Rising CO₂ concentrations may have large effects on aquatic microorganisms. In this study, we investigated how elevated pCO₂ affects the harmful freshwater cyanobacterium Microcystis aeruginosa. This species is capable of producing dense blooms and hepatotoxins called microcystins. Strain PCC 7806 was cultured in chemostats that were shifted from low to high pCO₂ conditions. This resulted in a transition from a C-limited to a light-limited steady state, with a ∼2.7-fold increase of the cyanobacterial biomass and ∼2.5-fold more microcystin per cell. Cells increased their chlorophyll a and phycocyanin content, and raised their PSI/PSII ratio at high pCO₂. Surprisingly, cells had a lower dry weight and contained less carbohydrates, which might be an adaptation to improve the buoyancy of Microcystis when light becomes more limiting at high pCO₂. Only 234 of the 4691 genes responded to elevated pCO₂. For instance, expression of the carboxysome, RuBisCO, photosystem and C metabolism genes did not change significantly, and only a few N assimilation genes were expressed differently. The lack of large-scale changes in the transcriptome could suit a buoyant species that lives in eutrophic lakes with strong CO₂ fluctuations very well. However, we found major responses in inorganic carbon uptake. At low pCO₂, cells were mainly dependent on bicarbonate uptake, whereas at high pCO₂ gene expression of the bicarbonate uptake systems was down-regulated and cells shifted to CO₂ and low-affinity bicarbonate uptake. These results show that the need for high-affinity bicarbonate uptake systems ceases at elevated CO₂. Moreover, the combination of an increased cyanobacterial abundance, improved buoyancy, and higher toxin content per cell indicates that rising atmospheric CO₂ levels may increase the problems associated with the harmful cyanobacterium Microcystis in eutrophic lakes.

Keywords: bicarbonate uptake, climate change, CO₂-concentrating mechanisms, harmful algal blooms, inorganic carbon uptake, microarrays, microcystins, phytoplankton

Introduction

Cyanobacterial blooms are a well-known cause of nuisance in eutrophic lakes (Chorus and Bartram, 1999; Huisman et al., 2005; Merel et al., 2013). They may increase the turbidity of the water column,
suppressing the growth of submerged water plants (Scheffer, 1998), and can produce considerable odor and taste problems (Watson et al., 2008). Moreover, cyanobacteria can produce a variety of potent toxins, including microcystins and anatoxins, which cause liver, digestive, and neurological disease in birds, mammals, and humans (Jochimsen et al., 1998; Carmichael, 2001; Codd et al., 2005). This has led to the closure of lakes and reservoirs for recreational use, aquaculture, drinking water, and irrigation water, often with considerable economic damage as a result (Verspagen et al., 2006; Dodds et al., 2008; Qin et al., 2010).

Several studies warn of an intensification of cyanobacterial blooms in eutrophic waters, due to the combination of global warming (Jöhnk et al., 2008; Paerl and Huisman, 2008; O’Neil et al., 2012) and rising CO₂ concentrations in the atmosphere (Verschoor et al., 2013; Verspagen et al., 2014a,b). The dissolved inorganic carbon (Ci) concentration in eutrophic lakes can vary strongly. Many lakes are supersaturated with dissolved CO₂ (dCO₂) with concentrations that can go up to 10,000 ppm (Cole et al., 1994; Sobek et al., 2005; Lazzarino et al., 2009), but lakes with high photosynthetic activities of dense cyanobacterial blooms have often undersaturating dCO₂ concentrations (Ibelings and Maberly, 1998; Balmer and Downing, 2011; Verspagen et al., 2014b). Depletion of dCO₂ during cyanobacterial blooms is accompanied by a strong increase in pH (Talling, 1976; Jeppesen et al., 1990; López-Archilla et al., 2004). With increasing pH, the speciation of dissolved inorganic carbon shifts from dCO₂ toward bicarbonate (HCO₃⁻) and carbonate (CO₃²⁻). Because phytoplankton species differ in their uptake rates of dCO₂ and bicarbonate (Rost et al., 2003; Price et al., 2008; Maberly et al., 2009), these changes in carbon speciation may strongly affect competitive interactions between the species (Tortell et al., 2002; Rost et al., 2008; Verschoor et al., 2013). In particular, cyanobacteria are believed to be very efficient competitors at low CO₂ conditions (Shapiro, 1997).

Many cyanobacteria have evolved a highly efficient CO₂-concentrating mechanism (CCM) to proliferate at low ambient dCO₂ levels and to overcome the low affinity of the primary CO₂ fixing enzyme, RuBisCO (Giordano et al., 2005; Price et al., 2008; Raven et al., 2012). The CCM of cyanobacteria works quite differently from CCMs found in eukaryotic algae. In the latter, a pH gradient across the chloroplast thylakoid membrane in the light secures Ci accumulation in the cytosol (Moroney and Ynalvez, 2007). In cyanobacteria, the CCM is based on accumulation of bicarbonate in specialized compartments, called carboxysomes, that contain the RuBisCO enzyme. Conversion of bicarbonate inside the carboxysomes by carbonic anhydrases raises the local CO₂ concentration, near RuBisCO, which can then efficiently fix CO₂ (Price et al., 2008). However, photorepiration and Mehler-like reactions have also been identified in cyanobacteria, signifying that cyanobacterial photosynthesis can still be limited by a low Ci availability despite their CCM (Helman et al., 2005; Zhang et al., 2009; Hackenberg et al., 2012). Up to four flavodiiron proteins (Flv1–4) are involved in the low Ci adaptation process, acting as an electron sink at photosystem I (PSI, for Flv1,3) and photosystem II (PSII, for Flv2,4) (Allahverdiyeva et al., 2011; Zhang et al., 2012; Bersanini et al., 2014).

The CCMs of fully sequenced cyanobacteria, like Synechocystis PCC 6803 and several Synechococcus strains, have been studied in detail (Omata et al., 1999; Price et al., 2004; Schwarz et al., 2011). This has revealed that cyanobacteria have several different Ci uptake systems: three systems for bicarbonate uptake have been identified and two systems for CO₂ uptake (Price, 2011). BicA and SbtA are both sodium-dependent bicarbonate symporters. BicA has a low affinity and high flux rate, whereas SbtA has a high affinity and low flux rate (Price et al., 2004). The third bicarbonate uptake system, BCT1, has direct ATP-dependent functionality and consists of four subunits (CmpABC). BCT1 has a relatively high affinity for bicarbonate and low flux rate, although its affinity is slightly lower than that of SbtA (Omata et al., 1999, 2002; Price et al., 2008). The two CO₂ uptake systems, NDH-13 and NDH14, convert CO₂ that passively diffuses into the cell to bicarbonate, and consist of multiple subunits (Price, 2011). The two CO₂ uptake systems are likely NADPH-dependent (Price et al., 2002). Functionally, NDH-13 has a high substrate affinity and low flux rate, whereas NDH-14 combines a lower substrate affinity with a higher flux rate (Maeda et al., 2002; Price et al., 2002).

From an environmental and ecological perspective, the harmful cyanobacterium Microcystis aeruginosa (hereafter called Microcystis) is of great interest. Microcystis is one of the more notorious cyanobacterial species, producing dense and often toxic blooms in eutrophic lakes all over the world (Chen et al., 2003; Verspagen et al., 2006; Michalak et al., 2013). Now that full genome analysis has been completed for a range of different Microcystis strains (e.g., Kaneko et al., 2007; Frangeul et al., 2008; Humbelt et al., 2013), knowledge on carbon acquisition is available, which enables detailed study of the response of Microcystis to rising CO₂ levels. Selection experiments have shown that rising CO₂ levels may shift the competitive balance between toxic and nontoxic Microcystis strains (Van de Waal et al., 2011). Furthermore, the genetic diversity of the CCM in different Microcystis strains was recently elucidated (Sandrini et al., 2014). This revealed that all investigated Microcystis strains contained genes encoding the two CO₂ uptake systems, the bicarbonate uptake system BCT1 and several carbonic anhydrases, but the strains differ in the presence of the bicarbonate uptake genes bicA and sbtA.

In this study, we investigate the response of the toxic Microcystis strain PCC 7806 to rising CO₂ levels, and how its gene expression and cell physiology, including the presence of its toxin microcystin, change at elevated pCO₂. For this purpose, Microcystis was cultivated in controlled laboratory chemostats that were shifted from low to high pCO₂ conditions. We provided the chemostats with a low CO₂ partial pressure (pCO₂) of 200 ppm to create Ci-limited conditions. After 36 days, we raised the pCO₂ level to 1450 ppm pCO₂, which is a representative level for many supersaturated lakes (Sobek et al., 2005). Our results show that elevated CO₂ leads to a highly specific transcriptome response of Microcystis, and affects the Ci uptake, biomass, cellular composition, and toxicity of Microcystis cells.
Materials and Methods

Chemostat Experiment
The axenic strain *Microcystis* strain PCC 7806 was obtained from the Pasteur Culture Collection (Paris, France). The strain was originally isolated from the Braakman reservoir, The Netherlands in 1972. It contains genes for the two CO₂ uptake systems, the bicarbonate uptake systems BCT1 (high affinity) and BicA (low affinity), but lacks the high-affinity bicarbonate uptake system SbtA (Sandrini et al., 2014). The *Microcystis* strain was pre-cultured in four 2-L Erlenmeyer flasks using modified BG11 medium (Rippka et al., 1979) with 10 mmol L⁻¹ NaNO₃ and without Na₂CO₃ or NaHCO₃, at an incident light intensity of 15 μmol photons m⁻² s⁻¹, 400 ppm CO₂, and a temperature of 25°C. Regular microscopy did not reveal contaminations.

The experiment was carried out in four replicate chemostats designed for phytoplankton growth (Huisman et al., 2002) using the same modified BG11 medium. Each chemostat consisted of a flat culture vessel that was illuminated from one side (the front surface) to obtain a unidirectional light gradient. We applied a constant incident irradiance (*Iₐ*) of 50 μmol photons m⁻² s⁻¹ using white fluorescent tubes (Philips Master TL-D 90 De Luxe 18 W/965, Philips Lighting, Eindhoven, The Netherlands). The chemostats had an optical path length of 5 cm and an effective working volume of 1.8 L. The temperature in the chemostats was maintained at 25°C using a stainless steel cooling finger connected to a water bath (Haake A28F/AC200; Thermo Fisher Scientific, Pittsburgh, PA, USA). The dilution rate was set at 0.01 h⁻¹.

The chemostats were bubbled with CO₂-enriched air at a flow rate of 25 L h⁻¹. The CO₂-enriched air was based on pressurized air (21% O₂, 78% N₂), from which the CO₂ was removed by a CO₂ adsorption air dryer (Ecodyr K-MT6; Parker Zander, Lancaster, NY, USA) and 4 m high columns filled with NaOH pellets. Subsequently, different amounts of pure CO₂ gas were added using GT 1355R-2-15-A 316 SS Flow Controllers (Metrohm Applikon B.V., Schiedam, The Netherlands) to sterilize the gas mixture. The gas was mixed twice with 25°C water to suppress evaporation and led through a 0.20 μm Midisart 2000 filter (Sartorius Stedim Biotech GmbH, Göttingen, Germany) to sterilize the air, before it entered the chemostats. The CO₂ concentration in the gas mixture was checked regularly with an Environmental Gas Monitor for CO₂ (EGM-4; PP Systems, Amesbury, MA, USA).

Prior to the experiment, the four chemostats were inoculated with *Microcystis* from exponentially growing pre-cultures. The cultures were allowed to acclimate to the new chemostat conditions for 10 days. Subsequently, the cultures were diluted to an initial cyanobacterial abundance of ~60 mm³ L⁻¹ to start the experiment. The CO₂ concentration in the gas mixture was 200 ± 10 ppm CO₂ during the first 36 days of the experiment (and also during the preceding acclimation phase). After 36 days, the CO₂ concentration was raised to 1450 ± 50 ppm CO₂. The experiment was run for 50 days, during which the chemostats were sampled 3–5 times per week.

Light and Cyanobacterial Abundance
The incident irradiance (*Iₐ*) and the irradiance penetrating through the chemostat vessel (*Iₐₕ*) were measured with a LI-COR LI-250 quantum photometer (LI-COR Biosciences, Lincoln, NE, USA) at ten positions on the front and back surface of the chemostat vessels, respectively. Cell numbers, biovolumes and average cell size of samples were determined in triplicate using a Casy 1 TCC cell counter with a 60 μm capillary (Scharfè System GmbH, Reutlingen, Germany). Dry weight was determined in duplicate by filtering 0.75–10 mL of sample over pre-weighted 1.2 μm pore size 25 mm GF/C glass filters (Whatman GmbH, Dassel, Germany). Filters with cells were dried for 2 days in a 60°C oven, transferred to a desiccator to cool to room temperature, and subsequently weighted again.

Aquatic Chemistry
The pH of the samples was measured immediately after sample collection with a Lab 860 pH meter in combination with a BlueLine 28 Gel pH electrode (SCHOTT Instruments GmbH, Mainz, Germany). For dissolved inorganic carbon (DIC) concentration, alkalinity, and nitrate measurements, samples of 40 mL were immediately centrifuged (5 min at 4000 g and 20°C). The pellets were used for cellular C and N analysis, whereas the supernatant was filtered over 0.45 μm pore size 47 mm polyethersulfone membrane filters (Sartorius AG, Goettingen, Germany). The filtrate was transferred to sterile plastic urine tubes (VF-109SURI; Terumo Europe N.V., Leuven, Belgium). The tubes were filled completely and stored at 4°C until further analysis. DIC (three to five technical replicates) was measured with a TOC-VPCH TOC analyzer (Shimadzu, Kyoto, Japan). Concentrations of dCO₂, bicarbonate, and carbonate were calculated from DIC and pH (Stumm and Morgan, 1996). Alkalinity was determined with a 716 DMS Titriso titrator (Metrohm Applikon B.V., Schiedam, The Netherlands), based on the amount of 0.01 or 0.1 mol L⁻¹ HCl added to reach pH 4.5 (ISO 9963-1:1994). The nitrate concentration was measured with a TNM-1 nitrogen detector (Shimadzu, Kyoto, Japan) attached to the TOC-VPCH TOC analyzer.

Cellular Composition
Cellular C and N contents were determined by gently washing the pellets obtained from the previous centrifugation twice (5 min at 4000 g and 20°C) with a C- and N-free solution (10 mmol L⁻¹ NaCl and 10 mmol L⁻¹ K₂HPO₄ pH 8.0). The washed pellets were stored at −20°C until further analysis. Subsequently, the pellets were freeze dried, and the C and N content of 5 mg homogenized freeze-dried powder was analyzed using a Vario EL Elemental Analyzer (Elementar Analysensysteme GmbH, Hanau, Germany).

To determine the cellular carbohydrate, lipid, protein, and phosphate content, 2 mL samples were centrifuged and the pellets were stored at −20°C until further analysis. Carbohydrate was quantified using the phenol-sulphuric acid method, with D-glucose (Merck Millipore, Darmstadt, Germany) as standard (Dubois et al., 1956). Lipids were extracted with methanol and chloroform, and subsequently the lipid content was quantified using the sulphuric acid-vanillin-phosphoric acid method, with
Trilein (>99%, Sigma-Aldrich Co, St Louis, MO, USA) as standard (Izard and Limberger, 2003). Proteins were quantified with the Bradford assay, using Brilliant Blue G-250 and bovine serum albumin as standard (Bradford, 1976). Cellular P was obtained by oxidizing cells with potassium persulfate for 1 h at 100°C (Wetzel and Likens, 2000), after which the phosphate concentration was measured colorimetrically according to Murphy and Riley (1962).

**in vivo Absorption Spectra**

Light absorption spectra of the samples were scanned from 400 to 750 nm with a bandwidth of 0.4 nm using an Aminco DW-2000 double-beam spectrophotometer (Olis Inc., Bogart, GA, USA). BG11 medium without cells was used as baseline and the spectra were normalized based on the absorbance at 750 nm.

**Low Temperature Fluorescence**

Relative amounts of PSI and PSII were determined using an Olis DM 45 77 K spectrophotometer connected to an Olis photon counter (Olis Inc., Bogart, GA, USA). Glycerol (30% final concentration) was added to the samples, which were transferred to 3 mL polystyrene cuvettes (Sigma-Aldrich Co, St Louis, MO, USA) and frozen in liquid nitrogen. The excitation wavelength was 440 nm for chlorophyll a. Emission spectra of the samples were measured in triplicate at 600 – 750 nm, and normalized based on the mean emission at 600 – 660 nm.

**Microcystin Analysis**

*Microcystis* PCC 7806 produces two microcystin variants, [Asp]^3^MC-LR and MC-LR (Tonk et al., 2009). To determine the intracellular unbound microcystin content (cf. Meißner et al., 2013), 1 – 5 mL samples were filtered over 1.2 μm pore size 25 mm GF/C filters (Whatman GmbH, Dassel, Germany). The filters were stored at −20°C and subsequently freeze dried. Microcystins were extracted with 75% MeOH and analyzed with HPLC according to Van de Waal et al. (2011), using a Shimadzu LC-20AD HPLC system with a SPD-M20A photodiode array detector (Shimadzu, Kyoto, Japan). Peaks of [Asp]^3^MC-LR and MC-LR could not be completely separated. Therefore, both peaks were summed and are referred to as total microcystin. Earlier chemostat experiments showed that extracellular microcystin concentrations in the water phase were negligible (e.g., Van de Waal et al., 2011).

**RNA Extraction**

RNA samples for transcriptome analysis were taken from all four chemostats, at 0 h (just before increasing the pCO₂) and at 0.75, 2, 4, 8, 24, 72, and 336 h after increasing the pCO₂ from 200 to 1450 ppm. Fresh culture samples of ~40 mL were immediately cooled on ice and centrifuged for 5 min at 4000 g and 4°C in a pre-cooled centrifuge. The pellets were immediately resuspended in 1 mL TRIzol (Life Technologies, Grand Island, NY, USA), frozen in liquid nitrogen and stored at −80°C. Subsequently, RNA was extracted with TRIzol (Invitrogen) according to the supplier’s instructions, using beads (0.5 mm BashingBeads; Zymo Research, Orange, CA, USA) to facilitate cell disruption. After the phase separation steps, the Direct-Zol™ RNA MiniPrep kit (Zymo Research) was used for RNA purification. The in-column DNase I digestion was included as well. RNA concentrations were quantified using a Nanodrop 1000 spectrophotometer (Thermo Scientific, San Jose, CA, USA), and all RNA samples had A_{260}/A_{280} and A_{260}/A_{230} values above 1.8. The quality of the RNA extracts was checked using an Agilent 2100 Bioanalyzer (Agilent Technologies, Amstelveen, the Netherlands).

The cDNA library was prepared using the Superscript III Reverse Transcriptase kit (Invitrogen, Carlsbad, CA, USA) according to Eisenhut et al. (2007), with incorporation of Cy3-DUTP or Cy5-DUTP (Amersham Biosciences Benelux, Roosendaal, the Netherlands) in the cDNA. Non-incorporated fluorescent nucleotides were removed with the QIAquick PCR purification kit (Qiagen, Venlo, the Netherlands). The reverse transcription and fluorescent dye incorporation efficiency were monitored with a Nanodrop 1000 spectrophotometer (Thermo Scientific, San Jose, CA, USA).

The transcriptome study was performed on two Agilent 8 × 60 K two-color microarray chips (Agilent Technologies, Amstelveen, the Netherlands). The microarray design and probe library of *Microcystis* PCC 7806 was based on Makower et al. (2015), which was partly derived from Straub et al. (2011). The sequence-specific oligonucleotide probes (60-mers) targeted 4691 protein-coding genes, which corresponds to 88.6% of the total predicted protein-coding genes in the annotated genome of *Microcystis* PCC 7806 (Frangeul et al., 2008). On average, five different probes per gene were used. Cy3- and Cy5-labeled cDNA probe samples from just before and at specific time points after increasing the pCO₂ in the four chemostats were combined. A loop design was used, in which samples from the same chemostat but different time points were compared (Supplementary Table 1). The hybridization, washing and array reading were performed as described by Eisenhut et al. (2007).

**Microarray Data Analysis**

The array data were analyzed with the R package Limma version 3.18.13 (Smyth, 2005; www.bioconductor.org; www.R-project.org). After background correction (“minimal method”), within-array normalization was applied using global loess normalization. Subsequently, the data was log₂ transformed. Between-array normalization was applied using A-quantile normalization (Bolstad et al., 2003). Log₂ expression values for the different time points (after increasing the pCO₂) were calculated with respect to the reference value at t = 0 (just before increasing the pCO₂). Expression values of multiple probes per gene were averaged. Hence, for each gene we obtained four expression values per time point, based on the four replicate chemostats. For each time point, p-values were calculated from the moderated t-statistic, and were adjusted for multiple hypothesis testing by controlling the false discovery rate (Storey and Tibshirani, 2003). Log₂ gene expression values of p < 0.9 or > 0.9 (similar to Nodop et al., 2008; Schwarz et al., 2011), and p < 0.01 were considered differentially expressed.
RT-qPCR Gene Expression Analysis

To validate the microarray results, we also investigated changes in gene expression of several CCM genes and the mcyB gene using RT-qPCR. We designed gene-specific primers (Supplementary Table 3). Secondary structure analysis of the primers was checked with OligoAnalyzer 3.1 (Integrated DNA Technologies, Coralville, IA, USA) and the in silico specificity was assessed using Primer-BLAST (Ye et al., 2012). The specificity of the primers was confirmed with normal PCR on genomic DNA using the GoTaq® Hot Start DNA polymerase kit (Promega GmbH, Mannheim, Germany) combined with gel electrophoresis.

For the RT-qPCR gene expression analysis, we used the same RNA samples as for the microarray analysis at the time points 0, 4, and 336 h (2 weeks) after increasing the CO₂ concentration. The specificity of the primers was confirmed with normal PCR on genomic DNA using the GoTaq® Hot Start DNA polymerase kit (Promega GmbH, Mannheim, Germany) combined with gel electrophoresis.

Amplification efficiencies of individual runs (E) were calculated with LinRegPCR (version 2012.3; Ramakers et al., 2003; Ruijter et al., 2009) and were between 1.8 and 2.0 (Supplementary Table 3). Time point 0 (just before the increase of CO₂) was used as reference sample, and 16S rRNA was used as reference gene. Each RT-qPCR plate contained a reference sample and samples with primers targeting 16S rRNA to overcome plate effects. For each individual sample, two technical replicates were measured and the average of the two measurements was used in the data analysis. The data were baseline corrected using LinRegPCR, and the same software was used to calculate quantification cycle (Cq) values. LinRegPCR did not detect samples without amplification, without a plateau, with a baseline error or noise error, or with deviating amplification efficiencies. Negative control samples did not show significant amplification. For each gene, we calculated the relative gene expression with respect to time point 0 using 16S rRNA as reference gene according to the 2^(-ΔΔCt) method (Livak and Schmittgen, 2001). MS Excel version 2010 and SPSS version 20.0 were used for the statistical analyses. A one-tailed t-test was used to assess whether the change in gene expression with respect to time point 0 was significant (again with n = 4 expression values per time point, based on the four replicate chemostats). An independent samples t-test was used to detect differences between the 4h and 2 week samples. The false discovery rate (FDR) was used to correct for multiple hypothesis testing (Benjamini and Yekutieli, 2001; FDR adjusted p < 0.05).

O₂ Optode Experiments

In mineral medium without nitrate, the O₂ evolution rate of cyanobacterial cells exposed to saturating light provides a good proxy of their Cᵢ uptake rate (Miller et al., 1988). We therefore measured O₂ evolution with an Oxy-4 mini O₂ optode (PreSens GmbH, Regensburg, Germany) to study the Cᵢ uptake of samples from the steady-state chemostats at 200 and 1450 ppm pCO₂. External carbonic anhydrase activity in *Microcystis* was previously shown to be negligible (Song and Qiu, 2007). Fresh cell samples were pelleted (4000 g for 5 min at 20°C), washed 1x and then resuspended in C₅₇ and nitrate-depleted modified BG11 medium (no added NaNO₃ and NaCO₃/NaHCO₃, but with 25 mmol L⁻¹ NaCl and 10 mmol L⁻¹ CAPSO-NaOH added at pH 9.8; the medium was aerated with N₂ gas for 4h before usage). The absorbance at 750 nm (A750) of washed and resuspended samples was 0.300. Three mL of sample was inserted into custom-made glass incubation chambers (four measurements were done at the same time), each connected to an O₂ optode. The glass chambers were connected to a RM6 water bath (Lauda, Lauda-Königshofen, Germany) to keep the temperature of the samples at 20.3°C. Magnetic stirring was used for mixing. The O₂ optode sensors were calibrated with N₂ gas (“0%”) and air (“100%). A saturating amount of light (500 μmol photons m⁻² s⁻¹) was used, which was provided by KLI500 compact Schott lamps (Schott AG, Mainz, Germany). Subsequently, specific amounts of NaHCO₃ were added (5, 20, 100, 300, 1000, or 10,000 μmol L⁻¹), after which the rate of O₂ evolution (μmol L⁻¹ min⁻¹) was measured. The evolution was expressed per mg of chlorophyll a. Photosynthetic pigments were extracted with 90% acetone and analyzed using HPLC with photodiode array detector (LC-20AD liquid chromatographs, SIL-20A auto sampler, CTO-20AC column oven, SPD-M20A diode array detector, RF-10AXL fluorescence detector; Shimadzu, Kyoto, Japan). Identification of chlorophyll a was based on the characteristic absorbance at 664 nm and the specific retention time compared with a standard obtained from DHI Group (Copenhagen, Denmark).

To evaluate the activity of the different Cᵢ uptake systems, we investigated O₂ evolution in the presence and absence of 25 mmol L⁻¹ LiCl. Lithium ions are known to inhibit the activity of the sodium-dependent bicarbonate uptake systems (e.g., Espie et al., 1988). The experiments were performed at pH 7.8 (using 10 mmol L⁻¹ TES-KOH pH 7.8 buffer) and pH 9.8 (using 10 mmol L⁻¹ CAPSO-KOH pH 9.8 buffer) to vary the relative availability of CO₂ and HCO₃⁻, using Cᵢ and N depleted modified BG11 medium containing 25 mmol L⁻¹ NaCl to which 200 μmol
L$^{-1}$ KHCO$_3$ was added after initial C$_i$ depletion. To test if O$_2$ evolution rates differed significantly between the treatments, one-way analysis of variance was used with post-hoc comparison of the means based on Tukey’s test ($n = 4$ replicates per treatment).

**Results**

**Population Dynamics and Inorganic Carbon Chemistry**

During the first phase of the experiment, we used a low pCO$_2$ concentration in the gas flow of 200 ppm to create C$_i$-limited conditions. In all four replicate chemostats, the cyanobacterial abundance gradually increased over time and approached a steady state after ~17 days (Figure 1A). Cell growth in the chemostats attenuated the light passing through, so that the light penetration I$_{out}$ at this first steady state was reduced to ~6 $\mu$mol photons m$^{-2}$ s$^{-1}$ (Figure 1A). The dCO$_2$ concentration was depleted to the nano-molar range (Figure 1B). This was accompanied by a rise in pH to ~11, a strong decrease in bicarbonate concentration to ~60 $\mu$mol L$^{-1}$ and a strong increase in carbonate concentration to ~300 $\mu$mol L$^{-1}$ (Figures 1B,C). The total DIC concentration was not much affected during this first phase of the experiment (Figure 1C).

After 36 days, we raised the pCO$_2$ level in the gas flow to 1450 ppm pCO$_2$. The transition from 200 to 1450 ppm led to major changes in pH and inorganic carbon chemistry (Figures 1B,C; Supplementary Figure 1). Within 24 h, the dCO$_2$ concentration increased over more than four orders of magnitude to ~30 $\mu$mol L$^{-1}$, while the pH dropped back from 11 to 8 and the bicarbonate concentration increased to ~2000 $\mu$mol L$^{-1}$ (Supplementary Figure 1). The enhanced CO$_2$ availability alleviated the cyanobacteria from C$_i$ limitation, thus enabling a strong increase in cyanobacterial abundance (Figure 1A). The resultant high biomass effectively absorbed all incident light, reducing light penetration through the chemostats to I$_{out} < 0.1$ $\mu$mol photons m$^{-2}$ s$^{-1}$ (Figure 1A). Nitrate uptake by the growing cyanobacterial population increased alkalinity (Supplementary Figure 2), which initiated a progressive further increase of the DIC concentration (Figure 1C). After 46 days a new steady state was attained, with a ~2.7-fold higher cyanobacterial abundance than the previous steady state, a DIC concentration of ~3500 $\mu$mol L$^{-1}$ consisting largely of bicarbonate and CO$_2$, but low light conditions (Figures 1A–C).

**Cell Volume, Cell Weight, and Cellular Composition**

Although the cell volume of *Microcystis* was hardly affected by the elevated pCO$_2$, the average dry weight of the cells decreased by 50%, from 12 to 6 pg cell$^{-1}$ (Figure 2A). This was accompanied by a decrease of the C and N content of the cells at elevated pCO$_2$ (Figure 2B). Remarkably, the molar C/N ratio of the cells also slightly decreased at elevated pCO$_2$ (Figure 2C), despite the strong increase in C$_i$ availability.

Major macromolecules (carbohydrates, proteins, and lipids) and phosphate stored in the cells were quantified just before and 2 weeks after raising the pCO$_2$ level (Figure 2D). The carbohydrate content (expressed as % dry weight) decreased significantly (Student t-test: $t_6 = 4.6$, $p < 0.01$), whereas the protein content increased significantly at elevated pCO$_2$ (Student t-test: $t_6 = -6.8$, $p < 0.001$) (Figure 2D), which is consistent with the decrease of the cellular C/N ratio (Figure 2C). Lipids and phosphate contributed less to the total average cell weight than carbohydrates. Genes involved in carbohydrate storage and polyhydroxyalkanoate (PHA) storage showed no large changes in expression during the experiment, although minor upregulation of the *pha* genes was noticeable 8 h after the switch to high pCO$_2$ (Table 1).
Pigments and Photosystems

Light absorption spectra normalized at 750 nm indicated that the cellular contents of the pigments chlorophyll $a$, phycocyanin, and $\beta$-carotene increased at elevated pCO$_2$ (Figure 3A). The phycocyanin peak (at 626 nm) increased slightly more than the chlorophyll $a$ peak (at 678 nm). The ratio of PSI to PSII changed, with less PSII and more PSI at elevated pCO$_2$ (Figure 3B). Yet, only a few genes involved in pigment synthesis and none of the photosystem genes changed expression significantly after exposure to high pCO$_2$ (Table 1).

Secondary Metabolites Including Toxins

The microcystin concentration stabilized at $\sim$300 $\mu$g L$^{-1}$ at low pCO$_2$ and increased 6-fold to $\sim$2000 $\mu$g L$^{-1}$ at high pCO$_2$ (Figure 4A). The microcystin content per cell was $\sim$15 fg cell$^{-1}$ at the steady state at low pCO$_2$, and increased to $\sim$38 fg cell$^{-1}$ at high pCO$_2$. Other secondary metabolites produced by Microcystis PCC 7806 include aeruginosin, microcyclamide, cyanopeptolin, and polyketides. However, expression of the microcystin, aeruginosin, microcyclamide, and cyanopeptolin operons did not change significantly (Figure 4B). In contrast, the expression of two polyketide synthase operons (PKS I/III) increased strongly 72 and 336 h after increasing the pCO$_2$.

Carbon, Nitrogen and Stress-Related Genes

Several but not all genes involved in the CCM of Microcystis responded to elevated CO$_2$ (Figure 5). Expression of the cmpABCD operon encoding the BCT1 bicarbonate uptake system and the bicA-nhaS3 operon encoding the BicA bicarbonate uptake system was strongly reduced after 2 h at high pCO$_2$ and remained low during the next 2 weeks. Expression levels of the transcriptional regulators ccmR (upstream of the high-affinity CO$_2$ uptake operon) and ccmR2 (upstream of the bicA-nhaS3 operon) were also downregulated at elevated pCO$_2$. In contrast, expression of the CO$_2$ uptake system genes remained unchanged, except for a slight downregulation of the ndhF3 gene involved in high-affinity CO$_2$ uptake. Expression of genes for carboxysome formation (ccmK2-4, ccmL, cmmM, ccmN, and ccmO), RuBisCO (rbcL, rbcS, and rbcX) and carbonic anhydrases (ccaA, ecaA, and ecaB) remained constant as well (Figure 5). Results of the microarray experiments were validated with RT-qPCR for selected CCM genes, which gave similar results (Supplementary Figure 3).

Only a few genes involved in C metabolism and N assimilation showed significant changes in expression at elevated pCO$_2$ (Table 1). Expression of glnN, encoding for a glutamine synthetase, was upregulated at elevated pCO$_2$. The genes nrtA and nrtB involved in nitrate uptake, nirA involved in nitrite reduction, and ntcB involved in the control of N assimilation were slightly upregulated shortly after increasing the pCO$_2$.

Several stress-related genes were downregulated at elevated pCO$_2$, including the flavodiiron protein genes flv2 and flv4, the iron-stress chlorophyll-binding protein gene isiA and the sigma factor sigH (Table 1).

Log2 values quantify gene expression at the given time point (after increasing the pCO$_2$) with respect to gene expression at t = 0 (just before increasing the pCO$_2$). Only the responsive genes are shown; the complete data set including all non-responsive genes is provided in Supplementary Table 4. IPF numbers are the locus tags of Microcystis PCC 7806 in the EMBL database (AM778843–AM778958). ns, not significant; GS/GOGAT, glutamine synthetase/glutamine-2-oxoglutarate amidotransferase; Gene function categories (CyanoBase), (1) amino acid biosynthesis; (2) biosynthesis of cofactors, prosthetic groups, and carriers; (5) central intermediary metabolism; (6) energy metabolism; (8) photosynthesis, and respiration; (12) transcription; (14) transport and binding proteins; (15) other categories; (16) hypothetical.

Physiological Assay of C$_i$ Uptake

To assess the activity of the bicarbonate uptake systems BicA and BCT1, O$_2$ evolution was studied as a function of bicarbonate availability (Figure 6A). We added 25 mmol L$^{-1}$ NaCl to enable sodium-dependent bicarbonate uptake by BicA. The experiments were performed at pH 9.8, at which DIC contains only $\sim$0.03% dCO$_2$. Without DIC in the medium the samples did not evolve O$_2$, but their O$_2$ evolution resumed after addition of NaHCO$_3$. Cells from the chemostats at 200 ppm pCO$_2$ had a higher affinity at low NaHCO$_3$ concentrations (5–100 µmol L$^{-1}$) than cells from the chemostats at 1450 ppm pCO$_2$. At higher NaHCO$_3$ concentrations (300–10,000 µmol L$^{-1}$), cells from both pCO$_2$ conditions reached a plateau in O$_2$ evolution (Figure 6A). These results suggest that the high-affinity bicarbonate uptake system BCT1 was active in the chemostats at low pCO$_2$ (200 ppm) but not at elevated pCO$_2$ (1450 ppm), while the low-affinity bicarbonate uptake system BicA was active at both pCO$_2$ levels.

To further explore the involvement of the C$_i$ uptake systems, we added lithium ions to inhibit the sodium-dependent bicarbonate uptake of BicA (Figure 6B). These experiments were performed at pH 7.8 and pH 9.8, at which DIC contains 3.7% and 0.03% dCO$_2$, respectively. For cells taken from both low and high pCO$_2$ chemostats, we found high activity at pH 7.8 and at pH 9.8. However, addition of 25 mmol L$^{-1}$ LiCl resulted in high activity at pH 7.8 but not at pH 9.8. At pH 7.8, the conversion of bicarbonate to CO$_2$ and subsequent uptake by
the CO₂ uptake systems likely compensated for the inactivation of BicA by lithium ions. In contrast, at pH 9.8, when dCO₂ is negligible and Cᵢ uptake relies on bicarbonate, the inactivation of BicA by lithium ions was not compensated and drastically reduced Cᵢ uptake. These results suggest that, in the chemostats, both BicA and the CO₂ uptake systems were active at both pCO₂ conditions.

**Discussion**

**Alleviation from Cᵢ Limitation**

During dense blooms in eutrophic and hypertrophic lakes, cyanobacterial growth can become limited by a low Cᵢ availability (Ibelings and Maberly, 1998; Balmer and Downing, 2011; Verspagen et al., 2014b). Our experiments show that at low atmospheric pCO₂ levels, the photosynthetic activity of the cyanobacteria depleted the dCO₂ concentration to the nanomolar range, while the bicarbonate and carbonate concentrations were orders of magnitude higher, which forced cells to primarily use bicarbonate as carbon source. An increase in pCO₂ shifted the growth conditions from very low dCO₂ concentrations and modest light availability to higher dCO₂ concentrations but lower light levels (Figure 1). The *Microcystis* population in our experiments benefited strongly from the increased dCO₂ availability, and accelerated cell division during the subsequent transient phase. This demonstrates that growth was indeed Cᵢ limited at low pCO₂ levels. The increased cyanobacterial abundance reduced light availability, until the cyanobacterial population settled at a new steady state. Hence, our experiments support the prediction (Verspagen et al., 2014b) that rising CO₂ levels will alleviate cyanobacteria from Cᵢ limitation, and are likely to increase the cyanobacterial abundance in eutrophic and hypertrophic lakes.
Surprisingly, the increase in pCO₂ induced changes in the expression of only 234 genes of *Microcystis* PCC 7806 (Supplementary Figure 4). This is only ∼5% of the total number of protein-encoding genes investigated in this study, and many of these showed differential expression at only a few time points. For instance, only 0.6% of the genes were differentially expressed at the time point of 24 h after the rise in CO₂. In contrast, in other studies, 20–25% of the genes of *Synechocystis* PCC 6803 (Eisenhut et al., 2007) and 50–55% of the genes of *Synechococcus elongatus* PCC 7942 (Schwarz et al., 2011) were differentially expressed after 24 h of Cᵃ limitation.

The much stronger transcriptome response in these two latter studies than in our results might be explained by differences in experimental design. (Eisenhut et al., 2007; Schwarz et al., 2011) exposed the cells to Cᵃ starvation, which ceased cell growth and induced a large stress response. In contrast, the growth rate in our chemostat experiments was kept relatively high, which resulted in a milder response to elevated CO₂. An alternative explanation might be that the cyanobacterium *Microcystis* shows a much more specific transcriptome response to changing Cᵃ conditions than *Synechocystis* and *Synechococcus*. *Microcystis* is a buoyant cyanobacterium that can develop dense blooms in eutrophic lakes, where it is typically exposed to a wide range of different CO₂ conditions (Verspagen et al., 2014b). A highly specific transcriptome response that mainly targets the Cᵃ uptake systems could preserve energy and offer a robust strategy for a species that often experiences strongly fluctuating Cᵃ conditions.

**Changes in Expression of CCM Genes**

Our results show that the bicarbonate uptake genes encoding for BCT1 and BicA were downregulated at elevated pCO₂ (Figure 5). Additionally, expression of the transcriptional regulator ccmR2, located upstream of the bicA-nhaS3 operon, was lowered.

BCT1 has a relatively high affinity for bicarbonate (Kₒ₅ ≈ 70–350 µmol L⁻¹) while it has a high flux rate (Price et al., 2004). Contrary to expectation, the bicA expression was highest at low pCO₂, where the bicarbonate concentration was only ∼60 µmol L⁻¹ (Figure 1B). This was also observed in a study of *Synechococcus* PCC 7002, where the expression of bicA was enhanced by Cᵃ limitation (Woodger et al., 2007). However, it differs from studies of *Synechocystis* PCC 6803, which found that the expression of bicA was not much affected by the pCO₂ encoding BCT1 was highest at the low pCO₂ condition. This is further supported by the bicarbonate response curves of the *O₂* optode experiments, which showed high-affinity bicarbonate uptake at low pCO₂ but not at high pCO₂ (Figure 6A). The high activity of BCT1 in low pCO₂ conditions is consistent with previous studies with other cyanobacteria, which showed enhanced expression of the *cmpABCD* genes upon induction of Cᵃ limitation (Woodger et al., 2003; Eisenhut et al., 2007; Schwarz et al., 2011).

Conversely, BicA has a relatively low affinity for bicarbonate (Kₒ₅ ≈ 10–15 µmol L⁻¹) and a low flux rate (Omata et al., 2002). In line with expectation, expression of the genes *cmpABCD*
level (Wang et al., 2004; Eisenhut et al., 2007). Our results show that, even though the \textit{bicA} gene of \textit{Microcystis} PCC 7806 was less expressed at high pCO$_2$, the BicA enzyme was still active at high pCO$_2$. This is apparent from the O$_2$ optode experiments in which we blocked BicA activity with lithium ions (Figure 6). Hence, BicA appears active at a relatively wide range of bicarbonate concentrations.

Compared to several other \textit{Microcystis} strains, \textit{Microcystis} PCC 7806 lacks the bicarbonate uptake system SbtA (Sandrini et al., 2014), which has an even higher affinity for bicarbonate (K$_{0.5} < 2 \mu$mol L$^{-1}$) than BCT1 (Price et al., 2004). Therefore, \textit{Microcystis} PCC 7806 seems less adapted to very low bicarbonate conditions than SbtA-containing \textit{Microcystis} strains, and was likely trying to take up as much bicarbonate as possible by expressing both BCT1 and BicA at the low pCO$_2$ condition, even though the BicA uptake system did not operate very efficiently at that stage.

In contrast to the strong response of the bicarbonate uptake genes, gene expression of the CO$_2$ uptake systems was not affected by elevated pCO$_2$ (Figure 5). For instance, the \textit{chpX} and \textit{chpY} genes, encoding for the CO$_2$ hydration subunit of the low-affinity and high-affinity CO$_2$ uptake systems, respectively, were constitutively expressed in \textit{Microcystis} PCC 7806. The constitutive expression of \textit{chpX} is consistent with studies of other cyanobacteria (Woodger et al., 2003; Wang et al., 2004; Schwarz et al., 2011). However, the constitutive expression of \textit{chpY} contrasts with studies of other cyanobacteria, which found that \textit{chpY} was highly inducible when cells were exposed to C$_i$ limitation (Price et al., 2004; Wang et al., 2004; Schwarz et al., 2011). Constitutive expression of the CO$_2$ uptake systems indicates that at low dCO$_2$ concentrations the \textit{Microcystis} cells were still capable of CO$_2$ uptake. This was confirmed by the O$_2$ optode experiments, which showed that CO$_2$ uptake was active at both pCO$_2$ levels when bicarbonate uptake was blocked by lithium ions (Figure 6B).

Expression of the transcriptional regulator \textit{ccmR}, located upstream of the high-affinity CO$_2$ uptake operon, was strongly downregulated at high pCO$_2$ (Figure 5). This is noteworthy, because expression of the high-affinity CO$_2$ uptake genes did not respond to elevated pCO$_2$. Possibly, CcmR regulates the expression of the \textit{cmpABCD} operon of \textit{Microcystis}, which was strongly downregulated at high pCO$_2$. This would be consistent with the observation that CmpR, a known transcriptional regulator of the \textit{cmpABCD} operon in other cyanobacteria, is lacking in \textit{Microcystis} (Sandrini et al., 2014). Indeed, Woodger et al. (2007) previously showed that CcmR in \textit{Synechococcus} PCC 7002 does not only control the high-affinity CO$_2$ uptake operon but also the expression of other CCM genes.

Interestingly, gene expression of several key components of the CCM, including carboxysome, RubisCO and carbonic anhydrase genes, was not affected by elevated pCO$_2$ (Figure 5), suggesting that cells did not alter carboxysome component numbers. This is counterintuitive, since C$_i$ availability strongly increased after the upshift in pCO$_2$. Yet, it seems that \textit{Microcystis} simply adjusted its C$_i$ uptake arsenal to deal with the change in C$_i$ availability. In contrast, studies that induced C$_i$ limitation in \textit{Synechocystis} PCC 6803 and \textit{Synechococcus elongatus} PCC 7942 observed downregulation of carboxysomal genes after 24h (Eisenhut et al., 2007; Schwarz et al., 2011). Possibly, the cyanobacteria in these latter studies did not need to produce new carboxysomes, because their growth rate was arrested in the experiments of Eisenhut et al. (2007) and Schwarz et al. (2011). This differs from our chemostat experiments, in which the growth rate was kept relatively high by the dilution rate, and hence carboxysome production should be maintained. Therefore, differences in experimental design might explain these results. Alternatively, the contrasting results might reflect species-specific differences, where \textit{Microcystis} displays a milder response to fluctuating C$_i$ conditions than these other cyanobacteria (see preceding discussion in section Alleviation from C$_i$ limitation).

**Reduced Expression of Stress-Related Genes**

Our results show reduced expression of several stress genes (\textit{flv2}, \textit{flv4}, \textit{isiA}, \textit{sigH}) at elevated CO$_2$ (Table 1). Flavodiiron proteins have previously been linked to acclimation to low C$_i$ conditions (Zhang et al., 2009; Allahverdiyeva et al., 2011; Bersanini et al., 2014). Flv2 and Flv4 are unique for cyanobacteria. They are involved in photoprotection of the PSII complex (Zhang et al., 2009), and can function as electron sink (Bersanini et al., 2014). Reduced expression of the flavodiiron protein genes \textit{flv2} and \textit{flv4} at elevated pCO$_2$ is in agreement with previous studies with \textit{Synechocystis} PCC 6803 (Wang et al., 2004; Eisenhut et al., 2007).

The iron-stress chlorophyll-binding protein IsiA can function as a storage unit for spare chlorophyll molecules, as a PSI antenna enhancing the light harvesting ability, and in addition can protect PSII from photooxidative stress (Yeremenko et al., 2004; Havaux et al., 2005). Reduced expression of the \textit{isiA} gene at elevated pCO$_2$ likely signifies lower levels of oxidative stress, which shifted the IsiA-bound spare chlorophylls to new chlorophyll protein complexes.

Sigma factors are involved in transcription initiation. \textit{sigH} expression typically increases with general stress (Huckauf et al., 2000; Hakkila et al., 2013). The expression of \textit{sigH} was lowered in our study after the increase in pCO$_2$ (Table 1), indicating that the cells perceived less stress at this stage.

**Increased Toxins per Cell at Elevated CO$_2$?**

Our results show that cells of \textit{Microcystis} PCC 7806 contained a 2.5 times higher microcystin content at elevated pCO$_2$. Similar results were found in an earlier study with \textit{Microcystis} HUB 5-2-4, where elevated CO$_2$ also produced a transition from C$_i$ to light limitation and an ~2–2.5-fold increase in microcystin content (Van de Waal et al., 2009). This suggests that rising CO$_2$ levels will increase the toxicity of \textit{Microcystis} cells.

In contrast to the increase of the cellular microcystin content, expression of the \textit{mcy} genes remained constant during the shift from low pCO$_2$ to high pCO$_2$ (Figure 4B). Gene expression may not be equivalent to abundance of the final gene product, and a further complication is that microcystins are synthesized by non-ribosomal peptide synthetases (Dittmann et al., 1997). The control mechanisms for the synthetase activity are largely unknown, but it has been suggested that amino acid availability may play a decisive role (Tonk et al., 2008; Van de Waal et al., 2010a).
The microarray results showed a strong increase in two polyketide synthase operons (PKS I/III) at elevated pCO$_2$ (Figure 4B). These operons were described previously (Franguel et al., 2008; Makower et al., 2015), yet the structure of the actual produced compounds and the exact function remain unknown. Polyketides have diverse biological functions and many have pharmacological and toxicological properties. Further research is needed to know more about the polyketides of cyanobacteria.

**Other Physiological Responses to Elevated CO$_2$**

Our results also point at several other physiological changes in response to rising pCO$_2$ levels. For example, the dry weight of cells decreased ~2-fold at elevated pCO$_2$, but the cells were hardly smaller (Figure 2A). This was accompanied by a reduced cellular C storage, lower cellular C/N ratio and reduced carbohydrate content at elevated pCO$_2$ (Figures 2B–D). A lower cellular C content at elevated CO$_2$ contradicts the common expectation that rising CO$_2$ levels will increase the carbon content of phytoplankton cells (e.g., Finkel et al., 2010; Van de Waal et al., 2010b; Verschoor et al., 2013). However, recent experiments showed that also other *Microcystis* strains do not increase their C/N ratio at elevated CO$_2$ when provided with an ample nutrient supply (Verspagen et al., 2014a). A possible explanation for these observations might be that cells do not require large amounts of C reserves in the presence of plentiful C$_i$ in the environment. Furthermore, changes in carbohydrate content are known to play a role in the vertical migration of *Microcystis* (Thomas and Walsby, 1985; Visser et al., 1997; Wallace et al., 2000). A strong decrease in cellular dry matter and carbohydrate content will increase the buoyancy of cells, which may be particularly advantageous when cells experience low light levels. The shift from C$_i$ to light limitation induced by rising CO$_2$ concentrations may thus stimulate the formation of surface blooms in *Microcystis*-dominated lakes.

Elevated pCO$_2$ levels also led to an increase in the photosynthetic pigments and in the PSI/PSII ratio of the cells (Figures 3A,B). Most likely, this response is due to the reduced light availability caused by the denser cultures at elevated pCO$_2$. This process, known as photoacclimation, is well-known to occur in cyanobacteria (Deblois et al., 2013). Yet, expression of the psa and psb genes for photosystem components remained unaltered.

We did not observe many changes in the genes involved in C and N metabolism (Table 1). One exception is the upregulation of glhnN, that encodes for a glutamine synthase. The expression of glhnN has been linked with nitrogen stress (Reyes et al., 1997). In this way the N metabolism of the cells responds subtly to changes in C$_i$ availability caused by high pCO$_2$ levels.

**Concluding Remarks**

We investigated the genetic and physiological response of the harmful cyanobacterium *Microcystis* to rising CO$_2$. The experiments were conducted in chemostats, which provide ideal conditions to study microorganisms in a controlled environment. Yet, chemostats provide a simplified experimental setting in comparison to the complexity of the natural world. In lakes, buoyancy regulation enables *Microcystis* populations to form dense blooms at the water surface (Reynolds and Walsby, 1975; Huisman et al., 2004), where they intercept the influx of atmospheric CO$_2$ (Ibelings and Maberly, 1998). Hence, the formation of surface blooms is a successful strategy to avoid low CO$_2$ availability deeper in the water column (Paerl and Ustach, 1982). However, despite their proximity to the surface, dissolved CO$_2$ concentrations can be strongly depleted and pH may exceed 9 during surface blooms of buoyant cyanobacteria (López-Archilla et al., 2004; Verspagen et al., 2014b). The high concentration of cells in blooms causes a high local demand for inorganic carbon and consequently extreme carbon limitation (Ibelings and Maberly, 1998), resembling the conditions in our CO$_2$-limited laboratory experiments.

In our experiments, elevated CO$_2$ alleviated *Microcystis* cells from C$_i$ limitation. In response, *Microcystis* induced changes in the expression of a relatively limited number of genes, including several genes involved in C$_i$ uptake. The expression of several stress-related genes was reduced at elevated CO$_2$, while only a few key genes at control sites of cellular C/N metabolism were regulated. At elevated CO$_2$, *Microcystis* cells halted its high-affinity bicarbonate uptake systems, and relied on CO$_2$ and low-affinity bicarbonate uptake systems. This supports earlier results that high-affinity bicarbonate uptake systems will become less essential with rising CO$_2$ (Sandrini et al., 2014). This may ultimately lead to an evolutionary loss of high-affinity C$_i$ uptake systems, as shown in evolution experiments with the green alga *Chlamydomonas reinhardtii*. This green alga lost its ability to induce high-affinity C$_i$ uptake while maintaining its low-affinity C$_i$ uptake after 1000 generations at elevated CO$_2$ levels (Collins and Bell, 2004; Collins et al., 2006).

In addition to changes in C$_i$ uptake, elevation of the CO$_2$ concentrations in our experiments also led to a higher population abundance, increased buoyancy of the cells, and higher toxin content per *Microcystis* cell. This indicates that the current rise in atmospheric CO$_2$ levels may strongly increase the problems associated with the harmful cyanobacterium *Microcystis* in eutrophic lakes.
