Co-authors’ contribution

T. Oluoch, N. de Keizer and R. Cornet conceptualized and designed the study. I. Alaska and D. Kwaro contributed to the clinical components of the study and manuscript review. P. Langat and N. Okeyo provided oversight to the data management team that conducted the chart abstraction, focus group discussion (FGD) and overall data cleaning. K. Ochieng did the programming in OpenMRS, including developing the user interface. All co-authors were involved in interpreting the results. T. Oluoch, N. de Keizer and R. Cornet drafted and revised the manuscript. All authors edited and reviewed the manuscript and gave their final approval for submission to the journal.
**Abstract:**

**Introduction**
Several studies conducted in sub-Saharan Africa (SSA) have shown that routine clinical data in HIV clinics often have errors. Key data elements such as diagnosis of AIDS-defining illnesses (ADIs) are often missing, resulting in incorrect inference of WHO clinical staging, an indicator of progression of HIV infection. This negatively impacts the quality of care provided.

**Methods:**
We used a structured framework to derive a reference set of concepts and terms used to describe ADIs. The four sources used were: (i) CDC/Accenture list of opportunistic infections (ii) SNOMED Clinical Terms (SNOMED CT) (iii) Focus Group Discussion (FGD) among clinicians and nurses attending to patients at a referral provincial hospital in western Kenya, and (iv) chart abstraction from the Maternal Child Health (MCH) and HIV clinics at the same hospital. Using the January 2014 release of SNOMED CT, concepts were retrieved that matched terms abstracted from approach iii & iv, and the content coverage assessed. Post-coordination matching was applied when needed.

**Results:**
The final reference set had 1,054 unique ADI concepts which were described by 1,860 unique terms. Content coverage of SNOMED CT was high (99.9% with pre-coordinated concepts; 100% with post-coordination). The resulting reference set for ADIs was implemented as the interface terminology on OpenMRS data entry forms.

**Conclusion:**
Different sources demonstrate complementarity in the collection of concepts and terms for an interface terminology. SNOMED CT provides a high coverage in the domain of ADIs. Further work is needed to evaluate the effect of the interface terminology on data quality and quality of care.
7.1 Introduction

AIDS-Defining opportunistic illnesses (ADIs), defined as illnesses that occur with more severity and higher frequency among persons with HIV, remain the main course of morbidity and mortality among HIV-infected persons (1;2). Although several studies show a decline in incidence of individual ADIs such as tuberculosis, Pneumocystis pneumonia and Kaposi sarcoma since the introduction of anti-retroviral therapy (ART) (3;4), mortality associated with ADIs remains high. Sub-Saharan Africa (SSA), which is home to nearly two-thirds of the world’s 33.6 million people living with HIV, also has the highest rates of HIV-ADI co-infection (5). The US Centers for Disease Control and Prevention (CDC) and the World Health Organisation (WHO) have released guidelines for prevention and treatment of ADIs, intended for use by healthcare providers and policy makers (6;7). WHO classifies ADIs into four clinical stages indicative of HIV disease progression to help clinicians in resource-limited settings (mainly in Africa and Asia) with no immediate access to CD4 T-cell count testing to make decisions on ART eligibility (8).

Many studies conducted in SSA have shown that routine clinical data often have errors and in several cases missing key data elements such as diagnosis of ADIs (9-11). Poor recording or incorrect inference of WHO clinical staging based on the ADIs can lead to under or over-treatment of patients. A majority of clinics providing HIV care and treatment in SSA use a fixed list of coarse-grained ADIs to perform clinical staging of HIV-infection as recommended by WHO (8). Kiragga et al estimate that ADIs in clinical settings are under-reported by up to 67% in HIV clinics in Uganda (10). The unstructured nature of free-text recording of diagnoses and the limited list of preselected common ADIs from which clinicians can select diagnoses limits data completeness and re-usability e.g. in decision support or statistical analysis as the diagnoses are not uniquely defined and identified with a code (10;12). Additionally, in busy clinics with over-worked health workers, ADIs are rarely recorded with a fine granularity including more specific disease sub-types. Lack of granular information on diagnosis may influence continuity of treatment given.

Jaramogi Oginga Odinga Teaching and Referral Hospital (JOOTRH) in Kisumu county, western Kenya has two busy HIV clinics where more than 7,000 patients receive care and treatment. The hospital does not have a standardized way of documenting signs, symptoms and disorders during patient visits. This potentially impacts the quality of data recorded, inference of WHO clinical staging as well as continuity of care for patients. In order to address this problem, we propose to standardize the recording of ADIs using a standard terminology. A terminology system such as SNOMED Clinical Terms (SNOMED CT) can contribute to data accuracy and re-use through concept-based definition of diagnoses and coded storage of data (13).

This study describes a structured approach to derive a comprehensive set of ADI concepts based on SNOMED CT and evaluates SNOMED CT’s content coverage for ADIs in a provincial referral hospital in Kenya. The resultant set of concepts will be integrated into Electronic Medical Record (EMR) systems and implemented as an interface terminology in OpenMRS at the JOOTRH providing clinicians with a standardized tool for fine-grained recording of ADIs and automated inference of WHO clinical staging.
7.2 Background

7.2.1 WHO Clinical Staging and ART Eligibility

The WHO clinical staging uses clinical presentation of patients to categorize HIV infection into 4 stages based on the severity of ADIs and prognosis. The stage reflect progression of HIV infection from asymptomatic to conditions where presumptive diagnoses can be made on the basis of clinical presentation or simple investigations (8). Clinical staging is progressive, meaning that when a patient has recovered from a condition defined in a higher stage, they retain the higher clinical stage and can never be classified at a lower stage. Patients with stage I and II HIV infection present with (or have a history of) conditions such as minor skin diseases and upper respiratory tract infections, which are indicative of early HIV infection. WHO clinical stages III and IV, which are indicative of advanced HIV disease, may manifest as one or more illnesses such as severe bacterial infection, extra-pulmonary tuberculosis and non-Hodgkin lymphoma. WHO recommends initiation of ART for patients who have stage III or stage IV conditions (8).

The Kenyan Ministry of Health (MOH) HIV care and treatment guidelines (14), which are adapted from the WHO guidelines, recommend that all HIV-infected pregnant women receive ART, irrespective of their immunological or clinical indication of opportunistic infections associated with HIV (7).

7.2.2 SNOMED CT

SNOMED CT is an international logic-based, controlled vocabulary used in clinical care that amongst other areas includes terms for diagnostic concepts (15). SNOMED CT enables meaning-based retrieval of clinical information from electronic health records (EHR) and is able to express finer-grained concepts than classification systems such as ICD-10. For this study, we used the January 2014 release of SNOMED CT which had 298,581 active concepts associated with 781,878 active descriptions. The concepts are interrelated by 896,942 active relationships which can be hierarchical (Is-A relationship) or non-hierarchical (e.g. “associated morphology” or “finding site”). A SNOMED CT reference set provides a mechanism to group concepts and/or descriptions for a common goal (such as diagnosis concepts for AIDS defining illnesses).

Rosenbloom et al describe an interface terminology as a systematic collection of health-care phrases or terms that support clinicians’ entry of patient-related information into computer programs and decision tools (16). Interface terminologies also support the display of computer-stored patient information to clinical users in simple human-readable format. The use of a SNOMED CT based terminology on the user interface of an EMR supports efficient selection of terms during data entry based on uniquely coded concepts and promotes data re-use in decision support and statistical analysis.

7.3 Methods

7.3.1 Study setting

The JOOTRH provides ambulatory HIV care and treatment services to over 7,000 active patients, of whom about 4,800 are receiving ART. The services are provided within the Maternal and Child Health (MCH), the HIV clinic/Patient Support Centre (PSC) and the Integrated Tuberculosis clinic. The three
clinics in the hospital use a hybrid system of paper records and EMR to manage patient data; the EMR system is currently under staged deployment and is expected to replace the paper records by the end of 2014. The study was conducted at the HIV/PSC clinic and the MCH clinic which includes the Ante-Natal Care (ANC) clinic.

7.3.2 Study participants

We extracted free-text data used to describe diagnoses, signs and symptoms from paper-based clinical notes for all HIV-positive patients receiving care and treatment services at the HIV/PSC as well as HIV-positive pregnant women presenting for antenatal care or at the labor and delivery room during the months of February and March 2014, and receiving Antiretroviral Therapy (ART). We also conducted a Focus Group Discussion (FGD) among clinicians and nurses who attend to patients visiting the MCH and HIV/PSC clinics.

7.3.3 Review of term-based ADI recording

A trained clinician (clinical officer) extracted terms for diagnoses, signs and symptoms recorded in the patient charts to determine the terms used to document ADIs at the ANC and HIV/PSC. Data were retrieved from the two clinics to ensure comprehensive coverage of terms used to describe ADIs. Although terms for diagnoses, signs and symptoms were retrieved from the charts, we only included in the analysis those that matched SNOMED CT “disorder” concepts as described later.

7.3.4 Deriving ADI reference set

Based on a framework developed by Bakhshi-Raiez et al (17), we derived the reference set of ADI concepts through a multi-step approach. The first three steps describe how the ADI reference set was derived as shown in Figure 7.1. In the first step, concept-based subsets of ADIs from SNOMED CT and Accenture/CDC (described below) were merged. The CliniClue Xplore browser (18) and NICTIZ terminology explorer (19) were used to explore the concepts. The second step entailed extraction of term-based concepts from patient charts and Focus Group Discussions. In step 3, the concept-based and term-based concepts were merged.

Step 1: Processing concept-based ADI subsets

(a) Accenture/CDC subset: The US Centers for Disease Control and Prevention (CDC) derived a list of opportunistic infections considered to be AIDS defining illnesses (6). CDC and Accenture mapped the diagnosis and organism concepts on to SNOMED CT to come up with a hierarchical set of SNOMED CT-based concepts stored in the Web Ontology Language (OWL) format (20). The Accenture/CDC subset contains 907 concepts and 1,528 associated descriptions for ADIs.

(b) SNOMED CT subset: We used structured query language (SQL) commands to select concepts and descriptions associated with ADIs from an instance of the January 2014 release of SNOMED CT which was stored in a MySQL database. The SQL commands were based on the conditions described below:

- Concepts described by terms including “assoc” and (“AIDS” or “HIV”)
- Concepts linked by the relationship “associated with” to the concept “HIV infection”
- All subtypes (descendants) of the above selected concepts
- The active descriptions of the resulting concepts in SNOMED CT
The SQL queries used to retrieve the data are in Appendix 7.1. Since all patients seen in the study clinics had HIV, those supertypes of concepts were retrieved that did not include the phrase “Associated with AIDS”. For example: *Pneumococcal Pneumonia associated with AIDS* (concept ID = 420787001) was replaced with the parent concept *Pneumococcal Pneumonia* (concept ID = 233607000).

The two ADI subsets described in steps (a) and (b) above were merged into subset A as shown in Figure 7.1, sorted by SNOMED CT concept ID and all duplicate concepts and terms deleted.

**Step 2: Deriving term-based concepts**

(a) **Free text abstraction**

Two clinical officers reviewed free-text records from 583 initial patient visits and 762 follow-up visits for the same patients who visited the JOOTRH ANC and HIV/PSC clinics in the months of February and March 2014 and abstracted terms used to describe ADIs at the clinic. The free-text terms were extracted from paper-based patient records as well as those entered in the OpenMRS EMR. Terms and description IDs from SNOMED CT that matched the free-text terms were retrieved by a medical informatician with SNOMED CT expertise (TO). These concepts and the terms describing them were stored as subset B (Figure 7.1).

(b) **Focus Group Discussion**

In this step, a focus group discussion (FGD) was held involving clinicians who attend to patients at the ANC and HIV/PSC clinics. A separate FGD was conducted among nurses working at the same clinics. All descriptions for the concepts from subset A were made available to the clinicians prior to the start of the FGD. Clinicians’ and nurses’ knowledge was sought on the most common ADIs in their setting (JOOTRH). Using local terms, they listed as many ADIs as they could in addition to the concepts and terms included in subset A. Clinicians and nurses were further asked what factors they consider in determining whether the symptoms and signs are suggestive of an ADI. Terms and description IDs from SNOMED CT that matched terms used for ADI diagnoses in the FGD were retrieved by the same medical informatician (TO).

The terms and concepts derived through abstraction of data from the MCH/PSC records and the FGD were merged into subset B and duplicates removed (see Figure 7.1). Concepts were retrieved from SNOMED CT based on the “exact match” and if needed, by post-coordination. The example below shows how we derived a post-coordinated concept *oropharyngeal candidiasis* which is not in SNOMED CT. CDC describes *oropharyngeal candidiasis* as *candidiasis that develops in the throat or mouth* (21).

\[
\text{Candidiasis (78048006) : finding site (363698007) = Mouth and/or pharynx structures (312533001).}
\]

**Step 3: Merging the subsets**

In the final step, all derived concepts (subsets A and B) and their descriptions were merged into a single subset C and all duplicate concepts and descriptions deleted.
Step 4: SNOMED CT subset extension

If terms could not be matched with SNOMED CT concepts and descriptions, these terms were presented to a team of clinicians and informaticians with expertise in SNOMED CT for review. They determined whether these could be considered as local extensions of SNOMED CT through post-coordination of concepts or as entirely new concepts or descriptions.

Step 5: Constraining the ADI subset

Several non-ADI concepts were deleted from the term-based subsets. Although these non-ADIs were common co-infections that HIV patients attending the clinics at JOOTRH present with, they were not considered for implementation of the interface terminology. Such non-ADI concepts included malaria (concept ID = 61462000) and urinary tract infection (concept ID = 68566005).

7.3.5 Implementation of the interface terminology

The resulting concept subset and description subset from the above steps were represented in the OpenMRS concept dictionary and implemented as the interface terminology on OpenMRS data entry forms to improve ease and accuracy of recording of ADIs. A separate set of non-ADI concepts representing common co-infections or signs, symptoms among patients seeking HIV treatment at JOOTRH was also created from the chart review and FGD for the purpose of presentation on the user interface. Subsetting the concepts into ADI and non-ADI disorders for the purpose of presentation on the user interface provides clinicians quick access to shorter lists of relevant diagnosis concepts to choose from. The ADI concepts were presented on the user interface as a dropdown menu with autocomplete/autosuggest textbox feature derived using a list builder. A 'more details' button is displayed for each of the ADIs selected for a particular patient. Clicking on this button allows the selection of qualifiers of a particular diagnosis.

The patients' WHO staging is automatically inferred based on the recorded ADI concept. To accomplish this, the ADI concept is matched with the corresponding WHO stage as defined in the HIV treatment guidelines (8;14). The WHO clinical staging list showing the ADI concepts and corresponding WHO clinical stage is in Appendix 7.2 (8).

7.3.6 Ethical considerations

The study was approved by the Associate Director for Science at the Center for Global Health of the US Centers for Disease Control and Prevention (CDC) and the Kenya Medical Research Institute (KEMRI) institutional review board. The women whose data were included in the study consented to the use of their data for clinical care and research studies taking place at the ANC clinic. As the study subjects were considered a vulnerable population (HIV-positive pregnant women), the study team ensured that the individual patient data were de-identified and their privacy and confidentiality maintained in line with the KEMRI guidelines on research ethics.
7.4 Results

A total of 1,104 ADI concepts were derived from the four data sources. The final reference set had 1,054 unique concepts after deleting 50 duplicate concepts. The 1,054 unique concepts were described by 1,860 unique terms. Figure 7.1 shows the number of terms and concepts used to describe ADIs in each subset.

Figure 7.1: Derivation of terms and concepts used to describe ADI from concept-based and term-based sources.

7.4.1 Concept-based terms (CDC ADI and SNOMED CT Subsets)

The CDC/Accenture ADI subset had 907 unique disorder concepts described by 1,528 terms. For the SNOMED CT subset, the first query (concepts described by terms including “assoc” and (“AIDS” or “HIV”)) yielded 102 concepts while the second query (concepts linked by the relationship “associated with” (ID=47429007) to the concept “HIV infection” (ID=86406008)) resulted in 107 unique concepts. Some 102 duplicate concepts between the two queries were deleted, resulting in 105 unique concepts. Finally, the subtype children of the resulting concepts were derived using the fourth query. Where relevant, these concepts were replaced by their supertype concept for which the description did not contain “associated with AIDS”. For the resulting 110 concepts, 254 terms together with their description ID were retrieved from SNOMED CT.

7.4.2 Term-based concepts (Abstraction from MCH and PSC, and Focus Group Discussions)

A total of 87 ADI concepts were derived from the term-based subset i.e. those abstracted from the paper records of patients attending the MCH clinic and PSC, and from the FGD. The concepts were described using 157 terms.
7.4.3 Content coverage

The overall content coverage was 99.9% with pre-coordinated concepts and 100% with post-coordination. All but two term-based concepts from the chart abstraction at the MCH and PSC, as well as the FGDs matched the SNOMED CT concepts. The two concepts that required post-coordination were: (i) Oropharyngeal candidiasis, and (ii) Genital ulcer disease. Oropharyngeal candidiasis was post-coordinated as: Candidiasis (78048006) : finding site (363698007) = Mouth and/or pharynx structures (312533001). Genital ulcer disease was post-coordinated as: Ulcer (429040005) : finding site (363698007) = Structure of genital organ (700037000).

7.4.4 Interface terminology implementation

The implementation of the interface terminology includes 1,860 terms describing 1,054 unique concepts. The implementation included qualifiers such as severity (e.g. “mild”, “moderate” or “severe”), onset (e.g. “sudden” or “gradual”) and laterality which describes the side of the body that is infected (e.g. right middle zone pneumonia indicative that the infection is in the right middle lobe of the lung). Defining characteristics which include causative agent were implicit to the interface terminology, allowing more specific types of diagnosis to be selected (e.g. for “pneumococcal pneumonia” where “pneumococcus” is the causative agent). Additional context information that can be selected is the type of diagnosis, i.e. presumptive (working), differential or final diagnosis (See Figure 7.2).

Figure 7.2: A screen-shot of a data entry form using ADI reference set
7.5 Discussion

More than 1,000 ADI concepts described by nearly 1,900 terms were derived from four data sources using a well-structured approach based on an earlier published framework for developing interface terminology reference sets (17). While most concepts were described by one term, some of the concepts were described using as many as 9 terms which provide a wide variety of relevant synonyms that include locally used terms from which clinicians can make selections to accurately describe diagnoses. Content coverage was high; consistent with the study by Rosenbloom et al (22). In our study, all but two concepts generated from the term-based sources matched SNOMED CT concepts.

Although signs and symptoms were included in the data abstracted from the MCH and PSC, as well as the FGD, we did not include them in the final reference set since they had a very broad scope and some were not associated with HIV infection. It is important to note that the WHO clinical staging list includes some signs and symptoms such as fever (concept ID = 421154002) together with ‘real’ ADIs used to determine the progression of HIV infection based on clinical presentation of the patient (8) (see Appendix 7.2). These will be added to the local concept dictionary through dynamic updates to support automated inferencing of WHO clinical staging. The ADI list of concepts will be shared with Columbia University that maintains the concept dictionary for OpenMRS users. It will also be shared with the International Health Terminology Standards Development Organization (IHTSDO) that maintains SNOMED CT for distribution to its members and affiliates. Access to the reference set can be gained by contacting IHTSDO.

An observation of the term-based data abstracted from the MCH clinic and PSC, as well as data recorded from the FGDs showed a number of spelling mistakes. This shows that lack of a structured list of ADIs with a rich selection of terms contributes to poor data quality on diagnoses entered in EMR systems, as observed elsewhere (12). The implementation of an interface terminology with the ADIs selected from a comprehensive reference set that includes child and parent concepts of key disorders will enhance the quality of data recorded leading to appropriate decisions on clinical care. Additionally, enhanced decision support through automated inference of WHO clinical stage based on the recorded ADIs will ensure that patients get appropriate treatment determined by the accurate recording of progression of HIV infection. The study benefited from data collection from a busy referral hospital that provides HIV care and treatment to a large number of patients with diverse conditions hence a broad coverage of terms used to describe ADIs. Furthermore, the use of chart abstraction and FGDs enabled the study team to collect context-specific terms that are most appropriate for local use at JOOTRH but may also be broadly used in similar contexts in low-resource settings.

Our study had a few limitations. The chart abstraction was conducted over a two-month period and this may not be long enough to provide the breadth of data required. The effect of the short data collection period was minimized since this is a high-volume hospital with diverse patients. Incorrect spellings and use of ADI terms that were not specific enough, made matching SNOMED CT concepts difficult. Consultation with the clinicians helped resolve the errors and all the terms were matched. Additionally, the EMR implementation has a provision for dynamic update of concepts which may be missing from the current list or those that will be derived through post-coordination of new and existing terms.

7.6 Conclusion

We described a structured approach to deriving an ADI reference set based on SNOMED CT and the implementation of an interface terminology for OpenMRS at a busy provincial referral hospital in a
resource-constrained setting. Use of different sources demonstrates complementarity in the collection of concepts and terms for an interface terminology. SNOMED CT provides a high coverage in the domain of ADIs. The context-specific reference set will support improved recording of high quality data ensuring completeness and reusability. Further work is needed to evaluate the effectiveness of the interface terminology on data quality and quality of care.

Acknowledgements:
The authors would like to acknowledge the KEMRI Director and his staff for the approval of this study and for reviewing and clearing the manuscript. We would also like to thank Ms. Mevis Omolo and Philister Anyango for outstanding work in recording and transcribing the FGD, and all staff at the JOOTRH that supported the data collection for this study and implementation of OpenMRS.

Conflicts of interest:
Authors are members of the Technical Committee (RC) and Quality Assurance Committee (NdK) of the International Health Terminology Standards Development Organization (IHTSDO), which publishes SNOMED CT. Their positions at the IHTSDO, however, had no bearing on the research study or results.
