Acylcarnitines: reflecting or inflicting insulin resistance?

Marieke G. Schooneman, Frédéric M. Vaz, Sander M. Houten, Maarten R. Soeters

*Diabetes* (2013) 62, 1-8
Introduction

The incidence of obesity and insulin resistance is growing and the increase in type 2 diabetes mellitus constitutes one of the biggest challenges for our healthcare systems. Many theories are proposed for the induction of insulin resistance in glucose and lipid metabolism and its metabolic sequelae. One of these mechanisms is lipotoxicity (1-4): here excess lipid supply and subsequent lipid accumulation in insulin sensitive tissues such as skeletal muscle interferes with insulin responsive metabolic pathways. Various lipid intermediates, like ceramides, gangliosides, diacylglycerol and other metabolites, have been held responsible for insulin resistance (2;3;5-10). These intermediates can exert such effects because they are signaling molecules and building blocks of cellular membranes, which harbor the insulin receptor. In addition, lipids play an important role in energy homeostasis. Fatty acids (FA) can be metabolized via mitochondrial FA oxidation (FAO), which yields energy (11). As such FAO competes with glucose oxidation in a process known as the glucose-fatty acid or Randle cycle (12).

Muioio and colleagues proposed an alternative mechanism in which FAO rate outpaces the TCA cycle, thereby leading to the accumulation of intermediary metabolites such as acylcarnitines that may interfere with insulin sensitivity (1;13;14). This accumulation of acylcarnitines corroborates with some human studies showing that acylcarnitines are associated with insulin resistance (15-17). In addition, acylcarnitines have a long history in the diagnosis and neonatal screening of FAO defects and other inborn errors of metabolism (18). This knowledge may aid to understand the interaction between FAO and insulin resistance and fuel future research. In this review, we discuss the role of acylcarnitines in FAO and insulin resistance as emerging from animal and human studies.

Physiological role of Acylcarnitines

Carnitine biosynthesis and regulation of tissue carnitine content

To guarantee continuous energy supply, the human body oxidizes considerable amounts of fat besides glucose. L-Carnitine transports activated long-chain FAs from the cytosol into the mitochondrion, and is therefore essential for FAO. Carnitine is mainly absorbed from the diet, but can be formed through biosynthesis (19). In several proteins, lysine residues are methylated to trimethyllysine (19). Four enzymes convert trimethyllysine into carnitine (19) of which the last step is the hydroxylation of butyrobetaine into carnitine by gamma-butyrobetaine dioxygenase (BBD). BBD is only present in human liver, kidney, and brain, which are the sites where actual carnitine biosynthesis takes place (19). Other tissues such as skeletal muscle must acquire carnitine from the blood. Treatment with a synthetic PPAR–alpha agonist increased BBD activity and carnitine levels in liver (20). This suggests that the nuclear receptor PPAR–alpha, which plays a crucial role in the adaptive response to fasting, is a regulator of (acyl)carnitine metabolism (20).

The plasmalemmal carrier OCTN2 is responsible for cellular carnitine uptake in various organs including reabsorption from urine in the kidney. As is the case for BBD, OCTN2
expression in liver is regulated by PPAR–alpha. A synthetic PPAR–alpha agonist increased OCTN2 expression in wild type mice and caused a rise in carnitine levels in plasma, liver, kidney, and heart (20). In PPAR–alpha −/− mice, low OCTN2 expression contributed to decreased tissue and plasma carnitine levels (20).

**The carnitine shuttle**

Once inside the cell, FAs are activated by esterification to CoA. Then, the carnitine shuttle transports long-chain acyl-CoAs into mitochondria via their corresponding carnitine ester (Figure 1) (21). Long-chain acyl-CoAs are converted to acylcarnitines by carnitine palmitoyltransferase 1 (CPT1), which exchanges the CoA moiety for carnitine. CPT1 is located at the outer mitochondrial membrane and three isoforms are known: CPT1a, 1b and 1c are encoded by separate genes (21). CPT1a is expressed in liver and most other abdominal organs, as well as human fibroblasts. CPT1b is selectively expressed in heart, skeletal muscle, adipose tissue and testes (11). CPT1c is only expressed in the endoplasmatic reticulum (and not the mitochondria) of neurons in the brain (22).

**FIGURE 1 The carnitine shuttle** After transportation into the cell by fatty acid transporters (FAT), fatty acids (FA) are activated by esterification to CoA. Subsequently, carnitine palmitoyltransferase 1 (CPT1) exchanges the CoA moiety for carnitine (C). The resulting acylcarnitine (AC) is transported across the inner mitochondrial membrane into the mitochondrion by carnitine acylcarnitine translocase (CACT). Once inside, carnitine palmitoyltransferase 2 (CPT2) reconverts the acylcarnitine back into free carnitine and a long-chain acyl-CoA that can undergo fatty acid oxidation for ATP production via the tricarboxylic acid cycle (TCA) and respiratory chain (ETC).
CPT1 is an important regulator of FAO flux. Glucose oxidation after a meal leads to inhibition of CPT1 activity via the FA-biosynthetic intermediate malonyl-CoA (23), which is produced by acetyl-CoA carboxylase (ACC) (24). There are two ACC isoforms. ACC1 plays a role in FA biosynthesis. ACC2 has been implicated in the regulation of FAO mainly because of its localization to the outer mitochondrial membrane (25). Conversely, in the fasting state, activated AMP-activated protein kinase inhibits ACC resulting in falling malonyl-CoA levels, thereby permitting CPT1 activity and thus FAO. CPT1a is limiting for hepatic FAO and ketogenesis (26). Although the inhibition of malonyl-CoA on CPT1b is more potent than on CPT1a, no unequivocal evidence exists showing its control over muscle FAO (27).

FAO is also regulated at the transcriptional level. PPAR-alpha, but also PPAR-beta/-delta, regulates the transcription of many enzymes involved in FAO. There is ample evidence that both PPARs participate in the transcriptional regulation of CPT1b (28–30). Regulation of CPT1a by PPAR is less prominent (21).

After production of acylcarnitines by CPT1, the mitochondrial inner membrane transporter carnitine acylcarnitine translocase (CACT or SLC25A20) transports the acylcarnitines into the mitochondrial matrix. The FA transporter CD36 possibly facilitates transfer of acylcarnitines from CPT1 to CACT (31). Finally, the enzyme CPT2 reconverts acylcarnitines back into free carnitine and long-chain acyl-CoAs, which can then be oxidized (21) (Figure 1).

**Analysis of acylcarnitines**

With the introduction of tandem mass spectrometry (MS) in clinical chemistry in the 1990’s, it became relatively easy to measure acylcarnitine profiles. In these profiles, the mass-to-charge ratio reflects the length and composition of the acyl chain (32). This technique rapidly became the preferred screening test to diagnose inherited disorders in FAO, which lead to prominent changes in the acylcarnitine profile, with a pattern specific for the deficient enzyme. More recently, acylcarnitine analysis is employed to investigate more common metabolic derangements such as insulin resistance.

Although most acylcarnitines are derived from FAO, they can be formed from almost any CoA ester (18). Other intermediates that yield acylcarnitines are ketone bodies (C4-3OH-carnitine (33)), degradation products of lysine, tryptophane, valine, leucine and isoleucine (C3- and C5-carnitine and others), and carbon atoms from glucose (acetylcarnitine) (18).

The standard acylcarnitine analysis using tandem MS cannot discriminate between stereoisomers and other isobaric compounds, which have the same nominal mass but a different molecular structure. These compounds can be separated using liquid chromatography-tandem MS (34). This is illustrated by C4-OH-carnitine, which can be derived from the CoA ester of the ketone body D-3-hydroxybutyrate, (D-C4-OH-carnitine), the FAO intermediate L-3-hydroxybutyryl-CoA (L-C4-OH-carnitine), and L-3-hydroxyisobutyryl-CoA, an intermediate in the degradation of valine (L-isoC4-OH-carnitine) (33).

**The origin of plasma acylcarnitines**

The fact that acylcarnitines can be measured in plasma, illustrates that they are transported across cell membranes. Two transporters have been implicated in the export of
acylcarnitines. In addition to import, OCTN2 can export (acyl)carnitines (35). Also, the monocarboxylate transporter 9 (SLC16A9) may play a role in carnitine efflux (36). Although these putative transporters have been identified, the exact nature of this transport is unknown, but seems largely dependent on the intracellular acylcarnitine concentration (35). Early studies in rodent heart, liver, and brain mitochondria proved mitochondrial efflux of acylcarnitines and suggested this to be dependent on the substrate and tissue as well as the availability of alternative acyl-CoA utilizing reactions (37). In humans, acylcarnitine efflux is exceptionally well evidenced by the acylcarnitine profiles of patients with a FAO defect (18). From a more physiological view, diets and fasting modulate the plasma acylcarnitine profile, which reflects changes in flux through the FAO pathway (13;16;38;39). However, exact rates of acylcarnitine production in relation to the FAO flux under different conditions remain to be determined.

It is expected that muscle or liver contribute largely to acylcarnitine turnover. Early studies showed that liver acylcarnitines correlated with plasma acylcarnitines in fasted macaques, but the individual chain lengths were not studied (40). A liver–plasma relation is plausible, considering that the liver accounts for most of the FAO activity during fasting. Human data are lacking, but muscle acylcarnitines did not correlate with plasma acylcarnitines during short-term fasting (16).

The physiological role of acylcarnitine efflux to the plasma compartment is unknown, but several scenarios are likely. Acylcarnitine formation prevents CoA trapping, allowing continuation of CoA-dependent metabolic processes (21;41). In addition to plasma, acylcarnitines are found also in bile and urine (42;43), suggesting that acylcarnitine efflux may serve as a detoxification process. Combined, the total daily bile and urine production of acylcarnitine is less than 200 μmol. This can be calculated to be less than 0.01 % of daily energy requirements which is a negligible amount in terms of potential energy loss. Moreover, intestinal re-uptake of bile acylcarnitines is possible. Alternatively, plasma acylcarnitines may serve as a means of transportation between cells or organs or sink for cellular/tissue acylcarnitine sequestration. Questions that remain are the contribution of specific tissues and organs to plasma acylcarnitine levels and the turnover rates of the individual acylcarnitine species in plasma.

Acylcarnitine metabolism in relation to insulin resistance

Current views on lipid metabolism in insulin resistance

FAO may be quantitatively and qualitatively different in insulin resistant subjects compared to healthy subjects, but a more pertinent conundrum is if increased FAO is either capable to limit insulin resistance via decreasing lipid accumulation or increasing insulin resistance via accumulation of incomplete FAO products such as acylcarnitines (1-3;13;14). Several theories describe mechanisms within the cytosol that can cause insulin resistance (figure 2). It has generally been accepted that chronic overnutrition leads to increased cytosolic lipid content of insulin responsive tissues (such as liver and skeletal muscle). This negatively affects the insulin sensitivity of these tissues by inhibiting insulin
FIGURE 2. Mechanisms of lipid-induced insulin resistance After transportation into the cell, fatty acids (FA) can be stored, oxidized or used as building blocks and signaling molecules (not all shown). Excess lipid supply and subsequent accumulation in insulin sensitive tissues such as skeletal muscle, is proposed to interfere with different insulin responsive metabolic pathways via various mechanisms. Firstly [1], increased intracellular lipid content inhibits insulin signaling via lipid intermediates such as ceramides, diacylglycerol (DAG) or gangliosides (GM3), via effects on protein phosphatase A2 (PPA2) and protein kinase B (AKT), protein kinase C (PKC) or effects on the insulin receptor in the cell membrane (1;3;5-8;44). Effects of lipid intermediates on inhibitors of nuclear factor-kappa beta kinase subunit beta (IKKbeta) and c-Jun N-terminal kinase 1 (JnK1) are not depicted. The second mechanism [2] is a decreased number of functional mitochondria resulting in lower FAO rates and increased accumulation of cytosolic lipid, again interfering with insulin sensitivity (2;9). Finally [3], metabolic overload of mitochondria leads to incomplete beta-oxidation. Here, oxidation of fatty acids (FA) outpaces the tricarboxylic acid cycle (TCA) and respiratory chain (RC), resulting in intramitochondrial accumulation of FAO intermediates like acylcarnitines. These subsequently impinge on insulin signaling (1;48;50-56). Here, only the direct effects of acylcarnitines on nuclear factor-kappa beta (NF-k beta) have been proposed (70).
signaling via intermediates as ceramide, diacylglycerol, gangliosides and possible other long-chain FA-derived metabolites (1;3;5-8;44). Although contested now, cytosolic lipid accumulation was also suggested to arise from mitochondrial dysfunction and as a consequence decreased FAO rate (2;9;14;45;46). Likewise, increased levels of malonyl-CoA were suggested to limit the mitochondrial entrance of long-chain FAs by blocking CPT1; thus resulting in accumulating cytosolic long-chain FAs and decreasing FAO rate (10). Alternatively, more recent mechanistic (13;47;48) and metabolomic (49-54) studies associated obesity-induced insulin resistance with intramitochondrial disturbances. In this model, lipid overload leads to increased rather than decreased FAO in skeletal muscle. This coincides with accumulating acylcarnitines, an inability to switch to carbohydrate substrate and a depletion of TCA cycle intermediates suggesting that FAO flux does not match TCA cycle flux leading to incomplete FAO (13;47;48). In vitro interfering with FA uptake in L6 myocytes or a coordinate induction of FAO and TCA cycle enzymes by exercise or PGC1alpha overexpression prevented insulin resistance (13;48). Moreover, using carnitine to stimulate FAO without affecting the TCA cycle in these myocytes was dose dependently associated with insulin resistance (13). Zucker Diabetic Fatty (ZDF) rats, a model for more severe insulin resistance, had higher acylcarnitines but lower TCA cycle intermediates (such as citrate, malate and succinate) in skeletal muscle, again suggesting that increased FAO induces insulin resistance when not followed by proportionally increased TCA cycle activity (13). Additionally, the malonyl-CoA decarboxylase (MCD)-/- mouse that had decreased FAO due to higher malonyl-CoA concentrations, resisted diet-induced insulin resistance, which further implicated FAO in the pathogenesis of insulin resistance (13). The available studies on acylcarnitine metabolism and the relationship with insulin resistance will be discussed in the next sections with a focus on human studies.

The effect of increased lipid flux on mitochondrial FA uptake and oxidation: implications for insulin sensitivity.

Insulin dependent type 2 diabetes mellitus patients had lower (~25%) carnitine concentrations especially with longer standing or complicated disease (55;56). Interestingly, carnitine infusions increased FAO in lean healthy subjects, but only when high dose insulin was co-administered (57;58), which may be explained by an increased muscle OCTN2 expression under these conditions (59). The importance of insulin for cellular carnitine uptake is underscored by the finding that insulin and carnitine administration lowered muscle malonyl-CoA and lactate concentrations while muscle glycogen increased (58). These findings are supported by animal studies, which demonstrated that carnitine levels were diminished in skeletal muscle of multiple insulin resistant rat models. A high fat diet (HFD) exacerbated the age-related decrease of tissue carnitine content in these rats (primarily skeletal muscle, liver and kidney) (60). Moreover carnitine supplementation of HFD animals decreased plasma glucose levels and HOMA indices (60;61). Likewise, carnitine supplementation improved insulin-stimulated glucose disposal in mouse models of diet-induced obesity and genetic diabetes (62). Recently it was shown that six months of carnitine supplementation improved glucose homeostasis in insulin-resistant humans (14). Although supplementation of carnitine possibly augments FAO and insulin sensitivity; the
lower carnitine levels in diabetes patients are unexplained. On the one hand carnitine uptake is insulin-dependent and therefore the a) absence of, or b) resistance to insulin may be the cause of lower carnitine levels. On the other hand, higher lipid load may lead to higher acylcarnitine concentrations and thus lower free carnitine.

In addition, several studies reported on the carnitine shuttle and its effects on the rate of FAO in the development of insulin resistance. Obese subjects had lower CPT1 and citrate synthase content in muscle and lower FAO, suggesting that lesions at CPT1 and post-CPT1 events (i.e. mitochondrial content) may lower FAO in obesity (63). Although short-term inhibition of CPT1 with etomoxir in humans did not impede insulin sensitivity despite increased intramyocellular lipid accumulation (64), prolonged inhibition in rats resulted in the accumulation of intramyocellular lipid and increased insulin resistance while doubling adiposity despite feeding a low fat diet (65). These results all led to the assumption that low FAO rates due to decreased function of CPT1 were associated with insulin resistance, possibly caused by an accumulation of intramyocellular lipid intermediates and their interference with insulin signaling. Indeed, CPT1 activity increased after an endurance training program in obese subjects, coinciding with increased FAO, improved glucose tolerance and insulin sensitivity (66). However, this may also be explained by the stimulatory effect of endurance training on mitochondrial function (i.e. TCA cycle and respiratory chain activity), thereby relieving the heavy lipid burden on mitochondria (48;67). In contrast to the model where excess FAO induces insulin resistance, these data suggest that decreasing mitochondrial FA uptake results in elevated intramuscular lipid levels and subsequent insulin resistance. However, increasing FAO by carnitine treatment in animals and humans permits mitochondrial FA uptake and oxidation that benefits insulin sensitivity. These observations will have to be reconciled with other studies that implicated incomplete FAO and acylcarnitine accumulation in the pathogenesis of insulin resistance.

**Short chain acylcarnitines in insulin resistance**

Older work reported elevated acylcarnitine levels in obese insulin resistant subjects (15), but acylcarnitines were not suggested to be implicated in insulin resistance at that time. The shortest acylcarnitine, acetylcarnitine, is of particular interest since it may illustrate the controlling role of acetyl-CoA on substrate switching and thus metabolic flexibility. The mitochondrial enzyme carnitine acetyltransferase (CrAT) converts acetyl-CoA to the membrane permeable acetylcarnitine and permits mitochondrial efflux of excess acetyl-CoA that otherwise could inhibit pyruvate dehydrogenase (68). Infusing intralipid decreased insulin sensitivity while increasing muscle acetylcarnitine (69). The same was true for plasma and muscle acetylcarnitine levels under high FAO conditions (starving) suggesting upregulation of CrAT to traffic acetyl-moieties (16). In contrast to lower CrAT expression in diabetic subjects (68), plasma acetylcarnitine levels showed significant positive correlation with HbA1c levels over a wide range of insulin sensitivity suggesting upregulation of CrAT in insulin resistant states (70). There is some complexity as both lipid and glucose oxidation funnel into acetylcarnitine as supported by different findings (68;71). First, the insulin mediated suppression of
muscle acetylcarnitine occurred under high FAO conditions, but not postabsorptively (i.e. higher glucose availability) (16). Also, muscle acetylcarnitine correlated negatively with FAO in the postabsorptive state (71), whereas plasma acetylcarnitine correlated with plasma glucose levels in the postprandial state (72). In light of these data, the question is interesting if CrAT really favours fatty acid-derived acetyl-CoA over glucose-derived acetyl-CoA since this might imply intracellular compartmentalisation of acetyl-CoA (68). Moreover, glucose-derived acetyl-CoA can be carboxylated by ACC, producing the CPT1 inhibitor malonyl-CoA. Direct effects of FAO-derived acetyl-CoA on insulin action are unknown.

C4-OH-carnitine (i.e. the carnitine ester of 3-hydroxybutyrate) has been proposed to cause insulin resistance: hepatic overexpression of malonyl-CoA decarboxylase (MCD) in rats on a high fat diet reversed whole-body, liver, and muscle insulin resistance whilst only decreasing C4-OH-carnitine within the acylcarnitine profile (47). In fasted humans, plasma and muscle C4-OH-carnitine increased (33). The increase in C4-OH-carnitine in these animal and human studies is quantitatively much more pronounced then the increase in acetylcarnitine; thus C4-OH-carnitine production may exert greater demands on cellular carnitine stores. Moreover ketone bodies yield acetyl-CoA, which stimulates PDK4 and thus inhibits glucose oxidation (73). In summary, under conditions characterized by higher FAO, elevated short chain acylcarnitines may reflect higher lipid fluxes but a direct relation to insulin resistance remains to be established.

Amino acid-derived acylcarnitines in insulin resistance
Metabolomics showed that branched-chain and aromatic amino acids (isoleucine, leucine, valine, tyrosine and phenylalanine) (74), significantly correlated with present or future diabetes (54;74;75). In line with this, the branched-chain amino acid-derived C3- and C5-carnitine, together with FA-derived C6- and C8-carnitine, were higher in obese and DM2 subjects compared to lean controls (17;54). In the same study, C4-dicarboxylcarnitine (C4DC-carnitine), also derived from branched-chain amino acid metabolism, showed a positive correlation with basal glucose levels and HbA1c (17). In comparison to obese non insulin resistant subjects, DM2 subjects also had higher C3- and C5-carnitine levels compared to controls during insulin administration. Here, C3- but not C5-carnitine correlated negatively with glucose disposal (17).

At first glance, correlations of acylcarnitines to surrogate markers of insulin resistance fit with mitochondrial overload and incomplete FAO. Acylcarnitines, however, also directly reflect the oxidation rate of FA and amino acids, which is supported by human nutrition-al intervention studies (16;33;38;39). The uncertainty regarding the direct interference of short chain acylcarnitines and their metabolism with insulin signaling processes and insulin sensitivity warrants care when attributing a primary role for amino acid-derived acylcarnitines in the induction of insulin resistance.

Medium- and long-chain acylcarnitines: more evidence for insulin resistant effects?
Long chain fatty acids such as palmitic acid were associated with insulin resistance, making a role for long chain acylcarnitines such as C16 in insulin resistance conceivable.
In 1980, Hoppel et al showed that the fasting-induced increase in plasma acylcarnitines was restored upon refeeding in lean subjects within 24 hours opposed to four days in obese subjects suggesting an impaired metabolic flexibility in the latter (15). The hypothesis that obesity-induced alteration in the acylcarnitine profile are caused by incomplete FAO was based largely on two animal studies by the same group showing that long-chain acylcarnitine species (C16, C18:2, C18:1 and C18) were persistently increased in diet-induced obese rats, in both fed and fasted state (13;48). As reported for humans, most acylcarnitine species decreased upon refeeding in the chow fed control group, but not in the obese animals, suggesting they were incapable of adjusting their metabolism in response to refeeding. Although excessive and incomplete FAO can be responsible for insulin resistance, it can be argued that FAO probably must be in relative excess to oxidation in TCA and respiratory chain in order to guarantee continuous energy supply. Obese and insulin resistant humans had higher plasma long-chain acylcarnitine levels compared to lean controls (17). Upon insulin infusion, long-chain acylcarnitines decreased overall, but to a lesser degree in the diabetic subjects. This was in agreement with lower resting energy expenditure (RER), indicating ongoing FAO or lipid flux (metabolic inflexibility) (17). Moderate correlations between acylcarnitine profiles and various clinical characteristics (i.e. higher BMI, basal FFA levels, insulin sensitivity) point at a causal relationship. The DM2 subjects were unable to suppress acylcarnitines during insulin infusion in contrast to matched obese controls: therefore, elevated long-chain acylcarnitines in the diabetic group likely reflect increased lipid flux and illustrates the tight connection of acylcarnitines with FAO flux (17).

Postprandially, plasma long-chain acylcarnitines did decrease in obese insulin resistant subjects, but the magnitude of this decrease correlated with both pre-meal insulin-mediated glucose disposal rates and FAO and has been largely explained by nadir levels of C12:1, C14, and C14:1-carnitine (72). This showed that the more insulin sensitive subjects are, the more capable they are at metabolizing FAs. Metabolomics in healthy overweight calorie restricted subjects yielded comparable results: here acylcarnitines correlated significantly with plasma insulin and FFA levels albeit with low correlation coefficient (49). All in all, acylcarnitines with longer chain lengths are associated with insulin resistance, which seems logic in the light of known effects of long-chain FAs on insulin signaling. Indeed, acylcarnitines can reside in cell membranes since they are amphipathic molecules. Increasing chain length favors partitioning into the membrane phase (e.g. C16- and 18-carnitine) (76). It is interesting to speculate that long-chain acylcarnitines can interfere with insulin signaling directly within the cell membrane (3). On the other hand, acylcarnitines seem to track with higher lipid flux and as such may only indicate higher FAO.

**Acylcarnitines: reflecting or inflicting insulin resistance?**

The concept of lipotoxicity is generally accepted in the field of obesity-induced impairment of insulin sensitivity and more and more attention has attributed to intramitochondrial alterations and impairments in FAO thereby focusing on acylcarnitines (1). Collected evidence shows that acylcarnitines have distinct functions in mitochondrial lipid metabolism. The transmembrane export of acylcarnitines suggests that they not only prevent
the accumulation of noxious acyl-CoAs, but also reduce CoA trapping which is crucial for many metabolic pathways (21;41). Additionally, the metabolism of short chain acylcarnitines and the interaction of acetyl-CoA and acetylcarnitine via CrAT may regulate the pyruvate dehydrogenase complex thereby affecting glucose oxidation (68). Besides mitochondrial need to liberate CoA and export acetyl-CoA, acylcarnitines may simply reflect the FAO flux.

The concept of increased, though incomplete FAO by disproportional regulation of FAO, TCA cycle and respiratory chain is attractive to explain insulin resistance. However, there remains doubt about this mechanism and there is no proof that acylcarnitines play a role in the induction of insulin resistance itself. Acylcarnitines are present under physiological conditions and their levels vary according to dietary circumstances (13;16;38;39). The acylcarnitine fluxes are unknown but probably much lower than FAO flux. Moreover, it can be argued that flux of FAO probably will be in relative excess to downstream oxidation in TCA and respiratory chain to guarantee continuous substrate supply and allow fine tuning and anticipation for metabolic changes (e.g. activity). Otherwise, the organism’s response to increased energy demands will be attenuated leading to more severe impairment of mitochondrial function as evidenced by the inherited FAO disorders.

Observational studies associating different acylcarnitines to a variety of endpoints may yield new hypotheses but are unlikely to move the field forward from a mechanistic perspective. Many questions are unanswered and some issues deserve particular attention. Tracer studies can quantify FAO flux and acylcarnitine production in different insulin resistant models on the cellular, tissue and whole organism level. Multiple animal and human models can help to investigate the effect of carnitine availability on insulin sensitivity. Mouse models for and humans with primary carnitine deficiency can be used to investigate the effect of carnitine availability on substrate switching and insulin sensitivity. In vitro work in muscle or liver cell lines is still important to dissect the influence of acylcarnitines on conventional insulin signaling or mechanisms of nutrient-induced mitochondrial stress. In this respect, different animal and human FAO disorders that accumulate acylcarnitines may undergo insulin sensitivity testing. The contribution of different organs to plasma acylcarnitines can be investigated using transorgan arterio-venous balance isotope dilution techniques under different conditions. Finally, we may set foot in new areas where acylcarnitines may have unexpected roles like interaction with the insulin receptor in the plasma membrane or signaling in the gut when co-secreted with bile. Recently, magnetic resonance spectroscopy was shown to image tissue acetylcarnitine in humans enabling noninvasive techniques to assay tissue acetylcarnitine (77). All these studies and more are necessary to decide to what extent acylcarnitines are reflecting or inflicting insulin resistance.
