by removing the tuples of concepts that are less general than some tuple of concepts in the set. In the end, only most-general explanations are returned. At first, in line 1, for each element of the tuple \(\bar{a} = \langle a_1, \ldots, a_m \rangle\), we build the set \(C(a_i)\) containing all the concepts in \(C\) whose extension contains \(a_i\). Then, in line 2, we build the set of all possible explanations by picking a concept in \(C(a_i)\) for each position in \(\bar{a}\), and by discarding the ones that have a non empty intersection with the answer set \(Ans\). Finally, in lines 3–5, we remove from the set those explanations that have a strictly more general explanation in the set.

We now show that Exhaustive Search Algorithm is correct (i.e., it outputs the set of all most-general explanations for the given why-not instance w.r.t. the given S-ontology), and runs in exponential time in the size of the input.
### Algorithm 1: Exhaustive Search Algorithm

**Input**: a why-not instance \((S, I, q, \text{Ans}, \overline{\alpha})\), where \(\overline{\alpha} = (a_1, \ldots, a_m)\), a finite \(S\)-ontology \(\mathcal{O} = (\mathcal{C}, \sqsubseteq, \text{ext})\)

**Output**: the set of most-general explanations for \(\overline{\alpha} \not\in \text{Ans}\) wrt \(\mathcal{O}\)

1. Let \(\mathcal{C}(a_i) = \{C \in \mathcal{C} \mid a_i \in \text{ext}(C, I)\}\) for all \(i, 1 \leq i \leq m\)
2. Let \(\mathcal{X} = \{(C_1, \ldots, C_m) \mid C_i \in \mathcal{C}(a_i)\) and \((\text{ext}(C_1, I) \times \ldots \times \text{ext}(C_m, I)) \cap \text{Ans} = \emptyset\}\)
3. foreach pair of explanations \(E_1, E_2 \in \mathcal{X}\), \(E_1 \neq E_2\) do
   4. if \(E_1 >_\mathcal{O} E_2\) then
   5. remove \(E_2\) from \(\mathcal{X}\)
6. return \(\mathcal{X}\)

**Theorem 6.5.2.** Let a why-not instance \((S, I, q, \text{Ans}, \overline{\alpha})\) and an \(S\)-ontology \(\mathcal{O}\) be an input to Exhaustive Search Algorithm and let \(\mathcal{X}\) be the corresponding output. The following hold:

   (i) \(\mathcal{X}\) is the set of all most-general explanations for \(\overline{\alpha} \not\in \text{Ans}\) (modulo equivalence);

   (ii) Exhaustive Search Algorithm runs in \(\text{ExpTime}\) in the size of the input (in \(\text{PTime}\) if we fix the arity of the input query).

Theorem 6.5.2, together with Theorem 6.4.2, yields the following corollary (recall that, by construction of \(\mathcal{O}_B\), it holds that every input instance \(I\) is consistent with \(\mathcal{O}_B\)).

**Corollary 6.5.1.** There is an algorithm that takes as input a why-not instance \((S, I, q, \text{Ans}, \overline{\alpha})\) and an OBDA specification \(B = (\mathcal{T}, S, \mathcal{M})\), where \(\mathcal{T}\) is a DL-Lite\(\mathcal{R}\) TBox and \(\mathcal{M}\) is a set of GAV mappings, and computes all the most-general explanations for \(\overline{\alpha} \not\in \text{Ans}\) w.r.t. the \(S\)-ontology \(\mathcal{O}_B\) in \(\text{ExpTime}\) in the size of the input (in \(\text{PTime}\) if the arity of \(q\) is fixed).

### 6.5.2 Case 2: Ontologies from an instance

We now study the why-not problem w.r.t. an \(S\)-ontology \(\mathcal{O}_I\) that is derived from an instance. First, note that the presence of nominals in the concept language guarantees a trivial answer for the Existance-of-Explanation W.R.T. \(\mathcal{O}_I\) problem. An explanation always exists, namely the explanation with nominals corresponding to the constants of the tuple \(\overline{\alpha}\). In fact, a most-general explanation always exists, as follows from the results below.

**Definition 6.5.5.** The **Compute-one-MGE** w.r.t. \(\mathcal{O}_I\) is the following computational problem: given a why-not instance \((S, I, q, \text{Ans}, \overline{\alpha})\), find a most-general explanation w.r.t. \(\mathcal{O}_I\) for \(\overline{\alpha} \not\in \text{Ans}\), where \(\mathcal{O}_I\) is the \(S\)-ontology that is derived from \(I\), as defined in Section 6.4.2.

First, we state an important proposition, that underlies the correctness of the algorithms that we will present. The following proposition shows that, when we search for explanations w.r.t. \(\mathcal{O}_I\), we can always restrict our attention to a particular finite restriction of this ontology.
Proposition 6.5.1. Let \((S, I, q, \text{Ans}, \overline{a})\) be a why-not instance. If \(E\) is an explanation for \(\overline{a} \not\in \text{Ans}\) w.r.t. \(\mathcal{O}_I\) (resp. \(\mathcal{O}_S\)), then there exists an explanation \(E'\) for \(\overline{a} \not\in \text{Ans}\) such that \(E \preceq_{\mathcal{O}_I[K]} E'\) (resp. \(E \preceq_{\mathcal{O}_S[K]} E'\)), where \(K = \text{dom}(I) \cup \{a_1, \ldots, a_m\}\) and each constant in \(E'\) belongs to \(K\).

In our proof, we iteratively reduce the number of constants occurring in the explanation. That is, for every explanation \(E\) with concepts containing constants outside of \(\text{dom}(I) \cup \{a_1, \ldots, a_m\}\), we produce a new explanation \(E'\) which is more general than \(E\) and which contains less constants outside of \(\text{dom}(I) \cup \{a_1, \ldots, a_m\}\).

Notice that since, in principle, it is possible to materialize the ontology \(\mathcal{O}_I[K]\) (i.e., to explicitly compute all the concepts \(\mathcal{C}\) in the ontology, the subsumption relation \(\subseteq_I\), and the extension \(\text{ext}\)), the exhaustive search algorithm, together with Proposition 6.5.1, gives us a method for solving \(\text{compute-one-MGE}\) w.r.t. \(\mathcal{O}_I\). In particular, given a schema, exhaustive search algorithm solves \(\text{compute-one-MGE}\) w.r.t. \(\mathcal{O}_I\) in \(2\text{EXPTIME}\) (in \(\text{EXPTIME}\) if the arity of \(q\) is fixed). This is because to find a most-general explanation w.r.t. \(\mathcal{O}_I\), it is sufficient to restrict to the concept language \(\mathcal{L}_S[K]\) and its fragments, where \(K = \text{dom}(I) \cup \{a_1, \ldots, a_m\}\). Then \(\text{compute-one-MGE}\) w.r.t. \(\mathcal{O}_I\) is solvable in \(2\text{EXPTIME}\) follows from the fact that the \(\mathcal{S}\)-ontology \(\mathcal{O}_I[K]\) is computable in at most \(2\text{EXPTIME}\).

We now present a more effective algorithm for solving \(\text{compute-one-MGE}\) w.r.t. \(\mathcal{O}_I\). (See Algorithm 2.) We start by introducing the notion of a least upper bound of a set of constants \(X\) w.r.t. an instance \(I\), denoted by \(\text{lub}_I(X)\). This intuitively corresponds to the most-specific concept whose extension contains all constants of \(X\). We first consider the case in which \(\text{lub}_I(X)\) is expressed using selection-free \(\mathcal{L}_S\) concepts. The following lemma states two important properties of \(\text{lub}_I(X)\) that are crucial for the correctness of Algorithm 2.

Lemma 6.5.1. Given an instance \(I\) of schema \(S\) and a set of constants \(X\), we can compute in polynomial time a selection-free \(\mathcal{L}_S\) concept, denoted \(\text{lub}_I(X)\), that is the smallest concept whose extension contains all the elements in \(X\) definable in the language. In particular, the following hold:

(i) \(X \subseteq \text{ext}(\text{lub}_I(X), I)\),

(ii) there is no concept \(C'\) in selection-free \(\mathcal{L}_S\) such that \(C' \subseteq_I \text{lub}_I(X)\) and \(X \subseteq \text{ext}(C', I)\).

We are now ready to introduce Algorithm 2. We will start with a high-level description of the idea behind it. The algorithm navigates through the search space of possible explanations using an incremental search strategy and makes use of the above defined notion of \(\text{lub}\). We start with an explanation that has, in each position, the \(\text{lub}\) of the constant (i.e., nominal) that occurs in that position. Then, we try to construct a more general explanation by expanding the set of constants considered by each \(\text{lub}\).

Notice that incremental search algorithm produces explanations which are tuples of conjunctions of concepts. Therefore it produces an explanation whose concepts are concept expressions in the language \(\mathcal{L}_S\) or selection-free \(\mathcal{L}_S\). We will study the behavior of the algorithm for each of these languages separately.

First, we focus on the case in which incremental search algorithm produces most-general explanations using selection-free \(\mathcal{L}_S\) concepts. We show that the algorithm
6.5. Algorithms for computing most-general explanations

**Algorithm 2: Incremental Search Algorithm**

**Input:** a why-not instance \((S, I, q, \text{Ans}, \bar{a})\)

**Output:** a most-general explanation for \(\bar{a} \notin \text{Ans}\) wrt \(O_I\)

1. Let \(K = \text{dom}(I) \cup \{a_1, \ldots, a_m\}\)
2. Let \(\mathcal{X} = (X_1, \ldots, X_m)\) s.t. each \(X_j = \{a_j\}\). // support set
3. Let \(E = (C_1, \ldots, C_m)\) s.t. each \(C_j = \text{lub}_I(X_j)\). // first candidate explanation
4. foreach \(1 \leq j \leq m\) do
   5. foreach \(b \in K \setminus \text{ext}(E_j, I)\) do
   6. \(X'_j = X_j \cup \{b\}\)
   7. Let \(C'_j = \text{lub}_I(X'_j)\). // a more general concept in position \(j\)
   8. Let \(E' := (C_1, \ldots, C'_j, \ldots, C_m)\). // a more general explanation
   9. if \(E' \cap \text{Ans} = \emptyset\) then
      10. \(E := E'\)
      11. \(\mathcal{X} := (X_1, \ldots, X'_j, \ldots, X_m)\)
12. return \(E\)

is correct, i.e., that it outputs an explanation for \(\bar{a} \notin \text{Ans}\) wrt \(O_I\), and that it runs in polynomial time with selection-free \(L_S\).

**Theorem 6.5.3** (Correctness and running time of Incremental Search Algorithm).
Let the why-not instance \((S, I, q, \text{Ans}, \bar{a})\) be an input to Incremental Search Algorithm and \(E\) the corresponding output. The following holds:

(i) \(E\) is a most-general explanation for \(\bar{a} \notin \text{Ans}\) wrt \(O_I = (C, \sqsubseteq_I, \text{ext})\), where \(C\) is selection-free \(L_S\);

(ii) Incremental Search Algorithm runs in PTime in the size of the input.

Now we extend our analysis of Incremental Search Algorithm to the general case in which it works with \(L_S\). First, we state an analogue of Lemma 6.5.1 for \(L_S\).

**Lemma 6.5.2.** Given an instance \(I\) of \(S\) and a set of constants \(X\), we can compute in exponential time a \(L_S\) concept, denoted \(\text{lub}^*_I(X)\), that is the smallest concept whose extension contains all the elements in \(X\) definable in the language. Such a concept is polynomial-time computable for bounded schema arity. In particular, the following hold:

(i) \(X \subseteq \text{ext}(\text{lub}^*_I(X), I)\),

(ii) there is no concept \(C'\) in \(L_S\) such that \(C' \sqsubseteq_I \text{lub}^*_I(X)\) and \(X \subseteq \text{ext}(C', I)\).

By Incremental Search Algorithm with Selections we will refer to the algorithm obtained from Incremental Search Algorithm by replacing \(\text{lub}_I(X)\) with \(\text{lub}^*_I(X)\) in line 3 and line 7.

The following theorem shows that Incremental Search Algorithm with Selections is correct, i.e., that it outputs an explanation for \(\bar{a} \notin \text{Ans}\) wrt the \(S\)-ontology \(O_I\), and that it runs in exponential time (in polynomial time for bounded schema arity).

**Theorem 6.5.4** (Correctness and running time of Incremental Search Algorithm with Selections). Let the why-not instance \((S, I, q, \text{Ans}, \bar{a})\) be an input to In-
6. High-Level Why-Not Explanations using Ontologies

Mental Search Algorithm with Selections and $E$ the corresponding output.  

The following hold:

(i) $E$ is a most-general explanation for $\pi \notin \text{Ans}$ w.r.t. \( \mathcal{O}_1 = (\mathcal{C}, \sqsubseteq_I, \text{ext}) \), where $\mathcal{C}$ is $L_S$;

(ii) Incremental Search Algorithm runs in ExpTime in the size of the input (in PTIME for bounded schema arity).

We close this section with the study of the following problem.

Definition 6.5.6. The \textsc{Check-MGE} w.r.t. $\mathcal{O}_1$ problem is the following decision problem: given a why-not instance $(S, I, q, \text{Ans}, \overline{a})$ and a tuple of concepts $E = (C_1, \ldots, C_n)$, is $E$ a most-general explanation w.r.t. $\mathcal{O}_1$ for $\overline{a} \notin \text{Ans}$?

Our next proposition states the running time of our algorithm for the \textsc{Check-MGE} w.r.t. $\mathcal{O}_1$ for various fragments of our concept language. The algorithm operates very similarly to lines 4–11 of Incremental Search Algorithm. Given a tuple of concepts, we check whether that tuple of concepts can be extended to a more general tuple of concepts through ideas similar to lines 4–11 of Incremental Search Algorithm.  

If the answer is “no”, then we return “yes”. Otherwise, we return “no”.

Proposition 6.5.2. There is an algorithm that solves \textsc{Check-MGE} w.r.t. $\mathcal{O}_1$ in:

- PTIME for selection-free $L_S$, or for $L_S$ with bounded schema arity;
- ExpTime for $L_S$ in the general case.

6.5.3 Case 3: Ontologies from schema

We now study the case of solving the why-not problem w.r.t. to an $S$-ontology $\mathcal{O}_S$ that is derived from a schema. As in the previous case, the presence of nominals in the concept language guarantees that the trivial explanation always exists. Therefore we do not consider the decision problem \textsc{Existence-of-Explanation} w.r.t. $\mathcal{O}_S$.

Definition 6.5.7 (\textsc{Compute-One-MGE} w.r.t. $\mathcal{O}_S$). \textsc{Compute-One-MGE} w.r.t. $\mathcal{O}_S$ is the following computational problem: given a why-not instance $(S, I, q, \text{Ans}, \overline{a})$, find a most-general explanation w.r.t. $\mathcal{O}_S$ for $\overline{a} \notin \text{Ans}$, where $\mathcal{O}_S$ is the $S$-ontology that is derived from $S$, as defined in Section 6.4.2.

The complexity of \textsc{Compute-One-MGE} w.r.t. $\mathcal{O}_S$ depends on the complexity of subsumption checking for $L_S$. As can be seen in Table 6.1, subsumption checking with respect to arbitrary integrity constraints is undecidable. Therefore, for the general case in which no restriction is imposed on the integrity constraints, \textsc{Compute-One-MGE} w.r.t. $\mathcal{O}_S$ is unlikely to be decidable. The restrictions on the integrity constraints of $S$ allow for the definition of several variants of the problem that, under some restrictions, are decidable.

We restrict now to the cases in which we are able to materialize the $S$-ontology $\mathcal{O}_S[\mathcal{K}]$, with $\mathcal{K} = \text{dom}(I) \cup \{a_1, \ldots, a_m\}$. Exhaustive Search Algorithm gives us a method for solving \textsc{Compute-One-MGE} w.r.t. $\mathcal{O}_S$. The following proposition gives us a double exponential upper bound for \textsc{Compute-One-MGE} w.r.t. $\mathcal{O}_S$ in the general case, and a polynomial case under specific assumptions (cf. Table 6.1).
6.6 Variations of the framework

Proposition 6.5.3. There is an algorithm that solves \textsc{Compute-one-MGE} w.r.t. \( \mathcal{O}_S \)

- in \( 2\text{ExpTime} \) for \( L_S \), provided that the input schema \( S \) is from a class for which concept subsumption can be checked in \( \text{ExpTime} \),

- in \( \text{ExpTime} \) for selection-free \( L_S \), and projection-free \( L_S \), provided that the input schema \( S \) is from a class for which concept subsumption can be checked in \( \text{ExpTime} \),

- in \( \text{PTime} \) for \( L_S^{\min} \), if the arity of \( q \) is fixed and provided that the input schema \( S \) is from a class for which concept subsumption can be checked in \( \text{PTime} \).

We end with the definition of \textsc{Check-MGE} w.r.t. \( \mathcal{O}_S \).

Definition 6.5.8. The \textsc{Check-MGE} w.r.t. \( \mathcal{O}_S \) problem is the following decision problem: given a why-not instance \((S, I, q, \text{Ans}, \overline{\alpha})\) and a tuple of concepts \( E = (C_1, \ldots, C_n) \), is \( E \) a most-general explanation w.r.t. \( \mathcal{O}_S \) for \( \overline{\alpha} \notin \text{Ans} \)?

As for \textsc{Compute-one-MGE} w.r.t. \( \mathcal{O}_S \), the undecidability of concept subsumption in the general case suggests that it is unlikely for \textsc{Check-MGE} w.r.t. \( \mathcal{O}_S \) to be decidable without imposing any restriction on \( \Pi \) and \( \Sigma \). However, also this problem allows for the characterization of several decidable variants.

In particular, since \textsc{Check-MGE} is solvable in \( \text{PTime} \) (see Theorem 6.5.1), by materializing \( \mathcal{O}_S[\mathcal{K}] \) we can derive some upper bounds for \textsc{Check-MGE} w.r.t. \( \mathcal{O}_S \) too.

Proposition 6.5.4. There is an algorithm that solves \textsc{Check-MGE} w.r.t. \( \mathcal{O}_S \)

- in \( 2\text{ExpTime} \) for \( L_S \) concepts, provided that the input schema \( S \) is from a class for which concept subsumption can be checked in \( \text{ExpTime} \),

- in \( \text{ExpTime} \) for selection-free \( L_S \), and projection-free \( L_S \), provided that the input schema \( S \) is from a class for which concept subsumption can be checked in \( \text{ExpTime} \),

- in \( \text{PTime} \) for \( L_S^{\min} \), provided that the input schema \( S \) is from a class for which concept subsumption can be checked in \( \text{PTime} \).

The proof is analogous to the one for Proposition 6.5.3.

We expect that the upper bounds for \textsc{Compute-one-MGE} w.r.t. \( \mathcal{O}_S \) and \textsc{Check-MGE} w.r.t. \( \mathcal{O}_S \) can be improved. Pinpointing the complexity of these problems is left for future work.

6.6 Variations of the framework

We consider several refinements and variations to our framework involving finding short explanations, and providing alternative definitions of explanations and of what it means to be most general.

Producing a Short Explanation. A most general explanation may contain redundant concepts as conjuncts. An explanation that is equivalent but shorter may be more helpful to the user. To simplify our discussion, we restrict our attention to ontologies that
are derived from an instance and show that the problem of finding a most-general explanation of minimal length is NP-hard in general, where the length of an explanation \( E = (C_1, \ldots, C_k) \) is measured by the total number of symbols needed to write out \( C_1, \ldots, C_k \).

Proposition 6.6.1. Given a why-not instance \((S, I, q, \text{Ans}, \overline{\pi})\), the problem of finding a most-general explanation to \( \overline{a} \notin \text{Ans} \) of minimal length is NP-hard.

Given that computing a shortest most-general explanation is intractable in general, we may consider the task of shortening a given most-general explanation. The Incremental Search Algorithm produces concepts that may contain superfluous conjuncts. It is thus natural to ask whether the algorithm can be modified to produce a most-general explanation of a shorter length. This question can be formalized in at least two ways.

Let \( I \) be an instance of a schema \( S \), and let \( C = \cap \{C_1, \ldots, C_n\} \) be any \( L_S \) concept expression. We may assume that each \( C_i \) is intersection-free. We say that \( C \) is irredundant if there is no strict subset \( X \subset \{C_1, \ldots, C_n\} \) such that \( C \equiv_{\text{O}_1} \cap X \). We say that an explanation (with respect to \( \text{O}_1 \)) is irredundant if it consists of irredundant concept expressions. We say that explanations \( E_1 \) and \( E_2 \) are equivalent w.r.t. an ontology \( \text{O} \), denoted as \( E_1 \equiv_{\text{O}} E_2 \), if \( E_1 \leq_{\text{O}} E_2 \) and \( E_2 \leq_{\text{O}} E_1 \).

Proposition 6.6.2. There is a polynomial-time algorithm that takes as input an instance \( I \) of a schema \( S \), as well as an \( L_S \) concept expression \( C \), and produces an irredundant concept expression \( C' \) such that \( C \equiv_{\text{O}_1} C' \).

Hence, by combining Proposition 6.6.2 with Incremental Search Algorithm, we can compute an irredundant most-general explanation w.r.t. \( \text{O}_1 \) in polynomial time.

We say that an explanation \( E = (C_1, \ldots, C_k) \) is minimized w.r.t. \( \text{O}_1 \) if there does not exist an explanation \( E' = (C_1, \ldots, C_k) \) such that \( E \equiv_{\text{O}_1} E' \) and \( E' \) is shorter than \( E \). Every minimized explanation is irredundant, but the converse may not be true. For instance, let \( \text{O} \) be an ontology with three atomic concepts \( C_1, C_2, C_3 \) such that \( C_1 \equiv_{\text{O}} C_2 \cap C_3 \) and \( C_2 \cap C_3 \equiv_{\text{O}} C_1 \). Then the concept \( C_2 \cap C_3 \) is irredundant with respect to \( \text{O} \). However, \( C_1 \) is an equivalent concept of strictly shorter length.

Proposition 6.6.3. Given a why-not instance \((S, I, q, \text{Ans}, \overline{\pi})\) and an explanation \( E \) to why \( \overline{a} \notin \text{Ans} \), the problem of finding a minimized explanation equivalent to \( E \) is NP-hard.

Cardinality based preference. We have currently defined a most-general explanation to be an explanation \( E \) such that there is no explanation \( E' \) with \( E' >_{\text{O}} E \). A natural alternative is to define “most general” in terms of the cardinality of the extensions of the concepts in an explanation. Formally, let \( \text{O} = (C, \subseteq, \text{ext}) \) be an \( S \)-ontology, and \( I \) an instance. We define the degree of generality of an explanation \( E = (C_1, \ldots, C_m) \) with respect to \( \text{O} \) and \( I \) to be the (possibly infinite) sum \( |\text{ext}(C_1, I)| + \cdots + |\text{ext}(C_m, I)| \).

For two explanations, \( E_1, E_2 \), we write \( E_1 >_{\text{O,I}}^\text{card} E_2 \), if \( E_1 \) has a strictly higher degree of generality than \( E_2 \) with respect to \( \text{O} \) and \( I \). We say that an explanation \( E \) is \( >_{\text{O,I}}^\text{card} \)-maximal (with respect to \( \text{O} \) and \( I \)) if there is no explanation \( E' \) such that \( E' >_{\text{O,I}}^\text{card} E \).

Proposition 6.6.4. Assuming \( P \neq \text{NP} \), there is no \( \text{PTIME} \) algorithm that takes as input a why-not instance \((S, I, q, \text{Ans}, \overline{\pi})\) and an \( S \)-ontology \( \text{O} \), and produces a \( >_{\text{O,I}}^\text{card} \)-maximal explanation for \( \overline{a} \notin \text{Ans} \). This holds even for unary queries.
6.7. Conclusion

In particular, this shows (assuming $P \neq NP$) that computing $>^{\text{card}}$-maximal explanations is harder than computing most-general explanations. The proof of Proposition 6.6.4 goes by reduction from a suitable variant of $\text{Set Cover}$. Our reduction is in fact an $L$-reduction, which implies that there is no $\text{PTIME}$ constant-factor approximation algorithm for the problem of finding a $>^{\text{card}}$-maximal explanation.

**Strong explanations.** We now examine an alternative notion of an explanation that is essentially independent to the instance of a why-not question. Recall that the second condition of our current definition of an explanation $E = (C_1, \ldots, C_m)$ requires that $\text{ext}(C_1, I) \times \cdots \times \text{ext}(C_1, I)$ does not intersect with $\text{Ans}$, where $I$ is the given instance. We could replace this condition by a stronger condition, namely that $\text{ext}(C_1, I') \times \cdots \times \text{ext}(C_1, I')$ does not intersect with $q(I')$, for any instance $I'$ of the given schema that is consistent with the ontology $\mathcal{O}$. If this holds, we say that $E$ is a *strong explanation*.

A strong explanation is also an explanation but not necessarily the other way round. When a strong explanation $E$ for $\bar{a} \notin \text{Ans}$ exists, then, intuitively, the reason why $\bar{a}$ does not belong to $\text{Ans}$, is essentially independent from the specific instance $I$, and has to do with the ontology $\mathcal{O}$ and the query $q$. In the case where the ontology $\mathcal{O}$ is derived from a schema $\mathcal{S}$, a strong explanation may help one discover possible errors in the integrity constraints of $\mathcal{S}$, or in the query $q$. We leave the study of strong why-not explanations for future work.

6.7 Conclusion

We have presented a new framework for why-not explanations, which leverages concepts from an ontology to provide high-level and meaningful reasons for why a tuple is missing from the result of a query. Our focus in this chapter was on developing a principled framework, and on identifying the key algorithmic problems. The exact complexity of some problems raised in this chapter remains open. In addition, there are several directions for future work.

Recall that, in general, there may be multiple most-general explanations for $\bar{a} \notin q(I)$. While we have presented a polynomial time algorithm for computing a most-general explanation to a why-not question w.r.t. $\mathcal{O}_I$ for the case of selection-free $L_S$, the most-general explanation that is returned by the algorithm may not always be the most helpful explanation. In future work, we plan to investigate whether there is a polynomial delay algorithm for enumerating all most-general explanations.

Although we only looked at *why-not explanations*, it will be natural to consider *why explanations* in the context of an ontology, and in particular, understand whether the notion of most-general explanations, suitably adapted, applies in this setting. In addition, Roy and Suciu (2014) recently initiated the study of what one could call “why so high” and “why so low” explanations for numerical queries (such as aggregate queries). Again, it would be interesting to see if our approach can help in identifying high-level such explanations.

We have focused on providing why-not explanations to missing tuples of queries that are posed against a database schema. However, our framework for answering the why-not question is general and could, in principle, be applied also to queries posed against the ontology in an OBDA setting.
Finally, we plan to explore ways whereby our high-level explanations can be used to complement and enhance existing data-centric and/or query-centric approaches. We illustrate this with an example. Suppose a certain publication $X$ is missing from the answers to query over some publication database. A most-general explanation may be that $X$ was published by Springer (supposing all Springer publications are missing from the answers to the query). This explanation provides insight on potential high-level issues that may exist in the database and/or query. For example, it may be that all Springer publications are missing from the database (perhaps due to errors in the integration/curation process) or the query has inadvertently omitted the retrieval of all Springer publications. This is in contrast with existing data-centric (resp. query-centric) approaches, which only suggest fixes to the database instance (resp. query) so that the specific publication $X$ appears in the query result.
6.A Missing proofs for Section 4

6.A.1 Proofs for Section 6.4.1

**Theorem 6.4.1.** [Calvanese et al. (2007); Poggi et al. (2008)] Let \( T \) be a DL-Lite\(_R\) TBox.

(i) There is a PTIME-algorithm for deciding subsumption. That is, given \( T \) and two concepts \( C_1, C_2 \), decide if \( T \models C_1 \sqsubseteq C_2 \).

(ii) There is an algorithm that, given an OBDA specification \( B \), an instance \( I \) over \( S \) and a concept \( C \), computes \( \text{certain}(C, I, B) = \bigcap\{\mathcal{I}(C) \mid \mathcal{I} \text{ is a solution for } I \text{ w.r.t. } B\} \). For a fixed OBDA specification, the algorithm runs in PTIME (\( AC^0 \) in data complexity).

**Proof.** Item (i). The subsumption problem in DL-Lite\(_R\) is known to be in PTIME in the size of the TBox (Calvanese et al., 2007).

Item (ii). First, observe that DL-Lite\(_R\) is FO-rewritable (Calvanese et al., 2007), i.e., given a TBox \( T \) and an Abox \( A \), for every CQ \( q \) asked against \( T \cup A \), there exists a query \( q' \) such that \( \text{certain}(q, I, T \cup A) = q'(A) \), where \( q' \) is a UCQ called the perfect rewriting of \( q \) w.r.t. \( T \). Such \( q' \) is PTIME computable.

Then, let \( B \) be an OBDA specification. If we replace the ABox with \( M \cup I \), we have that for every query CQ \( q \) asked against \( B \), there exists a query \( q' \) such that \( \text{certain}(q, I, B) = q'(M \cup I) \), where \( q' \) is as defined above. Then, let us denote by \( \text{unf}_M(q') \) the unfolding of \( q' \) w.r.t. \( M \), i.e., the UCQ query obtained from \( q' \) by substituting each atom from \( \Phi_C \cup \Phi_R \) with the union of bodies of the mappings from \( M \) that have the atom as the head. Unfolding is also PTIME computable (Poggi et al., 2008). Then, computing \( \text{certain}(q, I, B) \) amounts to evaluate \( \text{unf}_M(q') \) on \( I \), which is in PTIME.

Finally, notice that computing \( \text{ext}(C, I) \) requires one to evaluate the unary query \( q(x) = C(x) \) over \( B \). This task, also known as instance retrieval, takes polynomial time in light of the above results.

**Theorem 6.4.2.** The S-ontology \( \mathcal{O}_B = (\mathcal{C}_B, \sqsubseteq_B, \text{ext}_B) \) can be computed from a given OBDA specification \( B = (T, S, M) \) in PTIME if \( T \) is a DL-Lite\(_R\) TBox and \( M \) is a set of GAV mappings.

**Proof.** The size of \( \mathcal{C}_B \) is polynomial in the size of \( T \). From Theorem 6.4.1, it follows that concept subsumption can be decided in PTIME for DL-Lite\(_R\) TBoxes, and also that computing the extension \( \text{ext}(C, I) \) of each concept \( C \in \mathcal{C}_B \) requires PTIME (\( AC^0 \) in data complexity).

6.A.2 Proof of Theorem 6.4.3

In this section we give proofs for the results stated in Table 6.1.

Before turning to the proofs, we note that we only consider the subsumption problem for input concepts that do not contain nominals. Indeed, we can show that in this case the problem can be easily solved. First, however, we prove the following
Proposition 6.A.1. Let $S$ be a schema, $C_1$ a concept in $L_S$ and $C_i^1, 1 \leq i \leq n$ concepts in intersection-free $L_S$. Then

$$C_1 \sqsubseteq_S C_2^1 \cap \ldots \cap C_2^n \iff C_1 \sqsubseteq_S C_i^1 \text{ for every } i \leq n.$$  

Proof. ($\Rightarrow$). Let $I$ be an instance of $S$, and $a \in [C_1]^I$. Then for every $i, 1 \leq i \leq n$ it holds $a \in [C_i^1]^I$. This means that $a \in [C_2^1 \cap \ldots \cap C_2^n]^I$, as required.

($\Leftarrow$). Let $I$ be an instance of $S$, and $a \in [C_1]^I$. Then it holds $a \in [C_2^1 \cap \ldots \cap C_2^n]^I$, which means $a \in [C_i^1]^I$ for every $i, 1 \leq i \leq n$. 

Henceforth, this proposition allows restrict ourselves to the case of subsumption in an intersection-free concept $L_S$. Let $C_1 \sqsubseteq_S C_2$ be an instance of a subsumption problem, where $C_1 \in L_S$ and $C_2$ is from intersection-free $L_S$ and $C_1$ or $C_2$ contain a nominal. First, if $C_1$ contains a nominal as a conjunct, then in fact $C_1$ is equivalent to this nominal or inconsistent. In the latter case subsumption trivially holds. The following proposition shows how we deal with the remaining cases.

Proposition 6.A.2. Let $S$ be a schema. Then for every $a, b \in \text{Const}$ the following hold

(i) $\{a\} \not\subseteq_S \{b\}$, $\{a\} \subseteq_S \{a\}$,

(ii) $\{a\} \subseteq_S \pi_A(\sigma_\theta(R))$,

(iii) $\cap_{i=1}^n \pi_{A_i}(\sigma_{\theta_i}(R_i)) \subseteq_S \{a\}$ iff for every $i, 1 \leq i \leq n$ it holds $\theta_i \models A_i = a$.

Proof. ($i$) follows from the definitions. For ($ii$), we can pick the empty instance in which $R^I = \emptyset$, thus giving a counter example for subsumption. We show ($iii$). From the definition it follows that $\cap_{i=1}^n \pi_{A_i}(\sigma_{\theta_i}(R_i)) \subseteq_S \{a\}$ if and only if $[\pi_{A_i}(\sigma_{\theta_i}(R_i))]^I = a$ for every $i \in \{1, \ldots, n\}$ and every instance $I$ of $S$. For every $i \in \{1, \ldots, n\}$, if it holds that $\theta_i \models A_i = a$, then clearly $[\pi_{A_i}(\sigma_{\theta_i}(R_i))]^I = a$ for every instance $I$ of $S$. For the opposite direction, suppose there is a $j$ such that $\theta_j \not\models A_j = a$. Then let $J$ be an instance of $S$ such that $b \in R^J_j$, $b$ satisfies $\theta_j$ and $\pi_{A_j}(b) \neq a$. Then $[\pi_{A_j}(\sigma_{\theta_j}(R_j))]^J$ contains $\pi_{A_j}(b)$ which is not equal to $a$, a contradiction.

Thus from now on, we only deal with the subsumption problem for concepts that do not contain nominals.

Schema with UCQ-view definitions

In this section we assume a schema $(S, \Sigma)$, where $\Sigma$ is a collection of (nested) UCQ-view definitions. We first consider the simplest fragments of $L_S$.

Selection-free fragments of $L_S$

The complexity results for subsumption come from the known results for the containment problem of Datalog queries. For the semantics of Datalog we refer to Chapter 2. Let $\Pi_1$ and $\Pi_2$ be Datalog queries defined over the same set of extensional predicates $EDB$. We say that a Datalog query $\Pi_1$ is contained in a Datalog query $\Pi_2$, denoted as $\Pi_1 \subseteq \Pi_2$, if it holds $G_1^{\Pi_1(I)} \subseteq G_2^{\Pi_2(I)}$ for every instance $I$ over $EDB$, where $G_i$ is the goal predicate of $\Pi_i$. 

132
Claim 6.A.1. The containment problem for Datalog and the subsumption problem in $L_S^{\min}$ or selection-free $L_S$ with respect to $S$ are PTIME-equivalent.

Proof. (sketch) Let $\Sigma$ be a collection of nested UCQ-view definitions without comparisons. We may see it as a non-recursive Datalog program as was noted in Preliminaries.

- Reduction from the subsumption problem to the containment problem. We show the case of selection-free $L_S$, then the case of $L_S^{\min}$ follow. Let $C_1 = \Pi_{i=1}^{n_1} \pi_{A_1^i}(R_1^i)$ and $C_2 = \Pi_{j=1}^{n_2} \pi_{A_2^j}(R_2^j)$ be from selection-free $L_S$, and $C_1 \subseteq_S C_2$ an instance of the subsumption problem. We then define the Datalog query $\Pi_{i=1}^{n_1} \pi_{A_1^i}(R_1^i)$, $\Pi_{j=1}^{n_2} \pi_{A_2^j}(R_2^j)$ be from selection-free $L_S$ and $C_1 \subseteq_S C_2$ an instance of the containment problem. We show it is a non-recursive Datalog program as was noted in Preliminaries.

- Reduction from the containment problem to the subsumption problem. We show the reduction for the case $L_S^{\min}$, then the case of selection-free $L_S$ would follow. Let $\Pi_1 \subseteq \Pi_2$ be an instance of Datalog containment problem, and $EDB$ the common set of extensional predicates. Let $G_1$ and $G_2$ be the corresponding goal predicates. W.l.o.g. we can assume that both $G_1$ and $G_2$ are unary. Indeed, it can be shown that an $n$-ary ($n \geq 2$) containment can be reduced to a unary containment of Datalog queries. We define $C_i := \pi_1(G_i) = G_i$ and a schema $(S, \Sigma)$, where $S = EDB \cup IDB(\Pi_1) \cup IDB(\Pi_2)$ and $\Sigma = \Pi_1 \cup \Pi_2$ (written as nested UCQ-view definitions). Then it holds $\Pi_1 \subseteq \Pi_2$ if and only if $C_1 \subseteq \Pi_2$.

We make use of the following results that can be found in (Benedikt and Gottlob, 2010; Nutt, 2013; Shmueli, 1993).

Theorem 6.A.1. The containment problem $\Pi_1 \subseteq \Pi_2$, where $\Pi_1$ and $\Pi_2$ are Datalog queries, is undecidable. It is decidable and coNEXPTIME-complete if both $\Pi_1$ and $\Pi_2$ are non-recursive. The hardness result holds even for a fixed input schema. Additionally it is

1. $\Pi_2^P$-complete if both $\Pi_1$ and $\Pi_2$ linear;
2. NP-complete if $\Pi_1$ and $\Pi_2$ are collections of UCQ-view definitions, and
3. $\Pi_2^P$-complete if $\Pi_1$ and $\Pi_2$ are collections of UCQ-view definitions with comparisons.

In particular, item 3. follows from the results on containment of CQs with comparisons. In (Nutt, 2013) a $\Pi_2^P$ lower bound was shown where CQs have comparisons of type $x \text{op} c$, $\text{op} \in \{\leq, >\}$. Then using the reduction in Claim 6.A.1 and Theorem 6.A.1 we have the following.

Corollary 6.A.1. Let $S$ be a schema with a collection of view definitions $\Sigma$ as integrity constraints. The subsumption problem $C_1 \subseteq_S C_2$, where $C_1$ and $C_2$ are from $L_S^{\min}$ or selection-free $L_S$, is

a) coNEXPTIME-complete if $\Sigma$ is a collection of nested UCQ-view definitions without comparisons,
6. High-Level Why-Not Explanations using Ontologies

b) $\Pi^P_2$-complete if $\Sigma$ is a collection of linearly nested UCQ-view definitions without comparisons,

c) $\Pi^P_2$-complete if $\Sigma$ is a collection of UCQ-view definitions.

d) NP-complete if $\Sigma$ is a collection of UCQ-view definitions without comparisons.

In the next section we show that the upper bounds still hold even for the case of nested UCQ-view definitions with comparisons.

Full $L_S$

In this section we consider the subsumption problem for the concept language $L_S$ w.r.t. a schema with a collection of view definitions. For an upper bound, we reduce the subsumption problem to Datalog containment. Let $C_1 \sqsubseteq_S C_2$ be an instance of the subsumption problem for $L_S$.

We prove the following.

**Proposition 6.3.** Let $(S, \Sigma)$ be a schema with $\Sigma$ a collection of nested UCQ-view definitions, $C_1$ and $C_2$ concepts in $L_S$. Then there exist PTIME computable non-recursive Datalog queries $\Pi_1$ and $\Pi_2$ such that

$$C_1 \sqsubseteq_S C_2 \iff \Pi_1 \subseteq \Pi_2.$$ 

Moreover, if $\Sigma$ is linearly nested, then $\Pi_1$ and $\Pi_2$ are linear non-recursive Datalog queries.

**Proof.** Let $S, C_1$ and $C_2$ be as in the statement. It is convenient to represent $C_1$ and $C_2$ as conjunctive queries. This is done via the standard translation of relational algebra expressions to first order logic. Assume that $C_1(x)$ and $C_2(x)$ are (unary) conjunctive queries with arithmetic comparisons corresponding to $C_1$ and $C_2$ respectively. First we note that the subsumption problem $C_1 \sqsubseteq_S C_2$ is equivalent to the containment problem of two Datalog queries where the goal predicates are defined as $C_1(x)$ and $C_2(x)$ respectively. The latter containment can be reduced to Boolean containment of Datalog queries (in PTIME). Thus assume we have reduced our problem to Datalog containment $\Pi'_1 \subseteq \Pi'_2$, where $\Pi'_i$ has the form $\Pi \cup \{ G_i:Q_i \}$ with the Boolean goal predicates $G_i$. Note this reduction preserves the syntactic restrictions (i.e., non-recursiveness and linearity) on the datalog programs. Let $D$ denote EDB predicates.

Let $K \subseteq \text{Const}$ be the set of constants appearing in $\Pi'_1$ or $\Pi'_2$. For every constant $c \in K$ we introduce new unary EDB predicates $P_{op,c}, op \in \{\leq, =, >\}$. Additionally, we introduce a new unary EDB predicate $\text{Dom}(\cdot)$. Let $D^{op}$ be the set of the newly introduced unary predicates. Let $\Pi'_i, i = 1, 2$, denote the result of the following operations on $\Pi'_i$:

(i) Replace each occurrence of $x \text{op} c$ with $P_{op,c}(x), op \in \{\leq, =, \geq, <, >\}$. The predicates $P_{\leq c}$ and $P_{\geq c}$ are IDB predicates defined below.

(ii) For every rule of $\Pi'_i$ and every variable $x$ in the rule, add $\text{Dom}(x)$ to the antecedent of the rule.
Then we define $\Pi_1$ as follows.  
$\Pi_1 = \Pi'_1 \cup \Pi^{\leq \geq} \cup \Pi^{Dom}$ and $\Pi_2 = \Pi'_2 \cup \Pi^{\leq \geq} \cup \Pi^{Dom} \cup \{G_2 \ :- \ Bad\} \cup \Pi^{Bad}$. 
The program $\Pi^{\leq \geq}$ is defined by the following rules, for every $c \in C$:

$$P_{\leq c}(x) :- P_{< c}(x), \quad P_{\leq c}(x) :- P_{= c}(x), \quad P_{\geq c}(x) :- P_{= c}(x).$$

The program $\Pi^{Dom}$ is defined by the following rules, for every $c \in C$:

$$Dom(x) :- P_{= c}(x), \quad Dom(x) :- P_{< c}(x), \quad Dom(x) :- P_{> c}(x).$$

$Bad$ is a 0-ary IDB predicate defined by the program $\Pi^{Bad}$, which lists all possible inconsistencies that we try to avoid. For every $c, c_1, c_2 \in K$ such that $c_1 < c_2$ and $\text{op}_1, \text{op}_2 \in \{<, =, >\}$ with $\text{op}_1 \neq \text{op}_2$, $\Pi^{Bad}$ contains:

$$Bad :: P_{\text{op}_1 c}(x), P_{\text{op}_2 c}(x), \quad Bad :: P_{= c_1}(x), P_{= c_2}(x), \quad Bad :: P_{< c_1}(x), P_{> c_2}(x), \quad Bad :: P_{< c_1}(x), P_{= c_2}(x), \quad Bad :: P_{> c_1}(x), P_{= c_2}(x).$$

Additionally, if $(\text{Const}, <)$ has the left endpoint $c_l$ and/or the right end point $c_r$, then $\Pi^{Bad}$ also contains the rules

$$Bad :: P_{< c_1}(x), \quad Bad :: P_{> c_r}(x).$$

Moreover, for every $c_1$ and $c_2$ from $K$ such that $c_1 < c_2$ and there is no $c' \in \text{Const}$ with $c_1 < c' < c_2$, $\Pi^{Bad}$ contains:

$$Bad :: P_{> c_1}(x), P_{< c_2}(x).$$

Clearly $\Pi_1$ and $\Pi_2$ are PTIME computable and satisfy the syntactic restrictions (i.e., non-recursiveness and linearity). We claim that $\Pi'_1 \subseteq \Pi'_2$ iff $\Pi_1 \subseteq \Pi_2$. 

$(\Leftarrow)$. Suppose there is an instance $I'$ over $D$ such that $\Pi'_1(I') \models G_1$ and $\Pi'_2(I') \not\models G_2$. We then define an instance $I$ over $D \cup D^{op}$ as the instance with the same active domain as $I$. Moreover, the interpretation of EDB predicates is defined as follows.

- $R(\bar{a}) \in I$ iff $R(\bar{a}) \in I'$, for every $R \in D$,
- $P_{\text{op}_c}(a) \in I$ iff $a \in \text{adom}(I)$ and $(\text{Const}, <) \models a \text{op} c$, where $\text{op} \in \{=, <, >\}$,
- $\text{Dom}(a) \in I$ iff $a \in \text{adom}(I)$. 

135
6. High-Level Why-Not Explanations using Ontologies

It is straightforward to show that $\Pi_1(I) \models G_1$ and $\Pi_2(I) \not\models G_2$. In particular, to show the latter we use the fact that $Bad$ is not satisfied in $\Pi_2(I)$ by definition of the interpretations of the predicates $P_{\text{op}}$. Thus, we have provided a counterexample for $\Pi_1 \subseteq \Pi_2$.

$(\Rightarrow)$. Suppose there exists an instance $\tilde{I}$ over $D \cup D^{\text{op}}$ such that $\Pi_1(\tilde{I}) \models G_1$ and $\Pi_2(\tilde{I}) \not\models G_2$. We define a new instance $I$ as the restriction of $\tilde{I}$ to $\text{Dom}$, i.e., the domain is defined as $\text{adom}(I) = \{a \mid \text{Dom}(a) \in \tilde{I}\}$. Note that the extension of $\text{Dom}$ in $\Pi_1(I)$ and $\Pi_2(I)$ are the same and not empty. Note also that $I$ is still a counterexample for the containment $\Pi_1 \subseteq \Pi_2$, i.e., $\Pi_1(I) \models G_1$ and $\Pi_2(I) \not\models G_2$. We prove the following.

**Claim 6.A.2.** For every $a \in \text{adom}(I)$ there exists $c \in \text{Const}$ such that for every $c' \in K$ and $\text{op} \in \{<,=,>\}$ it holds

$I \models P_{\text{op}}c'(a) \text{ iff } (\text{Const}, <) \models \text{op} c'$.

**Proof.** By definition of $I$, it holds $\text{Dom}(a) \in I$ for every $a \in \text{adom}(I)$. This means that either $P_{=c}(a)$ or $P_{>c}(a)$ or $P_{<c}(a)$ holds in $I$ for every $c \in K$. In case $P_{=c}(a)$ holds in $I$, there is no other fact $P_{=c'}(a)$ in $I$ for some $c' \neq c$ because of $Bad$. Then using $Bad$ we can show that $I \models P_{\text{op}}c'(a) \text{ iff } (\text{Const}, <) \models \text{op} c'$. Thus, $c$ is as needed. Suppose there is no $c$ such that $I \models P_{=c}(a)$. Let $c_1$ be the maximal element of $K$ such that $P_{>c_1}(a) \in I$ and $c_2$ the minimal element of $K$ such that $P_{<c_2}(a) \in I$. In case $(\text{Const}, <)$ has endpoints, we have that $c_1 \leq c_2$ and $c_2 \leq c_2$ due to $Bad$. Furthermore, we have that $c_2$ is not the immediate successor of $c_1$ by $Bad$. Thus there exists $c \in \text{Const} \setminus K$ such that $c_1 < c < c_2$. Moreover, by the choice of $c$ for every $c' \in K$ it holds $I \models P_{\text{op}}c'(a) \text{ iff } (\text{Const}, <) \models \text{op} c'$.

We then define an instance $I'$ as the homomorphic image $f(I)$, where $f$ is such that for every $a \in \text{adom}(I)$ we define $f(a) = c$, where $c$ is as from Claim 6.A.2.

We need to show that (A) $\Pi_1'(I') \models G_1$ and (B) $\Pi_2'(I') \not\models G_2$.

This follows from the next claim. For a CQ with arithmetic comparisons $Q(\overline{x})$, by $\tilde{Q}(\overline{x})$ we denote the result of replacing each comparison $x \text{op} c$ with the atom $P_{\text{op}}c(x)$ and adding the conjunct $\text{Dom}(x)$.

**Claim 6.A.3.** Let $Q(\overline{x})$ be a CQ with arithmetic comparisons over $D \cup I\text{DB}(\Pi)$. Then

$$\overline{\Pi} \cup \Pi^{\leq,\geq} \cup \Pi^{\text{Dom}}(I) \models \tilde{Q}(\overline{a}) \text{ iff } \Pi(I') \models Q(f(\overline{a})).$$

**Proof.** The proof is by the induction on the depth of the datalog program. Base of induction: EDB predicates and arithmetic comparisons.

- Let $Q(x) = x \text{op} c$. Then $\overline{\Pi} \cup \Pi^{\leq,\geq} \cup \Pi^{\text{Dom}}(I) \models P_{\text{op}}c(a) \land \text{Dom}(a)$ iff $I \models P_{\text{op}}c(a)$ iff (by definition of $I'$) $I' \models f(a)\text{op} c$ iff $\Pi(I') \models f(a)\text{op} c$. The cases $\text{op} \in \{\leq,\geq\}$ can be treated similarly, though the predicates $P_{\leq c}$ and $P_{\geq c}$ are IDBs.
- $Q(\overline{x}) = R(\overline{x})$ for an EDB predicate $R$. Then $\overline{\Pi} \cup \Pi^{\leq,\geq} \cup \Pi^{\text{Dom}}(I) \models R(\overline{a}) \land \text{Dom}(a)$ iff $I \models R(\overline{a})$ iff (by definition of $I'$) $I' \models R(f(\overline{a}))$ iff $\Pi(I') \models R(f(\overline{a}))$.  

136
Step of induction. Let $R(\bar{x}) := R_1(\bar{x}, \bar{y}), \ldots, R_k(\bar{x}, \bar{y}), \text{Dom}(\bar{x}, \bar{y})$ be the rules in $\tilde{\Pi}$ defining $R(\bar{x})$, where each $R_i$ is a predicate over $D \cup D^{op} \cup \text{IDB}(\Pi)$. Then $\Pi \cup \Pi_{\leq \geq} \cup \Pi_{\text{Dom}}(\Pi) \models R(\bar{x})$ iff $\Pi \cup \Pi_{\leq \geq} \cup \Pi_{\text{Dom}}(\Pi) \models R_i(\bar{x}, \bar{b})$ \ldots $R_k(\bar{x}, \bar{b})$ for some $i$ and tuple $\bar{b}$ from $\text{dom}(\bar{I})$. By the induction hypothesis, the latter is equivalent to $\Pi(\bar{I}') \models R_i(f(\bar{\pi}), f(\bar{b})) \wedge \ldots \wedge R_k(f(\bar{\pi}), f(\bar{b}))$ (note if $R_j$ was from $D^{op}$, then it is replaced by the corresponding arithmetic comparison), which is equivalent to $\Pi(\bar{I}') \models R(f(\bar{\pi}))$. \hfill\square

We show how (A) and (B) follow from this claim. Recall $\Pi_1(I) \models G_1$, which is the same as $\Pi \cup \Pi_{\leq \geq} \cup \Pi_{\text{Dom}}(\Pi) \models \tilde{Q}_1$ for $Q_1$ being the body of the rule defining $G_1$. By Claim 6.A.3 it follows $\Pi(I') \models Q_1$, and thus $\Pi_2(I') \models G_2$. Similarly we can show (B). Indeed, suppose the opposite, i.e. $\Pi_2(I') \models G_2$. This is equivalent to $\Pi(I') \models Q_2$ for $Q_2$ being the definition of $G_2$. By Claim 6.A.3 it follows that $\Pi \cup \Pi_{\leq \geq} \cup \Pi_{\text{Dom}}(\Pi) \models \tilde{Q}_2$. This implies that $\Pi_2 \cup \Pi_{\leq \geq} \cup \Pi_{\text{Dom}}(\Pi) \models G_2$, which in turn implies $\Pi_2(I) \models G_2$, which is a contradiction. \hfill\square

Thus from Theorem 6.A.1 and Proposition 6.A.3 we obtain:

**Corollary 6.A.2.** Let $\Sigma$ be a schema with a collection of view definitions $\Sigma$ as integrity constraints. The subsumption problem $C_1 \sqsubseteq_S C_2$, where $C_1$ and $C_2$ are from $L_S$, is

a) In $\text{CONEXP}^\text{TIME}$ if $\Sigma$ is a collection of nested UCQ-view definitions,

b) In $\Pi_2^P$ if $\Sigma$ is a collection of linearly nested UCQ-view definitions.

### Schema with functional and inclusion dependencies

In this section we assume that the schema $S$ has functional and inclusion dependencies as integrity constraints. We first show that the subsumption problem w.r.t. $S$ is undecidable. We prove it by reduction from the implication problem for constraints.

**Definition 6.A.2.** Let $\text{IMPL}(C, D)$ be the following problem: given a set of constraints $\Sigma$ belonging to the class $C$ and a single constraint $\sigma$ belonging to the class $D$, decide whether $\Sigma \models \sigma$.

**Theorem 6.A.3** (Mitchell (1983), Chandra and Vardi (1985)). $\text{IMPL}(FDs + IDs, IDs)$ is undecidable.

Note that the undecidability result already holds in case the implied constraint $\sigma$ is unary inclusion dependency. We show the following.

**Claim 6.A.4.** The concept subsumption problem for $L^\text{min}_S$ w.r.t. $S$ is a special case of $\text{IMPL}(C, \text{UIDs})$ under the same set of constraints $\Sigma$ (where the set $\Sigma$ belongs to the class $C$).

**Proof.** Since $C_1, C_2 \in L^\text{min}_S$, they are of the form $\pi_A(R)$, i.e., unary projections over the relations of $S$. Let $C_1 = \pi_A(R)$ and $C_2 = \pi_B(S)$, where $R, S$ are two relation names and $A$ and $B$ are, respectively, attributes defined over $R$ and $S$ in $S$. Let $\sigma_C$ be the unary inclusion dependency $(\text{UID}) R[A] \subseteq S[B]$. Then $C_1 \sqsubseteq_S C_2$ iff $\Sigma \models \sigma_C$. \hfill\square

**Corollary 6.A.3.** The concept subsumption problem for $L^\text{min}_S$ w.r.t. $(S, \Sigma)$, where $\Sigma$ is a set of inclusion and functional dependencies is undecidable.
Subsumption for $\Sigma$ a set of Inclusion Dependencies

We begin with the concept subsumption problem for $L^\text{min}_S$ w.r.t. schema with a set of inclusion dependencies $\Sigma$. We assume familiarity with the chase procedure for inclusion dependencies (Abiteboul et al., 1995).

Let $\Sigma$ be a set of inclusion dependencies. We define a position graph $G\Sigma$ as follows.

**Definition 6.A.4.** Let $\Sigma$ be a set of inclusion dependencies. The position graph $G\Sigma$ of $\Sigma$ is a tuple $(V, E)$ such that $V = \{R[i] \mid R \in S, i \text{ an attribute of } R\}$ and $E = \{(R[i], Q[j]) \mid (R[\ldots,i,\ldots] \subseteq Q[\ldots,j,\ldots]) \in \Sigma\}$.

**Proposition 6.A.4.** Let $\Sigma$ be a set of inclusion dependencies, $\sigma$ a unary inclusion dependency $R[i] \subseteq Q[j]$. Then

$$\Sigma \models \sigma \iff Q[j] \text{ is reachable from } R[i] \text{ in } G\Sigma.$$  

**Proof.** ($\Rightarrow$). Suppose there is a path from $R[i]$ to $Q[j]$ in $G\Sigma$. Each edge of the path corresponds to the inclusion dependency $R_1[\ldots,A,\ldots] \subseteq R_2[\ldots,B,\ldots]$ in $\Sigma$. Thus, there is a sequence of inclusion dependencies in $\Sigma$ which derives $\sigma$.

($\Leftarrow$). Suppose $\Sigma \models R[i] \subseteq Q[j]$. Let $R(\overline{a})$ be a fact. Then it must hold that a fact $Q(\overline{b})$ with $b_j = a_i$ is contained in the result of chasing $\{R(\overline{a})\}$ with $\Sigma$. By induction on the length $L$ of the chase on $R(\overline{a})$ we show that $a_i$ is passed to reachable nodes only, i.e. if $Q(\ldots,a_i,\ldots) \in \text{chase}_\Sigma(\{R(\overline{a})\})$, then there is a path from $R[i]$ to $Q[j]$, where $j$ is the position in $Q$ where the value $a_i$ is.

$L = 0$. Trivially true since $R[i]$ is reachable from itself.

$L = k + 1$. Assume $Q(\overline{b})$, where $b_l = a_i$ for some $l$, is obtained by application of $\alpha = (P[\overline{a}] \subseteq Q[\overline{b}])$ to chase$_\Sigma(\text{chase}_\Sigma(\{R(\overline{a})\}))$. This means that there is a fact $P(\overline{c})$ in chase$_\Sigma(\{R(\overline{a})\})$ such that $c_j = a_i$ for some $j \in \overline{A}$. Hence, $P[j]$ is reachable from $R[i]$, by the induction hypothesis. Since also there is an edge from $P[j]$ to $Q[l]$, there is a path from $R[i]$ to $Q[l]$ as required.

Thus we can reduce the subsumption problem for $L^\text{min}_S$ w.r.t. $(S, \Sigma)$, where $\Sigma$ is a set of IDs, to graph reachability. Recall that graph reachability can be decided in PTIME.

**Corollary 6.A.4.** The concept subsumption problem for $L^\text{min}_S$ with respect to $(S, \Sigma)$, where $\Sigma$ is a set of IDs, can be solved in PTIME.

We then show that the subsumption problem for selection-free $L_S$ w.r.t. $(S, \Sigma)$, where $\Sigma$ is a set of IDs, can be reduced (in PTIME) to the one for $L^\text{min}_S$. This follows from the next two lemmas.

**Lemma 6.A.1.** Let $S$ be a schema, $C_1$ a concept in selection-free $L_S$, $C_2^j, j \leq n$ concepts in $L^\text{min}_S$. Then

$$C_1 \sqsubseteq_S C_2^1 \sqcap \ldots \sqcap C_2^n \iff C_1 \sqsubseteq_S C_2^j \text{ for every } j \leq n.$$  

**Proof.** ($\Rightarrow$). Let $I$ be an instance over $S$ and $a \in [C_1]^I$. Then by the assumption $a \in [C_2^1 \sqcap \ldots \sqcap C_2^n]^I$. The latter means that $a \in [C_j^j]^I$ for every $j, 1 \leq j \leq n$, as needed.

($\Leftarrow$). Let $I$ be an instance over $S$ and $a \in [C_1]^I$. By the assumption, $a \in [C_j^j]^I$ for every $j, 1 \leq j \leq n$, i.e., $a \in [C_2^1 \sqcap \ldots \sqcap C_2^n]^I$, as needed.
Lemma 6.A.2. Let $\Sigma$ be a set of IDs, and $(S, \Sigma)$ a schema. Then for concepts $C$, $C_1, \ldots, C_n \in L_S^\text{min}$ it holds,

$$C_1 \cap \ldots \cap C_n \sqsubseteq_S C \iff C_i \sqsubseteq_S C \text{ for some } i \leq n.$$ 

Proof. One direction (⇒) is trivial. We show (⇐). Suppose $C_i \not\sqsubseteq_S C$ for every $i \leq n$. There exist instances $I_i, i \leq n$ over $S$ such that each of $I_i$ is a counter-example for subsumption $C_i \not\sqsubseteq_S C$. We can assume that a constant $a$ witnesses every non-subsumption, i.e., $a \in [C_i]^{I_i}$ and $a \not\in [C]^{I_i}$. Let $I$ be the union of instances $I_i$. Note that $I$ satisfies $\Sigma$. Indeed, let $\sigma = (R_1[A] \subseteq R_2[B])$ be an inclusion dependency from $\Sigma$. Let for $\bar{a}$ it holds $R_1(\bar{a}) \in I$. This means that this fact holds in one of $I_i$. Since each $I_i$ satisfies $\sigma$, the fact $R_2(\bar{b})$ with $\bar{a}|_A = \bar{b}|_B$ holds in $I_i$. But this also means that this fact holds in the union $I$. Thus, $\sigma$ is satisfied in $I$. Moreover, $I$ is a counter-example for the subsumption $C_1 \cap \ldots \cap C_n \sqsubseteq_S C$, since $a \in [C_1 \cap \ldots \cap C_n]^{I}$ and $a \not\in [C]^{I}$. \hfill $\square$

Subsumption for $\Sigma$ a set of Functional Dependencies

We now consider the concept subsumption problem w.r.t. a schema $(S, \Sigma)$, where $\Sigma$ is a set of function dependencies.

We show that the subsumption problem is in PTIME.

Proposition 6.A.5. The concept subsumption problem for $L_S$ w.r.t $(S, \Sigma)$, where $\Sigma$ is a set of functional dependencies, is solvable in PTIME.

Proof. Recall that an order $(V, <)$ is dense if for every $x$ and $y$ in $V$ with $x < y$, there exists $z \in V$ such that $x < z$ and $z < y$.

Let $C_1$ and $C_2$ be $L_S$ concepts. It is convenient to consider them as unary CQ queries with comparisons. For a CQ $Q$ by $Var(Q)$ we denote the set of variables of $Q$.

Without loss of generality we may assume that CQs with comparisons are in normal form. We say that a CQ with a set of comparisons $\theta$ is in normal form if for every variable $x$ it holds that

- Either $\theta$ contains at most one equality of $x$ with a constant. Moreover, if such an equality occurs in $\theta$, then $\theta$ contains no other comparisons of $x$.

- Or $\theta$ contains at most one interval or semi-interval for $x$. That is, a semi-interval $x \leq c$, $x \geq c$, $x < c$, or $x > c$, or (open or closed) interval $c_1 \, \text{op}_1 \, x \, \text{op}_2 \, c_2$, where $\text{op}_1, \text{op}_2 \in \{<, \leq\}$. In case $(\text{Const}, <)$ contains a left endpoint, then $\theta$ contains at most one right semi-interval $x \geq c$ or $x > c$, or an interval for $x$. Similarly, if $(\text{Const}, <)$ contains a right endpoint, then $\theta$ contains at most one left semi-interval $x < c$ or $x < c$, or an interval for $x$.

Note that each CQ with comparisons can be converted (in PTIME) into an equivalent CQ with comparisons in normal form.

A generalized instance over $S$ and a set of variables $Var$ ($Var \cap \text{Const} = \emptyset$) is a set of relational facts of the form $R(x_1, \ldots, x_n)$ and comparisons $x \, \text{op} \, c$, where $R \in S, x_1, \ldots, x_n, x \in Var, \text{op} \in \{\,=, <, \geq\}$ and $c \in \text{Const}$, with the condition that $x$ must occur in some relational fact of $I$. We may assume that every consistent generalized instance is in normal form, as defined above for queries with comparisons.
For a generalized instance \( I \) and a conjunctive query \( Q \), by \( I \models Q \) we denote the fact that there is a homomorphism \( h \) from \( \text{Var}(Q) \), variables of \( Q \), to \( \text{Var} \) that preserves relational facts and arithmetic comparisons, that is, for a variable \( x \in \text{Var}(Q) \), the comparisons of \( h(x) \) must imply the comparisons \( \theta(x) \) of \( x \). By the canonical generalized instance \( I_Q \) of \( Q \) we mean the generalized instance consisting of the facts of \( Q \), i.e., the set \( \{ R(\bar{x}) \mid R(\bar{x}) \text{ is a conjunct of } Q \} \cup \{ x{\circ}pc \mid x{\circ}pc \text{ is a conjunct of } Q \} \). We may assume without loss of generality that relational facts do not contain constants since we can replace each constant by a fresh variable and equating it with the constant. For the algorithm, we use the chase technique adapted to deal with comparisons. Without loss of generality we may assume that every FD has one attribute as the consequent.

**Chase step.** Let \( I \) be a generalized instance over \( \text{Var} \). We assume there is a total order \( \leq_v \) on \( \text{Var} \). Let \( \sigma \) be an FD \( R : X \rightarrow B \). Let \( R(\bar{x}) \) and \( R(\bar{y}) \) be facts in \( I \) such that \( \pi_A(\bar{x}) = \pi_A(\bar{y}) \) for every \( A \in X \) and \( \pi_B(\bar{x}) \neq \pi_B(\bar{y}) \). By \( x \) and \( y \) we denote the variables \( \pi_B(\bar{x}) \) and \( \pi_B(\bar{y}) \), respectively. Let \( \theta(x) \) and \( \theta(y) \) be the comparisons of \( x \) and \( y \) in \( I \). Then the result of applying the FD to \( I \) is defined as follows, depending on the type of comparisons of \( x \) and \( y \). We consider all the possible cases for the shape of comparisons of \( x \) and \( y \) and depending on the cases either obtain “failure” or a variable \( z \) and the constraint \( \theta(z) \). Here \( z = \min_{\leq_v} \{ x, y \} \) and \( \omega = \max_{\leq_v} \{ x, y \} \). Then the result of applying FD is the instance \( I' \) obtained from \( I \) by substituting every occurrence of \( \omega \) with \( z \). Additionally, the constraint \( \theta(z) \) is added to \( I' \) and the old comparisons \( \theta(x) \) and \( \theta(y) \) are discarded.

- \( \theta(x) \) is \( x = c_1 \) and \( \theta(y) \) is \( y = c_2 \). Then “failure”.
- \( \theta(x) \) is \( x = c_1 \) and \( \theta(y) \) is constraints involving inequality only. If \( c_1 \) does not satisfy \( \theta(y) \), then “failure”. Otherwise, let \( \theta(z) \) be \( z = c_1 \).
- \( \theta(x) \) is \( c_1 \leq x \leq c_2 \) and \( \theta(y) \) is \( c_1 \leq y \leq c_2 \). If \( \{ c_1 \leq x \leq c_2 \} \cap \{ c_1 \leq y \leq c_2 \} = \emptyset \), then “failure”. Otherwise, let \( \theta(z) \) be \( c_1 \leq z \leq c_2 \), where \( c_1 = \max \{ c_1, c_1 \} \) and \( c_2 = \min \{ c_2, c_2 \} \).
- \( \theta(x) \) is \( c_1 \leq x \leq c_2 \) and \( \theta(y) \) is \( c_1 \leq y \leq c_2 \). If \( \{ c_1 \leq x \leq c_2 \} \cap \{ c_1 \leq y \leq c_2 \} = \emptyset \), then the result is “failure”. Otherwise, let \( \theta(z) \) be \( c_1 \text{op}_1 z \text{op}_2 c_2 \), where \( c_1 = \max \{ c_1, c_1 \} \), \( c_2 = \min \{ c_2, c_2 \} \), and \( \text{op}_1 \) is “\( \leq \)” if \( c_1 \) is \( c_1 \) and “\( < \)” otherwise, and \( \text{op}_2 \) is “\( < \)” if \( c_2 \) is \( c_2 \) and “\( \leq \)” otherwise.
- \( \theta(x) \) is \( x \text{op}_1 c_2 \), where \( \text{op}_1 \in \{ \leq, < \} \) and \( \theta(y) \) is \( y \text{op}_2 c_1 \), where \( \text{op}_2 \in \{ \geq, > \} \). If \( c_2 < c_1 \), then “failure”. Otherwise, let \( \theta(z) \) be \( c_1 \text{op}_2 c_2 \).
- Other cases are similar.

By \( I \rightarrow_{\sigma} I' \) we denote a chase step, where \( I' \) is the result of applying \( \sigma \) to \( I \).

**Chase sequence.** Let \( \Sigma \) be a set of FDs, and let \( I \) be a generalized instance over \( \text{Var} \). A chase sequence of \( I \) with \( \Sigma \) is a sequence of chase steps \( I_i \rightarrow_{\sigma} I_{i+1} \), with \( I_0 = I \) and \( \sigma \in \Sigma \). A finite chase of \( I \) with \( \Sigma \) is a finite chase sequence of length \( m \) with the requirement that either \( I_m \) = “failure” or there is no \( \sigma \in \Sigma \) that can be applied to \( I_m \). Then \( I_m \) is the result of the finite chase of \( I \) with \( \Sigma \), denoted as \( \text{chase}_\Sigma(I) \). The following facts can be proved similarly as for the classical chase for FDs.
Lemma 6.A.3. Let $I$ be a generalized instance and $\Sigma$ a set of FDs. Then every chase sequence of $I$ with $\Sigma$ is a finite chase of $I$ with $\Sigma$. Moreover, the length of the sequence is bounded by a polynomial in the size of $I$ and $\Sigma$.

Lemma 6.A.4. Let $I$ be a generalized instance and $\Sigma$ a set of FDs. Let $I_m$ be the result of a finite chase of $I$ with $\Sigma$ such that $I_m \neq \text{“failure”}$. Then $I_m$ satisfies $\Sigma$. If there exists a finite chase of $I$ with $\Sigma$ with the result “failure”, then there is no instance that satisfies $\Sigma$.

Lemma 6.A.5. Let $I_1 \rightarrow_\sigma I_2$ be a chase step, where $I_2 \neq \text{“failure”}$. Let $I$ be a generalized instance such that (i) $I$ satisfies $\sigma$ and (ii) there exists a homomorphism $h_1 : I_1 \rightarrow I$. Then there exists a homomorphism $h_2 : I_2 \rightarrow I$.

Our algorithm would proceed as follows. Let $Q_1$ be the CQ with comparisons corresponding to $C_i$. Clearly, $C_1 \subseteq S C_2$ iff $Q_1$ is contained in $Q_2$ w.r.t. $\Sigma$. The latter can be reduced to containment of Boolean queries and thus w.l.o.g. we can assume that $Q_1$ and $Q_2$ are Boolean. Note that for a concept from $\text{Const}, <$ is an infinite dense order, for every variable in $\text{chase}_\Sigma(I_{Q_1})$ we can assign a distinct constant such that every comparison in $\text{chase}_\Sigma(I_{Q_1})$ is satisfied. Let $I$ be the instance obtained from $\text{chase}_\Sigma(I_{Q_1})$ by this assignment. We have that $I \models Q_1$ and $I$ satisfies $\Sigma$. By assumption, it holds that $I \models Q_2$, i.e., there is a homomorphism $h : Q_2 \rightarrow I$. Since the assignment of the variables in $\text{chase}_\Sigma(I_{Q_1})$ is 1-1, we have that there is a homomorphism $g : Q_2 \rightarrow \text{chase}_\Sigma(I_{Q_1})$, i.e., $\text{chase}_\Sigma(I_{Q_1}) \models Q_2$, as needed.

Note that the conditions of Claim 6.A.5 can be checked in $\text{PTIME}$ according to Lemma 6.A.6 below.

Note that for a concept from $L_S$, the corresponding translation to first order logic is a CQ with comparisons of the form $\Phi(x, \bar{y}), \theta(x), \theta'(\bar{y})$, where $\Phi$ is a conjunction of atoms $R_i$ such that for $i \neq j$ it holds $\text{Var}(R_i) \cap \text{Var}(R_j) = \{x\}$, $\theta(x)$, and $\theta'(\bar{y})$
are comparisons. In the above proof we reduced the containment of such queries to Boolean containment. The corresponding Boolean CQ with comparisons has the form $P(z, x), \Phi(x, \overline{y}), \theta(x), \theta'(\overline{y})$, where $P$ is a fresh relational symbol. We show that such queries can be evaluated over a generalized instance in PTIME.

**Lemma 6.A.6.** Let $I$ be a generalized instance over $\mathcal{S}$ and $\text{Var}$, $Q$ the Boolean CQ with comparisons corresponding to a $L_\mathcal{S}$ concept. Then deciding if $I \models Q$ can be done in PTIME.

**Proof.** Checking $I \models Q$ amounts to checking existence of a homomorphism $h : \text{Var}(Q) \rightarrow \text{Var}$ such that

- if $R(\overline{x}) \in Q$ then $R(h(\overline{x})) \in I$,
- the comparisons of $h(x)$ must imply the comparisons of $x$.

From the above discussion we have that $Q$ has the form $\Phi(x, \overline{y}), \theta(x), \theta'(\overline{y})$, where $\Phi$ is a conjunction of atoms such that for $R_i, R_j \in \Phi, i \neq j$, it holds $\text{Var}(R_i) \cap \text{Var}(R_j) = \{x\}$, $\theta(x)$ and $\theta'(\overline{y})$ are comparisons. We provide the following algorithm. For each atom $R_i(x, \overline{y})$ (w.l.o.g. we can assume that $x$ is in the first attribute) in $Q$, we compute the set $\text{Var}_i = \{z \in \text{Var} \mid R_i(z, \overline{w}_i) \in I, \theta(z) = \theta(x), \theta'(\overline{w}_i) = \theta'(\overline{y})\}$. Such set can be computed in PTIME. Then $I \models Q$ if and only if $\cap_i \text{Var}_i \neq \emptyset$. 

\[\square\]

## 6.B Missing proofs of Section 5

### 6.B.1 Proofs for Section 6.5.1

**Theorem 6.5.1.**

(i) The problem **Check-MGE** is solvable in PTIME.

(ii) The problem **Existence-of-explanation** is NP-complete. It remains NP-complete even for bounded schema arity.

**Proof.**

(i) First, given a tuple of concepts $E = (C_1, \ldots, C_m)$, we can check in PTIME if $E$ is an explanation. Then, to check if $E$ is a most-general explanation, we need to check if for each $i$, the concept $C_i$ cannot be replaced by a concept $C'_i$ such that $C_i \sqcap \circ C'_i$ by keeping an empty intersection with $\text{Ans}$. Thus, for each position $i$ in $E$, we try to replace $C_i$ with all the possible concepts in $\mathcal{C} \setminus \{C_i\}$, which can be done in PTIME.

(ii) First, for membership in NP, we can guess a tuple of concepts of polynomial size, and check in PTIME if it is an explanation.

Secondly, we prove hardness via a reduction from **Set Cover**. Let us first recall the problem: given a triple $(S, X, k)$, where $S$ is a set, $X$ is a set containing subsets of $S$, and $k$ is an integer, **Set Cover** is the problem of deciding if there exists a subset of $X$ of size $k$ such that the union of the elements in the subset covers $S$. Given an instance $(S, X, k)$ of **Set Cover**, we build an instance of **Existence-of-explanation** with bounded schema arity.
Let the why-not instance \((S, I, q, Ans, \overline{a})\) be defined as:

\[
S = \{R(A)\}
\]
\[
I = \{R(s) \mid s \in S\}
\]
\[
q(x, \ldots, x) \dashv R(x) \text{ where the arity of } q \text{ is } k
\]
\[
\overline{a} = (a, \ldots, a) \text{ for some arbitrary } a \notin S
\]

Let \(O = (C, \subseteq, ext)\) be the S-ontology defined as:

\[
C = \{C_Y \mid Y \in \mathcal{X}\}
\]
\[
\subseteq = \{(C_Y, C_K) \mid K \subseteq Y\}
\]
\[
\text{ext}(C_Y, I) = S \cup \{a\} \setminus Y, \text{ for each } Y \in \mathcal{X}
\]

Note that \(I\) is consistent with \(O\). Indeed, \(C_Y \subseteq C_K\) is equivalent to \(K \subseteq Y\) which in turn implies \(S \cup \{a\} \setminus Y \subseteq S \cup \{a\} \setminus K\), i.e., \(\text{ext}(C_Y, I) \subseteq \text{ext}(C_K, I)\). Then we show that there exists a set cover of size \(k\) for \(S\) iff the answer for EXISTENCE-OF-EXPLANATION is “yes”.

\((\Rightarrow)\). Let \(Y_1, \ldots, Y_k\) be a solution for SET COVER. We show that \(E = (C_1, \ldots, C_k)\), where \(C_i = C_{Y_i}\), is an explanation for \(\overline{a} \notin Ans\).

Assume, towards a contradiction, that \(E\) is not an explanation for \(\overline{a} \notin Ans\). Then one of the following conditions must hold: (i) there exists \(C_i\) such that \(a \notin \text{ext}(C_i, I)\); (ii) \(\text{ext}(C_1, I) \times \ldots \times \text{ext}(C_k, I) \cap \text{Ans} \neq \emptyset\). Both these conditions lead to contradiction. In particular, by construction, for each \(i, a \in C_i\), which refutes (i). Suppose that (ii) holds. Then there exists an element \(s \in S\) such that for each \(i, s \in \text{ext}(C_i, I)\) and thus \(s \notin Y_i\) (since \(\text{ext}(C_i, I)\) is the complement of \(Y_i\) w.r.t. \(S \cup \{a\}\)). But this contradicts the assumption that \(Y_1, \ldots, Y_k\) is a set cover.

\((\Leftarrow)\). Let \(E = (C_1, \ldots, C_k)\), where \(C_i = C_{Y_i}\), be an explanation for \(\overline{a} \notin Ans\). We show that \(Y_1, \ldots, Y_k\) is a solution for SET COVER.

Suppose, towards a contradiction, that \(Y_1, \ldots, Y_k\) is not a set cover. Thus there exists at least one element \(s \in S\) such that \(s \notin Y_i\) for each \(i\), which, in turn, implies that \(s \in \text{ext}(C_i, I)\) for each \(i\). But then \(\text{ext}(C_1, I) \times \ldots \times \text{ext}(C_k, I) \cap \text{Ans} \neq \emptyset\), which contradicts the assumption that \(E\) is an explanation.

**Theorem 6.5.2.** Let a why-not instance \((S, I, q, Ans, \overline{a})\) and an S-ontology \(O\) be an input to EXHAUSTIVE SEARCH ALGORITHM and let \(X\) be the corresponding output. The following hold:

(i) \(X\) is the set of all most-general explanations for \(\overline{a} \notin Ans\) (modulo equivalence);

(ii) EXHAUSTIVE SEARCH ALGORITHM runs in ExpTime in the size of the input (in PTIME if we fix the arity of the input query).

**Proof.** (i) (Correctness) We show the correctness of EXHAUSTIVE SEARCH ALGORITHM by proving the following claims: (a) every most-general explanation belongs to \(X\); (b) every \(E \in X\) is a most-general explanation.
Suppose $E$ is a most-general explanation for $\overline{a} \notin \text{Ans}$. Since $E$ is an explanation, by definition its extension contains $\overline{a}$ and does not intersect $\text{Ans}$, thus it is part of $\mathcal{X}$ at the beginning (line 2). Moreover, since it is a most-general explanation, there is no explanation $E' \in \mathcal{X}$ such that $E' \supset \mathcal{O} E$, thus the test in line 4 fails and $E$ is never removed from $\mathcal{X}$. This proves claim (a). Suppose there exists an element $E \in \mathcal{X}$ that is not a most-general explanation for $\overline{a} \notin \text{Ans}$. First, observe that $E$ must be an explanation, otherwise it could not be in $\mathcal{X}$, according to line 2. Then it must be the case that there exists an explanation $E'$ such that $E' \supset \mathcal{O} E$. We may assume w.l.o.g. that $E'$ is a most-general explanation. Then, as proved in point (a), $E' \in \mathcal{X}$, therefore the pair $E, E'$ would have been considered for the comparison in line 4, and $E$ would have been removed from $\mathcal{X}$, which leads to a contradiction and proves point (b).

(ii) *(Running time)* First, notice that the extension $\text{ext}(C, I)$ of a concept is polynomial-time computable by definition. Let us call $p(k + |\text{adom}(I)|)$ this polynomial, where $k$ is the maximal size of concepts from $C$. Then, building each set $C(a_i)$ at line 1 requires $O(|C| \cdot p(k + |\text{adom}(I)|))$. Building the set $\mathcal{X}$ at line 2 requires $O((m \cdot ||C| \cdot p(k + |\text{adom}(I)|))m \cdot |\text{Ans}|)$, where $m$ is the arity of $q$. Finally, the steps from line 3 to 5 require $O(|C|^{2m})$ since the size of $X$ is bounded by $|C|^m$. Therefore the algorithm runs in $O(|C| \cdot p(k + |\text{adom}(I)|) + (m \cdot |C| \cdot p(k + |\text{adom}(I)|))m \cdot |\text{Ans}| + |C|^{2m})$, which is exponential in the size of the input. For a fixed $m$, the size of the query, the algorithm becomes polynomial.

### 6.2 Proofs for Section 6.5.2

**Proposition 6.5.1.** Let $(S, I, q, \text{Ans}, \overline{a})$ be a why-not instance. If $E$ is an explanation for $\overline{a} \notin \text{Ans}$ w.r.t. $\mathcal{O}_1$ (resp. $\mathcal{O}_S$), then there exists an explanation $E'$ for $\overline{a} \notin \text{Ans}$ such that $E \subset \mathcal{O}_1[\mathcal{K}] E'$ (resp. $E \subset \mathcal{O}_S[\mathcal{K}] E'$), where $\mathcal{K} = \text{adom}(I) \cup \{a_1, \ldots, a_m\}$ and each constant in $E'$ belongs to $\mathcal{K}$.

**Proof.** Before turning to the proof we note that each (consistent) selection expression is equivalent to a selection expression of the form $\sigma_C(R)$, where $C$ is a list of comparisons such that for every attribute name $A$, $C$ has at most one occurrence of $A < c_1$ or $A \leq c_1$ for arbitrary $c_1 \in \text{Const}$, and at most one occurrence of $A > c_2$ or $A \geq c_2$ for arbitrary $c_2 \in \text{Const}$. Additionally, if $C$ contains an expression $A = c$, then it is the only expression in $C$ mentioning the name $A$. From now on we assume that the selection expressions have this normalized form.

Let $I$ be an instance, $\overline{a} = (a_1, \ldots, a_m)$ a tuple of elements from $\text{Const}$, and $q$ a query such that $\overline{a} \notin \text{Ans}$. By $\mathcal{K}$ we denote the set $\text{adom}(I) \cup \{a_1, \ldots, a_m\}$. Let $E$ be of the form $(E_1, \ldots, E_n)$, where each $E_i$ is a conjunction $E_i^1 \land \ldots \land E_i^{l(i)}$ of atomic concepts of the form $\pi_A(\sigma_C(R))$ or nominals $\{c\}$. If $E$ contains only concepts that use values from $\mathcal{K}$ then there is nothing to prove. Suppose otherwise. First we note that all the nominal concepts in the conjunction $E_i$ must be exactly $\{a_i\}$, since otherwise $a_i \notin \text{ext}(E_i)$ which is a contradiction. Thus we only consider the case when a constant outside of $\mathcal{K}$ appears in a selection expression. For this, we iteratively apply the following procedure producing a more general explanation containing less concepts which contain
values outside of $\mathcal{K}$. Suppose there are indices $i$ and $j$ such that $E_j$ is a conjunct of $E_i$ of the form $\pi_A(\sigma_C(R))$ and $C$ contains an expression $B \circ p_c$ where $c \notin \mathcal{K}$. We show that we can replace $C$ with $C'$ that does not contain the expression anymore, resulting in an explanation $E'$ that is more general than $E$.

We distinguish the following cases.

- $\text{op} \in \{\leq, <\}$. Note $C$ contains only one expression of the form $B \circ p_c$. We distinguish two cases: when there exists or not $c'' \in \mathcal{K}$ such that $c < c''$.

  - There exists $c'' \in \mathcal{K}$ such that $c < c''$. Let $c'$ be an element of $\mathcal{K}$ which is closest to $c$ from above, i.e. $c' = \min\{c_1 \mid c < c_1$ and $c_1 \in \mathcal{K}\}$. Note such $c'$ exists due to the assumption $c'' \in \mathcal{K}$. Let $E'$ be the tuple of concepts obtained from $E$ by replacing $E_j = \pi_A(\sigma_C(R))$ with the concept $E_j^{\prime} = \pi_A(\sigma_{C'}(R))$, where $C' = (C \setminus \{B \circ p_c\}) \cup \{B < c'\}$.

    We claim that $E_j^{\prime}$ is an explanation that is more general than $E$. First, it is easy to see that for every $k \leq m$ it holds $a_k \in ext(E_k, I)$. Indeed, we only need to check that $a_i \in ext(E_j^{\prime}, I)$. Since $a_i \in ext(E_j^{\prime}, I)$, there is a tuple $\bar{b} \in R^l$ such that $\pi_A(\bar{b}) = a_i$ and $\pi_B(\bar{b}) \circ p_c$. By the choice of $c'$, we also have $\pi_B(\bar{b}) < c'$. Thus, the tuple $\bar{b}$ is a witness for $a_i \in ext(E_j^{\prime}, I)$.

    Now we show the extension of $E'$ does not intersect with the query answer. Suppose the opposite, there exists a tuple $\bar{b} \in (ext(E_1, I) \times \ldots \times ext(E_i, I) \times \ldots \times ext(E_n, I)) \cap \text{Ans}$. This implies $b_i \in ext(E_j^{\prime}, I)$ and thus there exists a tuple $\bar{d} \in R^l$ such that $\pi_A(\bar{d}) = b_i$ and $\pi_B(\bar{d}) < c'$. Note that each element of $\mathcal{K}$ is a conjunct of $\mathcal{K}$.

    Note that by construction, for every tuple $\bar{\pi}$ with $\pi_A(\bar{\pi}) = b_i$ and $\pi_B(\bar{\pi}) < c'$ it holds $\pi_B(\bar{\pi}) > c$. Indeed, otherwise $\bar{b} \in (ext(E_1, I) \times \ldots \times ext(E_i, I) \times \ldots \times ext(E_n, I)) \cap \text{Ans}$, which is a contradiction. Thus we have that $c < \pi_B(\bar{d}) < c'$ and $\pi_B(\bar{d}) \in \mathcal{K}$, which is a contradiction with the choice of $c'$.

    We show that $E'$ is more general than $E$ w.r.t. $\mathcal{O}_S$ (w.r.t. $\mathcal{O}_I$ would then follow). To this purpose, it is enough to show that $E_j^{\prime} \subseteq S E_j^{\prime}$. Let $I'$ be an arbitrary instance of $S$, and $b \in ext(E_j^{\prime}, I')$. This means there exists a tuple $\bar{d}$ such that $\pi_A(\bar{d}) = b$ and $\pi_B(\bar{d}) < c$. Since $c < c'$, we also have $\pi_B(\bar{d}) < c'$ and thus $b \in ext(E_j^{\prime}, I')$ as needed.

- There is no $c'' \in \mathcal{K}$ with $c < c''$. In this case let $E'$ be obtained from $E$ by replacing $E_j = \pi_A(\sigma_C(R))$ with the concept $E_j^{\prime} = \pi_A(\sigma_{C'}(R))$, where $C' = C \setminus \{B \circ p_c\}$. If $C'$ is empty, we take $E_j^{\prime} = \pi_A(R)$. Similarly to the previous case, it is easy to show that for every $k \leq m$, it holds $a_k \in ext(E_k, I)$. Suppose that there exists a tuple $\bar{b} \in (ext(E_1, I) \times \ldots \times ext(E_i, I) \times \ldots \times ext(E_n, I)) \cap \text{Ans}$. This implies $b_i \in ext(E_j^{\prime}, I)$ and thus there exists a tuple $\bar{d} \in R^l$ such that $\pi_A(\bar{d}) = b_i$ and $\bar{d}$ satisfies the constraints $C'$. Note that $\pi_B(\bar{d}) < c$ since $\pi_B(\bar{d}) \in \mathcal{K}$, $c \notin \mathcal{K}$ and there is no $c'' \in \mathcal{K}$ with $c < c''$. But
this implies that $\overline{b} \in (\text{ext}(E_1, I) \times \ldots \times \text{ext}(E_i, I) \times \ldots \times \text{ext}(E_n, I)) \cap \text{Ans}$ which is a contradiction.

Similarly to the previous case we can show that $E'$ is more general than $E$ w.r.t. $\mathcal{O}_S$. This holds essentially because we make the selection expression weaker, thus making $E'$ more general than $E$.

- $\text{op} \in \{\geq, >\}$. The argument is similar to the previous case. We either take the closest $c'$ from $K$ with $c' < c$ or remove the constraint $B_{\text{op}c}$.

Lemma 6.5.1. Given an instance $I$ of schema $S$ and a set of constants $X$, we can compute in polynomial time a selection-free $L_S$ concept, denoted $\text{lub}_I(X)$, that is the smallest concept whose extension contains all the elements in $X$ definable in the language. In particular, the following hold:

(i) $X \subseteq \text{ext}(\text{lub}_I(X), I)$,

(ii) there is no concept $C'$ in selection-free $L_S$ such that $C' \sqsubseteq_I \text{lub}_I(X)$ and $X \subseteq \text{ext}(C', I)$.

Proof. Let $\text{lub}_I(X) = \bigcap \{C \mid C \in L_S^{\text{min}}(\mathcal{K}) \text{ and } X \subseteq \text{ext}(C, I)\}$.

The first item holds by construction: for each conjunct $C$ of $\text{lub}_I(X)$, $\text{ext}(C, I)$ contains $X$. For the second item, suppose there exists a concept $C'$ such that $C' \sqsubseteq_I \text{lub}_I(X)$ and $X \subseteq \text{ext}(C', I)$. But since $X \subseteq \text{ext}(C', I)$, $C'$ must be in the conjunction defining $\text{lub}_I(X)$, which contradicts the fact that $C' \sqsubseteq_I \text{lub}_I(X)$.

Theorem 6.5.3 (Correctness and running time of \textsc{Incremental Search Algorithm}).

Let the why-not instance $(S, I, q, \text{Ans}, \overline{a})$ be an input to \textsc{Incremental Search Algorithm} and $E$ the corresponding output. The following holds:

(i) $E$ is a most-general explanation for $\overline{a} \notin \text{Ans}$ w.r.t. $\mathcal{O}_I = (C, \sqsubseteq_I, \text{ext})$, where $C$ is selection-free $L_S$;

(ii) \textsc{Incremental Search Algorithm} runs in PTime in the size of the input.

Proof. (i) (Correctness) First, observe that $E$ is an explanation. In particular, in the worst case $E$ is the trivial explanation that has in each position $j$ the nominal corresponding to the constant $a_j$ in the input tuple $\overline{a}$. Then, the proof builds on Lemma 6.5.1.

Now suppose that $E = (C_1, \ldots, C_m)$ is not a most-general explanation for $\overline{a} \notin \text{Ans}$. That is, there exists an explanation $E' = (C'_1, \ldots, C'_m)$ for $\overline{a} \notin \text{Ans}$ that is strictly more general than $E$, i.e., $E' \succ_{\mathcal{O}_I} E$. Thus, by definition, $C_j \sqsubseteq C'_j$ for every $j$, $1 \leq j \leq m$. Let $X = (X_1, \ldots, X_m)$ the support set used by the algorithm for computing $E$. Since $E' \succ_{\mathcal{O}_I} E$, there exists a position $j$ for which $C_j \sqsubseteq C'_j$, implying that $\text{ext}(C_j, I) \subseteq \text{ext}(C'_j, I)$. Let $b$ be an element in $\text{ext}(C'_j, I) \setminus \text{ext}(C_j, I)$. Then, since $b$ would have been considered in line 5, if it is not in $X_j$ it must be the case that adding it would cause the resulting explanation to intersect $\text{Ans}$. But $b \in \text{ext}(C'_j, I)$, thus $E' \cap \text{Ans} \neq \emptyset$, i.e., $E'$ is not an explanation, which contradicts our assumption. Finally, observe that \textsc{Incremental Search Algorithm} outputs a most-general explanation for $\overline{a} \notin \text{Ans}$ w.r.t. $\mathcal{O}_I[\mathcal{K}]$, but Proposition 6.5.1 guarantees that we can restrict to $\mathcal{O}_I[\mathcal{K}]$, with $\mathcal{K} = \text{dom}(I) \cup \{a_1, \ldots, a_m\}$, without losing any most-general explanation.
The following hold:

(ii) \textbf{(Running time)} Let $|L^\min_S|$ the number of distinct concept expressions, up to logical equivalence, that can be defined in $L^\min_S$ and let $m$ be the arity of $q$. First, observe that initializing the support set (line 2) takes $m$ steps, and that building the first candidate explanation (line 3) takes $O(m \cdot |L^\min_S| \cdot p(|\text{adom}(I)|)$, since each $\lub_I(X_j)$ takes $|L^\min_S| \cdot p(|\text{adom}(I)|)$ steps. Moreover, the nested for-loop (lines 4–11) takes $O(m \cdot |\text{adom}(I)| \cdot |L^\min_S| \cdot p(|\text{adom}(I)|))$. Thus the running time of the algorithm is $O(m + (m \cdot |L^\min_S| \cdot p(|\text{adom}(I)|)) \cdot (1 + |\text{adom}(I)|))$, and since $|L^\min_S|$ is polynomial in the size of $S$ (see Proposition 6.4.2), we can conclude that \textsc{Incremental Search Algorithm} runs in PTIME. \qed

\textbf{Lemma 6.5.2.} Given an instance $I$ of $S$ and a set of constants $X$, we can compute in exponential time a $L_S$ concept, denoted $\lub_I^\sigma(X)$, that is the smallest concept whose extension contains all the elements in $X$ definable in the language. Such a concept is polynomial-time computable for bounded schema arity. In particular, the following hold:

(i) $X \subseteq \text{ext}(\lub_I^\sigma(X), I)$,

(ii) there is no concept $C'$ in $L_S$ such that $C' \sqsubseteq_I \lub_I^\sigma(X)$ and $X \subseteq \text{ext}(C', I)$.

\textbf{Proof.} Let $\lub_I^\sigma(X) = \bigcap \{C \mid C = \text{intersection-free } L_S \text{ and } X \subseteq \text{ext}(C, I)\}$.

The proof is analogous to the proof of Lemma 6.5.1. In this case, however, the bound on the number of distinct concept definable via intersection-free $L_S$ is single exponential (see Proposition 6.4.2), therefore the set can be computed in EXPTIME. If we bound the arity of the schema, the bound on the number of concepts in intersection-free $L_S$ becomes polynomial, thus in this case $\lub_I^\sigma(X)$ can be computed in PTIME. \qed

\textbf{Theorem 6.5.4} (Correctness and running time of \textsc{Incremental Search Algorithm with Selections}. Let the why-not instance $(S, I, q, \text{Ans}, \overline{a})$ be an input to \textsc{Incremental Search Algorithm with Selections} and $E$ the corresponding output. The following hold:

(i) $E$ is a most-general explanation for $\overline{a} \notin \text{Ans}$ w.r.t. $O_I = (C, \sqsubseteq_I, \text{ext})$, where $C$ is $L_S$;

(ii) \textsc{Incremental Search Algorithm} runs in EXPTIME in the size of the input (in PTIME for bounded schema arity).

\textbf{Proof.} Both correctness (1) and running time (2) follow from the analysis in Theorem 6.5.3, and from the fact that in this case Lemma 6.5.2 guarantee that there is no explanation $E'$ using concepts from $L_S$ such that $E' >_O E$, and also that $\lub_I^\sigma(X)$ is exponential-time computable (polynomial-time computable for bounded schema arity). \qed

\textbf{6.5.3 Proofs for Section 6.5.3}

\textbf{Proposition 6.5.3.} There is an algorithm that solves \textsc{Compute-One-MGE} w.r.t. $O_S$

\begin{itemize}
  \item in 2EXPTIME for $L_S$, provided that the input schema $S$ is from a class for which concept subsumption can be checked in EXPTIME,
\end{itemize}
6. High-Level Why-Not Explanations using Ontologies

- in \textsc{ExpTime} for selection-free \(L_S\), and projection-free \(L_S\), provided that the input schema \(S\) is from a class for which concept subsumption can be checked in \textsc{ExpTime},

- in \textsc{PTime} for \(L_{S_{\text{min}}}\), if the arity of \(q\) is fixed and provided that the input schema \(S\) is from a class for which concept subsumption can be checked in \textsc{PTime}.

\textbf{Proof.} First, from Proposition 6.4.2, it follows that the number of distinct concept expressions that one can build up to logical equivalence is at most single exponential for selection-free or intersection-free \(L_S[K]\), and double exponential for \(L_S[K]\). Next, the computation of \(\sqsubseteq_S\) would require testing concept subsumption for exponentially many pairs of concepts. Moreover, since the \textit{ext} function is polynomial-time computable, we can therefore build \(O_S[K]\) in \textsc{ExpTime} for selection-free or intersection-free \(L_S[K]\), and in \(2\textsc{ExpTime}\) for the concept language \(L_S[K]\).

This gives us bounds on materializing \(O_S[K]\) depending on the concept language. Then we can use \(O_S[K]\) as input for \textsc{Exhaustive Search Algorithm}, and solve \textsc{Compute-one-MGE w.r.t.} \(O_S\).

We know, from Theorem 6.5.2, that \textsc{Exhaustive Search Algorithm} runs in \textsc{ExpTime} in the size of the input (\textsc{PTime} for bounded query arity). Moreover, the size of the materialized \(O_S[K]\) is in the order of \(2^{2^{|S|}}\). Therefore the main factor in solving \textsc{Compute-one-MGE w.r.t.} \(O_S\) is \(O(|O_S|^2^m)\), which is double exponential for \(L_S\), and single exponential for the other languages, even for bounded query arity, if concept subsumption can be checked in \textsc{ExpTime}. Moreover, solving \textsc{Compute-one-MGE w.r.t.} \(O_S\) is in \textsc{PTime} for \(L_{S_{\text{min}}}\) with bounded query arity, if concept subsumption can be checked in \textsc{PTime}.

\section{6.C Missing proofs for Section 6}

\textbf{Proposition 6.6.2.} There is a polynomial-time algorithm that takes as input an instance \(I\) of a schema \(S\), as well as an \(L_S\) concept expression \(C\), and produces an irredundant concept expression \(C'\) such that \(C \equiv_{O_1} C'\).

\textbf{Proof.} We provide an easy algorithm.

\begin{algorithm}
\caption{Irredundant concept}
\begin{algorithmic}[1]
\State \textbf{Input:} a concept \(C = \bigcap C\), an instance \(I\)
\State \textbf{Output:} an equivalent irredundant concept
\For{\(C_i \in C\)}
\If{\(\exists C_j \in C \text{ s.t. } C_j \neq C_i\) and \(C_i \sqsubseteq_I C_j\)}
\State \(C = C \setminus C_j\)
\EndIf
\EndFor
\State return \(\bigcap C\)
\end{algorithmic}
\end{algorithm}

The algorithm consists of one for-loops of length of \(C\). The inner if-statement can be checked in \textsc{PTime} since the subsumption \(C \sqsubseteq_I C'\) can be checked in \textsc{PTime}. Thus overall, Irredundant concept runs in \textsc{PTime}.
We now prove that the algorithm produces an $O_I$-equivalent concept. For this it is enough to make sure that the step on line 3 preserves equivalence. Suppose $C'$ was obtained from $C$ by removing the concept $C_j$ which satisfied the if-condition on line 2. Since $C' \subseteq C$, it holds $C \sqsupseteq I \subseteq C'$. Conversely, since $C = C' \cap C_j$ and $C'' \sqsubseteq I \subseteq C_j$ for some $C'' \in C$, it holds $C' \sqsubseteq I \subseteq C$.

There is no proper irredundant subset since we exhaustively remove concepts that are implied by other concepts in the conjunction.

**Proposition 6.6.1.** Given a why-not instance $(S, I, q, Ans, \bar{a})$, the problem of finding a most-general explanation to $\bar{a} \not\in Ans$ of minimal length is NP-hard.

**Proof.** We reduce from set cover problem. Recall, given a triple $(U, S)$, where $U$ is a set, $S$ is a set containing subsets of $U$, SET COVER is the problem of finding a minimal size subset of $S$ such that the union of the elements in the subset covers $U$. Given an instance $(U, S)$ of SET COVER, we build a why-not instance $(S, I, q, Ans, \bar{a})$ as follows.

\[
\begin{align*}
S & = \{ R_C(a) \mid C \in S \} \\
I & = \{ R_C(c) \mid C \in S, c \not\in C \} \cup \{ R_C(a), R_C(b) \mid C \in S \}, \\
q(x) & \vdash \cup_{C \in S} R_C(x) \setminus \{ a, b \} \\
Ans & = U \\
\bar{a} & = (a)
\end{align*}
\]

Let $O_I = (C, \sqsubseteq_I, ext)$, where $C$ is selection-free $LS$, be the $S$-ontology derived from $I$. Without loss of generality we can assume that the length of each atomic concept $\pi_1(R_C)$ is equal 1 (since each of the atomic concept is of the same size). Note that there are finitely many concepts in $C$ and the extension of each atomic concept $\pi_A(R_C)$ is equal to $(U \setminus C) \cup \{ a, b \}$. Thus, in order for a concept $C$ in selection-free $LS$ to be an explanation, its extension must be equivalent to either $\{ a \}$ or $\{ a, b \}$. Indeed, $ext(C, I)$ must contain $a$ and not intersect with $Ans = U$, which is only possible when $ext(C, I) = \{ a \}$ or $ext(C, I) = \{ a, b \}$. Thus, in order for a concept $C$ to be a most-general explanation w.r.t. $O_I$, its extension must be equivalent to $\{ a, b \}$. We prove that $\text{ext}(\{ \pi_1(R_{C_1}), \ldots, \pi_1(R_{C_n}) \}, I) = \{ a, b \}$ if and only if $\bigcup_{i=1}^n C_i = U$, i.e., it covers $U$. Indeed, $\text{ext}(\bigcap_{i=1}^n \{ \pi_1(R_{C_i}) \}, I) = \bigcap_{i=1}^n (U \setminus C_i) \cup \{ a, b \}$ and it is equal $\{ a, b \}$ iff $\bigcap_{i=1}^n (U \setminus C_i) = \emptyset$, i.e., $U = \bigcup_{i=1}^n C_i$. Note that the length of a most-general explanation precisely corresponds to the size of a set cover. Thus, finding a cover of $U$ of minimal is equivalent to finding a most-general explanation for $\bar{a} \not\in Ans$ of minimal length.

**Proposition 6.6.3.** Given a why-not instance $(S, I, q, Ans, \bar{a})$ and an explanation $E$ to why $\bar{a} \not\in Ans$, the problem of finding a minimized explanation equivalent to $E$ is NP-hard.

**Proof.** (Sketch) Again we reduce from SET COVER. The construction is exactly the same as in the previous proposition. Now as the input explanation $E$ we take $\bigcap \{ \pi_1(R_C) \mid C \in S \}$. The extension of this concept in $I$ is equal to $\{ a, b \}$. Thus arguing as in the previous Proposition, finding a minimal size explanation equivalent to $E$ amounts to finding a minimal size set cover for $U$. \[\square\]
6. High-Level Why-Not Explanations using Ontologies

6.C.1 Cardinality based preference

**Proposition 6.6.4.** Assuming \( P \neq NP \), there is no \( PTIME \) algorithm that takes as input a why-not instance \((S, I, q, \text{Ans}, \bar{a})\) and an \( S \)-ontology \( O \), and produces a \( > \text{card} \)-maximal explanation for \( \bar{a} \notin \text{Ans} \). This holds even for unary queries.

To show hardness we reduce from the following modified version of set cover problem.

**Problem 6.C.1.** (Subset cover problem)

- **Given:** a universe \( U \), its proper subset \( U_1 \) and a class of sets \( S \) such that \( \cup S \subseteq U \) and which covers \( U_1 \), i.e. \( U_1 \subseteq \cup S \).
- **Find:** a class of sets \( C \subseteq S \) such that it covers \( U_1 \) and \( |\cup C \setminus U_1| \) is minimal.

We prove the following.

**Proposition 6.C.1.** The subset cover problem is \( NP \)-hard.

**Proof.** We first recall the definition of \( L \)-reduction.

**Definition 6.C.1.** Let \( A \) and \( B \) be optimization problems and \( c_A \) and \( c_B \) their respective cost functions. A pair of functions \( f \) and \( g \) is an \( L \)-reduction of \( A \) to \( B \) if all of the following conditions are met:

- functions \( f \) and \( g \) are computable in polynomial time,
- if \( x \) is an instance of problem \( A \), then \( f(x) \) is an instance of problem \( B \),
- if \( y \) is a solution to \( f(x) \), then \( g(y) \) is a solution to \( x \),
- there exists a positive constant \( \alpha \) such that \( \text{OPT}_B(f(x)) \leq \alpha \text{OPT}_A(x) \),
- there exists a positive constant \( \beta \) such that for every solution \( y \) to \( f(x) \) \( |\text{OPT}_A(x) - c_A(g(y))| \leq \beta |\text{OPT}_B(f(x)) - c_B(y)| \).

In our case the cost functions are the following:

- Set cover problem: \( |C| \) for a solution \( C \),
- Subset cover problem: \( |\cup C \setminus U_1| \) for a solution \( C \).

We \( L \)-reduce the set cover problem to the subset cover problem. To this purpose we provide the functions \( f \) and \( g \) such that all the requirements are met. Let \((U, S)\) be an arbitrary instance of set cover problem. Then we define \( f(U, S) = (U', U'_1, S') \), where

- \( U' = U \cup \{a_1, \ldots, a_m\} \), where \( m = |S| \) and each \( a_i \) is a fresh element,
- \( U'_1 = U \),
- \( S' = \{C_i \cup \{a_i\} \mid C_i \in S\} \).
For a family of sets $C' \subseteq S'$ we define $g(C') = \{C \setminus \{A, \ldots, A_m\} | C \in C'\}$. It is clear from the definitions that both $f$ and $g$ are computable in PTIME. Next it can also be seen that if $C' \subseteq S'$ is a subset cover for $f(U, S) = (U', U'_1, S')$, then $g(C')$ is a set cover for $U$. The needed constants $\alpha$ and $\beta$ are equal to 1.

Proof. (of Proposition 6.6.4) We construct an L-reduction from the subset cover problem to the problem of finding a $<\text{card}$-maximal explanation.

Let $A$ be the subset cover problem and $B$ the problem of finding a $<\text{card}$-maximal explanation. As before, the cost function for $A$ for the input \((U, U_1, S)\) and the solution $s = C$ is defined as $c_A(x, s) = |U \setminus C|$. For the problem $B$, the cost function is defined as follows: let $x = (S, I, q, Ans, \bar{O})$ be an instance of $B$ and $s = (C_1, \ldots, C_k)$ an explanation to $\bar{a} \not\in Ans = (q_1(I), \ldots, q_k(I))$, then $c_B(x, s) = |I| - \sum_{i=1}^k |\text{ext}(C_i, I)| - \sum_{i=1}^k |q_i(I)|$.

For an instance $x = (U, U_1, S)$ of the subset cover problem we define $f(x) := (S, I, q, Ans, \bar{O})$, where

- $S = \{R_C(A) | C \in S\}$,
- $\bar{a} = (a)$, where $a \not\in U$ is a fresh element,
- $I = \{R_C(c) | C \in S, c \in C\} \cup \{R_C(a) | C \in C\}$ is an instance, which means that $\text{adom}(I) = U \cup \{a\}$,
- $q$ is such that $q(I) = Ans = U_1$,
- $\bar{O} = (\hat{\bar{C}}, \subseteq, \text{ext})$ such that $\hat{\bar{C}}$ consists of atomic concepts $\hat{C}$ for each set $C \in S$, their extensions in $I$ are defined as $\text{ext}((\hat{\bar{C}}, I)) = (U \setminus C) \cup \{a\}$, and $\hat{C}_1 \subseteq \hat{C}_2$ iff $C_2 \subseteq C_1$.

Next, let $\hat{\bar{C}} = \hat{C}_1 \cap \ldots \cap \hat{C}_k$ be a concept with $\hat{C}_i \in \hat{\bar{C}}$ for the input $f(U, U_1, S) = (S, I, q, Ans, \bar{O})$. We define $g(\hat{\bar{C}}) := \{C_1, \ldots, C_k\} \subseteq S$. It is clear that both $f$ and $g$ are computable in PTIME. Also

- If $(U, U_1, S)$ is an instance of the subset cover problem, then $f(U, U_1, S)$ is an instance of the problem of finding a $<\text{card}$-maximal explanation.

- Let $\hat{\bar{C}} = \hat{C}_1 \cap \ldots \cap \hat{C}_k$ be an explanation to $\bar{a} \not\in Ans$ with the input $f(U, U_1, S) = (S, I, q, Ans, \bar{O})$. Then we claim that $g(\hat{\bar{C}})$ is a subset cover for $(U, U_1, S)$. First, it holds that $(\text{ext}(\hat{C}_1 \cap \ldots \cap \hat{C}_k, I)) \cap Ans = \emptyset$. By definition we have $\text{Ans} = U_1$ and $\text{ext}(\hat{C}_1 \cap \ldots \cap \hat{C}_k, I) = \bigcap_i^k ((U \setminus C_i) \cup \{a\}) = (U \setminus \bigcup_i^k C_i) \cup \{a\}$. Since the intersection of those two sets is empty and also $U_1 \subseteq U$, we have that $U_1 \subseteq \bigcup_i^k C_i$, i.e. $g(\hat{\bar{C}}) = \{C_1, \ldots, C_k\}$ covers $U_1$.

- Let $\bar{C}$ be an optimal subset cover for $(U, U_1, S)$. Then the cost $|U \setminus C_1|$ is minimal. Let also $\bar{C} = \bar{C}_1 \cap \ldots \cap \bar{C}_k$ be a $<\text{card}$-maximal explanation to $\bar{a} \not\in Ans$ for the input $f(U, U_1, S) = (S, I, q, Ans, \bar{O})$. The cost of this explanation is $|I| - |\text{ext}(\bar{C}, I)| - |\text{Ans}| = |U \setminus C_1|$ which is minimal. Then it holds $|\cup C \setminus U_1| \leq \alpha(|\cup_i^k C_i| - |U_1|)$ for $\alpha = 1$. 

6.C. Missing proofs for Section 6
6. High-Level Why-Not Explanations using Ontologies

- Let $C$ be an optimal subset cover for $x = (U, U_1, S)$ and $\hat{C} = \hat{C}_1 \cap \ldots \cap \hat{C}_k$ a $<\text{card}$-maximal explanation to $a \notin \text{Ans}$ for the input $f(x) = (S, I, q, \text{Ans}, a, O)$.

Let also $y = \hat{C'} = \hat{C'}_1 \cap \ldots \hat{C'}_l$ be an arbitrary explanation to $a \notin \text{Ans}$ for the input $f(x)$, and $g(y) = \{C'_1, \ldots, C'_l\}$ the corresponding subset cover for $(U, U_1, S)$.

Then $|OPT_A(x) - c_A(g(y))| = \|\bigcup C \setminus U_1| - |\bigcup_i C'_i \setminus U_1\|$. This is equal to $\|\bigcup_i C'_i \setminus U_1| - |\bigcup_i C'_i \setminus U_1\|$, which is equal to $|OPT_B(f(x)) - c_B(y)|$. Thus we can take $\beta = 1$. \qed
In this thesis we contributed to the study of the containment problem for various query languages over trees and relational databases (Part I), and introduced a new framework for why-not explanations (Part II). Next we summarize the obtained results and end with future work.

7.1 Main findings

The first part of the thesis is devoted to the containment problem for expansions of XPath and conjunctive queries over trees, and conjunctive queries over relational databases. Firstly, we considered query languages over unranked trees and tried to answer the following question for a given query language $L$.

**RQ 1** What is the complexity of the containment problem for $L$ over unranked trees?

Concretely, $L$ was one of the following query languages over unranked trees.

- Positive XPath with attribute value comparisons (Chapter 3),
- Conjunctive Queries with attribute value comparisons (Chapter 3),
- Conditional Tree Patterns (Chapter 5)

Table 7.1 summarizes the results of Chapter 3, together with previously known results. We can see that adding attribute value comparisons of the form $@a \text{ op } c$ does not increase the complexity of containment. Moreover, when the underlying ordered domain for attributes is restricted to be either finite, discrete, or with endpoints, the complexity of

</tr>
</tbody>
</table>

Table 7.1: Complexity results for containment over trees for Positive XPath and CQ with attribute value comparisons (Chapter 3).
containment remains the same as well. However, when trees are required to have at least one attribute defined in every node, the containment becomes harder (PSPACE-hard). The latter hardness result is rather strong: it already holds for tree patterns with attribute value comparisons.

In Chapter 5 we expanded tree patterns with the conditional descendant axis, resulting in Conditional Tree Patterns (CTP). The conditional axis is a natural expansion for XPath, providing expressive completeness for first-order logic on ordered unranked trees (Marx, 2005). In Chapter 5 we proved that the containment problem for CTP is PSPACE-complete. Interestingly, the lower bound is proved via establishing the fact that containment is PSPACE-hard for tree patterns expanded with unrestricted label negation. The lower bound in case of CTP then follows from the fact that CTP is able to express this type of negation, as far as the containment problem is concerned. More precisely, there is a polynomial reduction from the containment problem for tree patterns with label negation to the containment problem for conditional tree patterns. Notably, when negation in tree patterns is restricted to be safe (that is, a negated label in a node must co-occur with a positive label), then containment drops to coNP, as Table 7.1 shows.

Each CTP formula can be conveniently represented as a tree in which each descendant edge is (recursively) labeled with the tree corresponding to a CTP subformula. Thus, tree patterns form a particular case when each descendant edge is labeled with $\top$. In fact, this edge labeling is the only topological addition to tree patterns offered by conditional tree patterns. The lower bound in Chapter 5 is quite strong: the PSPACE lower bound already holds for CTP with such nested edge labelling of depth 1 (or in other words, the edge labels are tree patterns).

In Chapter 4 we considered acyclic conjunctive queries with atomic negation and arithmetic comparisons, interpreted over relational databases. It is known that the acyclicity restriction on conjunctive queries allows for tractable containment (Gottlob et al., 2001). We considered the following

**RQ 2** Does acyclicity make the complexity of containment for conjunctive queries expanded with atomic negation or arithmetic comparison tractable? If not, what additional restrictions need to be imposed to make it tractable?

Table 7.2 summarizes the results of Chapter 4. According to Theorem 4.3.3, even the most restrictive notion of acyclicity — Berge-acyclicity — is not enough to make containment for conjunctive queries with atomic negation or arithmetic comparisons tractable. To address the second part of the research question, we have defined a special class of queries, called pointed Berge-acyclic queries with guarded atomic negation (arithmetic comparisons). This is the class of conjunctive queries with guarded atomic negation (or arithmetic comparisons) where each query

(i) is connected (that is, its hypergraph is connected),

(ii) every query in the class contains a fixed constant $r$ (“pointness”),

(iii) Berge-acyclic.

Theorem 4.3.3 implies that if at least one of these conditions is omitted, containment becomes coNP-hard. It is however not known whether containment for pointed Berge-acyclic queries with negation (comparisons) is solvable in PTIME. On a positive side, we

proved that containment for child-only tree patterns with guarded negation, a subclass of pointed Berge-acyclic queries, is solvable in PTIME using the homomorphism technique. Unfortunately, this technique is not extensible for pointed Berge-acyclic queries with guarded atomic negation (arithmetic comparisons) involving relations of high arity.

In the second part of the thesis we have introduced a new framework for why-not explanations. This framework makes use of ontologies to provide high-level explanations to why certain data is missing from query results. An ontology is a hierarchy of concepts, or a set of subsumption relations between concepts, which formalizes the domain knowledge. In Chapter 6 we have considered two cases how to obtain an ontology: either it is already provided externally (e.g., as a description logic ontology) or it is derived from the database instance or schema with integrity constraints. The latter was formalized in the following research question.

**RQ 3** How to extract an ontology from a database instance or a schema?

To answer this question, we first introduced an appropriate concept language \( L_{S} \) comprising nominals (that is, an element of the domain), projections of relation, projections of relations with selections, and conjunctions thereof. Having fixed this language, extracting an ontology from an instance or a schema amounts to decide which subsumptions hold with respect to the instance or schema. Thus we were interested in the following decision problems: given a database schema \( S \) (resp. instance \( I \)), two \( L_{S} \) concepts \( C_1 \) and \( C_2 \), decide whether \( C_1 \) is subsumed by \( C_2 \) with respect to \( S \) (resp. \( I \)), denoted as \( C_1 \models_S C_2 \) (\( C_1 \models_I C_2 \)). While subsumption with respect to an instance can be trivially solved in PTIME, the complexity of subsumption w.r.t. a schema \( S \) depends on the type of integrity constraints in \( S \).

Table 7.3 summarizes the complexity results for subsumption w.r.t. the database schema \( S \), where \( L_{S}^{\text{min}} \) is the language consisting of only the top concept, nominals and projections of relations. In Chapter 6 we were interested in “good” explanations, where by “good” we mean most general explanations (w.r.t. the ontology). Intuitively, these are concepts that cover the maximal number of missing answers and thus are high-level. We asked the following
7. Conclusion

Constraints Complexity of subsumption for $L_S$
---
UCQ-view def. (no comparisons) NP-complete
UCQ-view def. $\Pi_2^P$-complete
linearly nested UCQ-view def. $\Pi_2^P$-complete
nested UCQ-view def. CONEXPTIME-complete
Functional Dependencies (FDs) in PTIME
Inclusion Dependencies (IDs) $\alpha$ (in PTIME for selection-free $L_S$)
IDs + FDs Undecidable

All stated lower bounds already hold for $L_S^{\min}$ concept expressions.

Table 7.3: Complexity of concept subsumption w.r.t schema $S$.

RQ 4 How to produce “good” explanations?

Related to this research question, we considered three algorithmic problems: check if an explanation exists, check if a given concept is a most general explanation, and compute one most general explanation. These problems largely depend on how the ontology is obtained. If an ontology is provided externally, then we can check in PTIME if a concept is a most general explanation. However, checking existence of an explanation is an NP-complete problem. In light of this result we provide an algorithm for computing one most general explanation, which runs in exponential time.

When the ontology is derived from the instance or schema, existence of an explanation is trivial, because of the presence of nominals in the concept language. We have provided algorithms for checking if a concept is a most general explanation, whose running times depend on the complexity of the subsumption problem (w.r.t. a schema they are provided in Table 7.3). As for computing a most general explanation, we have provided an algorithm for the case of an ontology derived from the instance, which runs in PTIME. We have also provided a naive algorithm (running in exponential time) for computing a most general explanation in case the ontology is derived from the schema. Devising an optimal algorithm for this case is left for future work.

7.2 Future work

We list concrete open questions that stem from the work presented in this thesis.

In Chapter 3 we saw that for the coNP hardness proof of containment for tree patterns without the wildcard and with attribute value comparisons, both types of comparisons $\mathbb{A}_a = c$ and $\mathbb{A}_a \neq c$ are needed. Moreover, if we only allow attribute value comparisons of type $\mathbb{A}_a = c$, then containment becomes solvable in PTIME. It is an open problem what the exact complexity of containment is for tree patterns without the wildcard and with comparisons of the form $\mathbb{A}_a \neq c$ only.

In Chapter 4 we showed a number of coNP hardness proofs that led us to define a class of pointed Berge-acyclic conjunctive queries with guarded negation. We showed that for a particular subclass of it, namely child-only tree patterns with label negation, containment is tractable. However, it is an open question what the precise complexity of the containment problem for pointed Berge-acyclic queries with guarded negation is. Also in that chapter we showed that containment for $\alpha$-acyclic queries with guarded
negation where the arity of negated atoms is bounded by a constant, is in coNP. It is an open question whether containment is still in coNP or \( \Pi^P_2 \)-hard if there is no bound on arity of negated atoms.

In Chapter 5 we studied conditional tree patterns, which is the positive downward fragment of Conditional XPath without disjunction and union (Marx, 2005). We can also consider more expressive tree patterns – the positive downward fragment of Regular XPath without disjunction and union (ten Cate, 2006). Pictorially, these tree patterns can have regular expressions as the labels for descendant edges. The conditional descendant that is labeled with \( Q \) and ending with \( P \) can be expressed with regular tree patterns as 
\[
/\text{child} :: Q/\text{child} :: P.
\]

The complexity of containment for regular tree patterns thus must be between PSPACE and EXPTIME. It is open what the precise complexity is.

Expressivity characterization with respect to some yardstick logics (such as FO) is important. Such a characterization allows us to compare different fragments and derive properties from the known ones in the yardstick logics. In Chapter 5 we gave an expressivity characterization for unions of CTP with disjunction, similar to the one for the union of tree patterns in (Benedikt et al., 2005). It is interesting to determine what the exact FO fragment corresponding to Conditional Tree Patterns is.

In Chapter 6 we have introduced a new why-not framework, which is neither query-centric nor data-centric, in the sense that it does not suggest fixes for the query or the underlying data. It would be interesting to explore ways how high-level explanations produced by our framework can complement and enhance the existing approaches. Ultimately, it would be interesting to see usefulness of high-level explanations in practice. A concrete tool for generating these explanations should then be built.

An algorithm for generating all most general explanations (MGEs) provided in Chapter 6 is an exhaustive search algorithm and rather inefficient. It would be interesting to develop efficient algorithms for enumeration of all most general explanations. Typically, in such a setting with exponential number of output solutions, one is interested in algorithms with polynomial delay. That is, the time needed to produce the first solution, and, thereafter, the time delay between two consecutive solutions is bounded by a polynomial in the size of the input. In future work, we plan to investigate whether there is a polynomial delay algorithm for enumerating all most-general explanations.

Samenvatting

Het eerste deel van dit proefschrift gaat over het beslissen of de ene databank-vraag (query) een logisch gevolg is van een andere vraag. De analyse van de complexiteit van dit probleem voor verschillende families van vraagtaalen vormt één van de centrale problemen binnen de theorie van databanken. De ene vraag volgt logisch uit de andere als voor elke mogelijke databank, alle antwoorden op de eerste vraag ook antwoorden op de tweede vraag zijn. Dit probleem vindt onder meer zijn toepassing in het optimaliseren van databankvragen, het beantwoorden van vragen aan een databank met behulp van zogenaamde views en het beantwoorden van vragen onder constraints op de databank. Omdat dit probleem zo centraal staat, is het in het verleden uitgebreid bestudeerd voor meerdere querytalen en datamodellen.

In dit proefschrift vervolgen wij dit onderzoek voor diverse acyclische vraagtalen geïnterpreteerd op bomen en relationele databanken. Specifiek bekijken wij de volgende drie talen:

1) Conjunctieve en positieve XPath queries uitgebreid met negatie en met attribuutwaarde vergelijkingen, geïnterpreteerd op bomen;

2) Tree patterns uitgebreid met een conditionele descendant modaliteit, geïnterpreteerd op bomen; en

3) Acyclische conjunctieve queries uitgebreid met atomaire negatie en rekenkundige vergelijkingen geïnterpreteerd op relationele structuren.

We bewijzen de precieze complexiteit voor het beslissen van de logisch gevolg relatie voor deze talen.

Het tweede deel van dit proefschrift stelt een nieuw formeel raamwerk rondom zogeheten “waarom-niet verklaringen” voor. Onze waarom-niet verklaringen maken gebruik van concepten uit een ontologie om op hoog niveau en betekenisvol verklaringen te geven voor het feit dat bepaalde feiten ontbreken in de antwoorden op een query. In dit raamwerk zijn we geïnteresseerd in het vinden van de meest algemene verklaring in relatie tot een ontologie. Eerst richten we ons op het probleem van het extraheren van een ontologie uit een databaseinstantie of databaseschema. Wij tonen aan dat dit probleem gezien kan worden als het eerder genoemde probleem van logisch gevolg en verschaffen een complexiteitsanalyse. Daarna richten we ons op het probleem om de meest algemene verklaring te berekenen. We bestuderen de complexiteit van dit probleem en van vergelijkbare problemen. We geven tenslotte een algoritme voor het berekenen van waarom-niet verklaringen.
