Characterization of Porphyrin-Co(III)-‘Nitrene Radical’ Species Relevant in Catalytic Nitrene Transfer Reactions

Monalisa Goswami, Volodymyr Lyaskovskyi, Sérgio R. Domingos, Wybren Jan Buma, Sander Woutersen, Oliver Troepner, Ivana Ivanović-Buramazovic, Hongjian Lu, Xin Cui, X. Peter Zhang, Edward J. Reijerse, Serena DeBeer, Matti M. van Schooneveld, Florian Felix Pfaff, Kallol Ray, and Bas de Bruin

ABSTRACT: To fully characterize the CoIII(nitrene radical) species that are proposed as intermediates in nitrene transfer reactions mediated by cobalt(II) porphyrins, different combinations of cobalt(II) complexes of porphyrins and nitrene reagents were combined, and the generated species were studied using EPR, UV–vis, IR, VCD, UHR-ESI-MS, and XANES/XAFS measurements. Reactions of cobalt(II) porphyrins 1Pl (P1 = meso-tetraphenylporphyrin (TPP)) and 1P2 (P2 = 3,5-di(Bu-ChenPhyrin)) with organic azides 2Ns (NsN3), 2Ts (TsN3), and 2Troc (TrocN3) led to the formation of mono-nitrene species 3PlNs, 3P2Ts, and 3P2Troc, respectively, which are best described as [CoIII(nitrene)] nitrene radicals (imido radicals) resulting from single electron transfer from the cobalt(II) porphyrin to the nitrene moiety (Ns: R = SO2-C6H4NO2; Ts: R = SO2-C6H4OH; Troc: R = =C(O)OCH2CCl3). Remarkably, the reaction of 1P1 with N-nosyl iminoiodane (PhI=N=Ns) 4Ns led to the formation of a bis-nitrene species 5P1Ns. This species is best described as a triple-radical complex ([nitrene]CoIII(NITRENITRENE)) containing three ligand-centered unpaired electrons: two nitrene radicals (NR**) and one oxidized porphyrin radical (por**). Thus, the formation of the second nitrene radical involves another intramolecular one-electron transfer to the nitrene moiety, but now from the porphyrin ring instead of the metal center. Interestingly, this bis-nitrene species is observed only on reacting 4Ns with 1P1. Reaction of the more bulky 1P2 with 4Ns results again in formation of mainly mono-nitrene species 3P2Ns according to EPR and ESI-MS spectroscopic studies. The mono- and bis-nitrene species were initially expected to be five- and six-coordinate, respectively, but XANES data revealed that both mono- and bis-nitrene species are six-coordinate O3 species. The nature of the sixth ligand bound to cobalt(III) in the mono-nitrene case remains elusive, but some plausible candidates are NH3, NH2−, NsNH−, and OH−. Conversion of mono-nitrene species 3P1Ns into bis-nitrene species 5P2Ns upon reaction with 4Ns was demonstrated. Solutions containing 3P1Ns and 5P2Ns proved to be still active in catalytic aziridination of styrene, consistent with their proposed key involvement in nitrene transfer reactions mediated by cobalt(II) porphyrins.

INTRODUCTION

Catalytic functionalization of C–H bonds is a desirable tool in organic and organometallic chemistry, as it is an atom-, time-, and cost-efficient alternative to traditional hydrocarbon functionalization. Therefore, C–H insertion of carbenoid and nitrenoid species has emerged as a very promising protocol in the recent years. The insertion of metal carbenoids into C–H bonds is now a well-established transformation, and many transition-metal catalysts that can catalyze such reactions have been disclosed in the past decade. In addition to catalytic cyclopropanation and C–H insertion, metal-catalyzed carbene transfer has also made it possible to perform insertions into X–H bonds (X = O, N, S, Si) and to convert alkenes to cyclopropanes (including some cycloaddition reactions). Given the ubiquity of nitrogen atoms in biologically active compounds, nitrene transfer reactions also have very important applications in making molecules of interest. However, the applicability of metal-nitrenoids has so far been...
limited to alkene aziridination,\textsuperscript{9,10} C–H amination\textsuperscript{11,12} and amidation.\textsuperscript{13}

Among several catalysts that have been reported for nitrene transfer reactions, the most successful ones are still based on non-abundant Rh\textsuperscript{4−17} and Ru\textsuperscript{4,6,7,18−20} metals. Among the first row transition metals, there have been reports of Mn\textsuperscript{21,22}, Cu\textsuperscript{23−26} and Fe\textsuperscript{27} catalyzed systems. Besides being very efficient in carbene transfer reactions,\textsuperscript{28−31} cobalt(II) porphyrin catalysts have also attracted attention in nitrene transfer reactions. Until the early 2000s, it was quite common to use iminoiodanes\textsuperscript{32−36} or haloamine-T\textsuperscript{23,25,26} compounds as nitrene sources. These are, however, not the most benign nitrene sources as they lead to the formation of undesirable side products like phenyl iodide and other halogen-containing compounds. With the efforts of various groups, organic azides\textsuperscript{37,38} were discovered to be potentially greener resources to transfer nitrenes, as the only byproduct formed during the generation of nitrenes from azides is dinitrogen. The other disadvantage of using iminoiodanes is their poor solubility and the fact that there is not much scope to change the pre-existing functionality on the nitrogen atom.

With the use of differently meso-substituted cobalt(II) porphyrins (1\textsuperscript{P1}−1\textsuperscript{P4} in Figure 1) a variety of nitrene transfer reagents (Figure 2) have been employed. For example, with the use of reagents like diphenyl phosphoryl azide (DPPA),\textsuperscript{39,40} it is possible to further modify the substituent, as the nitrogen-phosphorus bond in the product aziridine is readily hydrolyzed.

In the pursuit of finding more nitrene transfer reagents with easily removable groups on the nitrogen atom, trichloroethoxysulfonyl azide\textsuperscript{41} (TcesN\textsubscript{3}, Tces = trichloroethoxysulfonyl = C\textsubscript{Cl}\textsubscript{3}CH\textsubscript{2}O(SO\textsubscript{2})\textsuperscript{−}) was found to be effective. Apart from the nitrene precursors itself, specially tailored cobalt porphyrins, for example, with H-bonding functionalities, have further enhanced the applicability of these systems (see Figure 1; P\textsubscript{1} = meso-

![Figure 1. Commonly used cobalt(II) porphyrins in nitrene transfer reactions.](image)

![Figure 2. Commonly used nitrene transfer reagents.](image)

![Scheme 1a. DFT-Calculated Mechanism of Co(II) Porphyrin-Mediated Benzylic C−H Amination of Ethylbenzene by N\textsubscript{3}C(O)OMe and (b) Co(II) Porphyrin-Mediated Aziridination of Styrene with PhSO\textsubscript{2}N\textsubscript{3}.](image)
and aziridination reactions, the DFT calculations revealed a stepwise radical process involving coordination of the azide to the cobalt(II) center, followed by release of dinitrogen to produce an unusual nitrene radical intermediate C (Scheme 1). In addition, experimental EPR spectroscopic studies, combined with DFT calculated EPR properties being in good agreement with the experimental data, revealed the formation of a (por)Co^{II}⁻N^*Y nitrene radical adduct C from the catalyst in the presence of an excess of the azide in benzene. Formation of a nitrene moiety at cobalt(II) effectively leads to electron transfer from the metal to the nitrene, thus reflecting the redox non-innocence of the nitrene ligand. The spin density of this intermediate resides almost entirely on the nitrogen atom of the nitrene moiety. A simplified molecular orbital picture showing the frontier \( \pi \)-interactions and explaining the unusual electronic structure of this intermediate is depicted in Scheme 2.

**Scheme 2. Redox Non-Innocent Behaviour of Nitrene Ligands Coordinated to Open-Shell Co^{II}(por) Species (A), a Simplified Bonding Scheme Explaining This Behavior (B), and Alternative Bonding Scheme Involving a Triplet Nitrene (C)**

Experimental detection of these radicaloid species led us to investigate the subsequent stepwise C–H amination sequence computationally. According to these investigations, the amination reaction follows a stepwise radical pathway, in which the nitrene radical intermediate C readily abstracts a hydrogen atom from the benzylic position of the organic substrate. This leads to formation of a close-contact pair (D) of the thus-formed organic radical R* and the cobalt^{II}⁻-amido complex (por)Co^{II}⁻-NHR'. Subsequent back-attack of the organic radical onto the amido moiety in D, in a rebound-type mechanism, leads to release of the desired amine products with regeneration of the cobalt(II) catalyst, which proceeds with low activation barriers according to DFT.

Nitrene transfer to styrene also proceeds in a stepwise manner via radical addition of the nitrene radical to the C=C double bond of styrene to form \( \gamma \)-alkyl radical intermediates D' (Scheme 1b). The cobalt(III) ion in D' has an intermediate (\( S = 1 \)) spin-state with its unpaired electrons antiferromagnetically coupled to the unpaired electron of the \( \gamma \)-alkyl radical, thus explaining its overall doublet (\( S = 1/2 \)) state. Species D' easily collapses in an almost barrierless ring closure reaction to form the aziridine, thereby regenerating the cobalt(II) porphyrin catalyst. Additionally, the computed free energy profile well explained the superior performance of the reported Co^{II}(porAmide) system 1P4 with H-bond donor functionalities over the non-functionalized system 1P1 (see Figure 2).42

Thus, the DFT calculations and the X-band EPR data gathered thus far strongly indicate the formation of substrate-centered (por)Co^{II}⁻N^*⁻R⁻ nitrene radicals, which are proposed to be key intermediates in the mechanisms of the catalytic C–H amination and alkene aziridination reactions mediated by Co^{II}(por) catalysts and employing organic azides as nitrene sources. These nitrene radicals have thus far only been detected by means of X-band EPR spectroscopy.9,43 Here we disclose their detection and characterization with a variety of spectroscopic and mass spectrometric techniques.

Ligand-centered radical complexes play a pivotal role in a number of bio- and “bioinspired” catalytic transformations, providing a powerful tool to control the reactivity and selectivity of the catalyst.41−46 Such species are well-studied and characterized for transition-metal complexes containing typical polynitrodate redox non-innocent ligands, such as semi quinone-type radical ligands47−49 and their nitrogen analogs,50−52 reduced bipyridine and terpyridine ligands,51−53 \( \alpha \)-iminopyridine ligands,54−56 and pyridine-2,6-diimine ligands.57−61 More recently, considerable efforts have been made to understand the (electronic) structure and reactivity of monodentate redox non-innocent substrate-type radicals, such as carbenes,62 which play a key role in catalytic carbeno transfer reactions.63,64 So far, only a few examples have been reported in which complexes bearing monodentate nitrogen-based radicaloid ligands were experimentally detected. Thus, well-studied complexes with redox active amylid ligand radicals are limited to only a few well-characterized examples,65 and related complexes bearing redox non-innocent nitrene ligands are even scarcer.9,43,66,67 Given the importance of these radicaloid nitrene species in metal-catalyzed nitrene transfer and C–H functionalization reactions,68,69 we gathered more experimental evidence for the formation of the previously reported mono-nitrene radical complexes upon reaction of cobalt(II) porphyrins with nitrene transfer reagents.9,43 Furthermore, we here reveal the first example of a bis-nitrene species of 1P1 upon reacting the stronger oxidizing nitrene transfer agent N-nosyl iminoiodane 4s4, with 1P1. This bis-nitrene species has a markedly different electronic structure than the previously detected mono-nitrene species and also differs from the electronic structure of the previously reported diamagnetic bis-imido Ru^{IV}-porphyrin species (por)Ru^{IV}(\( \equiv \) NR').59−73 The work described herein further bears some similarity with the mono- and bis-nitrene species of non-heme iron complexes disclosed by Che and co-workers,66 but again the electronic structures reported herein are entirely different.

**RESULTS AND DISCUSSION**

To study the key nitrene intermediates in nitrene transfer reactions mediated by cobalt(II) porphyrins, we chose to react a few of the commonly used nitrene sources with two different types of cobalt(II) porphyrins: the tetraphenyl-substituted porphyrin 1P1 and the bulkier (and chiral) H-bond donor appended porphyrin 1P2 (see Figure 1). Complex 1P2 serves as a model system for all reported cases where Co^{II} porphyrins with H-bonding moieties were proven to give superior catalytic results and where H-bonding stabilizes the formed nitrene intermediates.31,58 In total, four different nitrene sources were employed. As mentioned before, these sources are known in

J. Am. Chem. Soc. 2015, 137, 5468–5479
literature to be active in different nitrene transfer reactions like aziridination and amination.\textsuperscript{8−11} Three of these were organic azides 2\textsubscript{Ns}, 2\textsubscript{Troc} and 2\textsubscript{Ts} (see Figure 2): Nosyl azide (2\textsubscript{Ns}; Ns = Nosyl = p-NO\textsubscript{2}−PhSO\textsubscript{2}−), Tosyl azide (2\textsubscript{Ts}; Ts = Tosyl = p-MePhSO\textsubscript{2}−), and Troc azide (2\textsubscript{Troc}; Troc = 2,2,2-trichloroethoxycarbonyl = CCl\textsubscript{3}CH\textsubscript{2}O−). The fourth nitrene transfer reagent investigated was the stronger oxidizing N-nosyl iminodiode (Ph=NN=) 4\textsubscript{Ns}. To perform the EPR, ultra high-resolution electron spray ionization mass spectrometry (UHR-ESI), UV−vis, and X-ray absorption spectroscopy (XAS) studies, the following method was employed: To a solution of the catalyst in benzene-d\textsubscript{6} we added a 100-fold excess of the nitrene precursor. The catalyst concentrations of these solutions were typically 2.5 mM. The solvent used was benzene-d\textsubscript{6} in all cases, and this was chosen to avoid any cases of C−H insertions as is known for these systems in toluene, cyclohexane, and other related solvents.\textsuperscript{10,11} Unless mentioned otherwise, deuterated benzene was chosen as the solvent to further slow down any C−H activation of the benzene ring itself.

**EPR Spectroscopy of the Mono-Nitrene Species.** Upon reaction of 1\textsubscript{P1} with a 100-fold excess of 2\textsubscript{Ns} and 1\textsubscript{P2} with a 100-fold excess of either 2\textsubscript{Troc} or 2\textsubscript{Ts} (Scheme 3), clear gradual changes in the X-band EPR spectra occurred that point to the formation of mono-nitrene radical species, revealing the redox non-innocence of the nitrene moiety. The disappearance of signals characteristic for the cobalt(II) porphyrins is associated with appearance of signals corresponding to mono-nitrene radical species of the type 3 (for an example, see Figure SS-1; Supporting Information). The room-temperature (r.t.) EPR measurement of the same samples gave spectra characteristic for ligand radical species (Figure 3, top),\textsuperscript{42} and the simulated spectra fits best to a mono-nitrene species of the type 3.

The X-band EPR spectrum recorded from a reaction mixture of 1\textsubscript{P1} and 2\textsubscript{Ns} in frozen benzene-d\textsubscript{6}/o-terphenyl solution at 50 K was quite isotropic, but the g-anisotropy is clearly resolved in high-frequency (244 GHz) EPR measurements (Figure 3, bottom). The experimental g-anisotropy is very small, and smaller than calculated with DFT (Table 1). This may be caused by a small mismatch between the calculated and experimental geometries, as the calculated g-tensor is sensitive to the orientation of the −SO\textsubscript{2}Ar fragment of the nitrene radical moiety (e.g., optimization with and without dispersion corrections). It should further be noted at this point that complexes of type 3\textsubscript{P1}\textsubscript{Ns} need not be five-coordinate. Coordination of an additional ligand to the cobalt(III) center (see also Scheme SS-5; Supporting Information) is perhaps even likely (vide infra), and this will also have some influence on the (calculated) g-tensor and hyperfine coupling parameters of the mono-nitrene complex, albeit very small (see Table 1 for a comparison of the experimental EPR parameters and the DFT calculated values of five-coordinate 3\textsubscript{P1}\textsubscript{Ns} and its six-coordinate NsNH\textsuperscript{−} and OH\textsuperscript{−} adducts). Note that a variety of other six-coordinate analogs of 3\textsubscript{P1}\textsubscript{Ns} investigated, containing either neutral or anionic ligands bound trans to the nitrene radical moiety, all have very similar calculated g-values and HFIs with cobalt and the nitrogen atom of the spin-bearing nitrene radical ligand (see Table SS-1, Supporting Information).

Additionally, a quite anisotropic cobalt hyperfine interaction (HFI) tensor was revealed by Q-band Davies ENDOR measurements. The Q-band Davies ENDOR experiment (Figure SS-2; Supporting Information) revealed broad features spanning 1−60 MHz. Apart from the characteristic proton signals centered around 52 MHz, strong lines are observed around 22 and 12 MHz. The position of these features is consistent with the \textsuperscript{57}Co hyperfine parameters estimated from the high-field EPR spectrum (Figure 3), which are summarized in Table 1. Low-frequency contributions (<8 MHz) are

attributed to the porphyrin nitrogen atoms. The corresponding DFT calculated values match the experimental ones quite well (Table 1), albeit that the calculated anisotropy of the cobalt hyperfine tensor is a bit larger than in the experimental spectrum. Unfortunately, the anisotropic nitrene nitrogen hyperfine couplings were not resolved for technical reasons (see Supporting Information for discussion).

Interestingly, the mono-nitrene species \(3 \) did not form instantaneously upon mixing the azides and the \(\text{Co}^{II} \) porphyrin catalysts at r.t. For example, only 10% of the mono-nitrene species \(3P_{1N} \) was formed upon mixing \(1P_{2N} \) and azide \(2P_{1N} \) at r.t. after 15 min. These conversions were determined by comparison of the spin concentrations (double integration) with a sample of TEMPO of the same concentration. It should be mentioned that the relaxation times of TEMPO and the mono-nitrene species \(3 \) are likely markedly different, and hence the spin integrations gave only a rough qualitative comparison of the spin concentrations. However, upon heating the samples, higher intensities were observed immediately; and on letting them heat overnight at \(45^\circ\)C, the maximum intensities for all of these species were observed. The resulting solutions still contained the (excess) organic azide (as revealed by analysis of crystals recovered upon evaporation of the solvent) and were still catalytically active in aziridination of styrene (as confirmed by \(^{1}H\) NMR and GC-MS analysis of the crude reaction mixture). Among the series of complexes and nitrene precursors studied, the maximum intensities were obtained for the combination of \(1P_{2} \) and \(2_{Troc} \) (see Figure 4). This can be explained on the basis of better stabilization of the formed nitrene radical intermediate by H-bonding between the amide arms of the porphyrin backbone in \(1P_{2} \) and the nitrene transfer agent \(2_{Troc} \). The concentration of this species was found to be \(~80\%\) referenced against a sample of TEMPO with the same concentration as the cobalt precursor. Similar rough spin counting reveals the presence of \(~60\%) of EPR active \(3P_{1N} \) upon reaction of \(1P_{1} \) with excess \(2N_{s} \) after heating overnight at \(45^\circ\)C.

EPR Spectroscopy of the Bis-Nitrene Species 5P\textsubscript{1N}. In contrast to the use of organic azides that produced mono-nitrene species of the type \(3 \) upon reaction with the cobalt(II) porphyrin complexes, reaction of an excess of \(N\)-nosyl iminodiiodane \(4N_{s} \) with \(1P_{1} \) at room temperature in benzene-\(d_{6} \) yielded an entirely different species (Scheme 4), as revealed by X-band EPR spectroscopy in solution at r.t. A completely new isotropic spectrum was observed with \(4N_{s} \) (Figure 5) that is not ascribable to the formation of a one-electron oxidized porphyrin ligand. Isomerization of the central \(\pi\) electron to the porphyrin ring system occurs with the “\(\pi\)-cation radical” convention commonly used in cytochrome P450 chemistry, but this is in fact a mono-anionic por\(\text{P}^{•−} \) ligand.
To prove that the largest detected nitrogen hyperfine couplings stem from the two equivalent nitrene moieties, we further prepared the $^{15}$N-labeled iminoiodane $^{15}$N-couplings.

The spectrum could be satisfactorily simulated based on the small, even smaller than in the mono-nitrene case (25 MHz).

observed with ESI-MS measurements (Figure S4-20; Supporting Information). These results clearly show that the bis-nitrene species 5 is more reactive than the mono-nitrene species 3 and that complex 1P1 is more stable than complex 1P1 when combined with N-nosyl iminoiodane 4Ns. The latter can perhaps be attributed to stabilizing H-bonding interactions between the nitrene radical moiety and the H-bond-donating amido functionalities incorporated in the porphyrin backbone of 1P1, as was previously observed in azidination reactions and studied previously using DFT.8,41 At the same time, it also suggests that N-nosyl iminoiodane 4Ns is not a very benign nitrene transfer reagent for these reactions as it seems to undergoes subsequent side reactions with the catalyst (especially for the less bulky catalysts and in the absence of another substrate).

UHR-ESI-MS Spectrometry. To further corroborate the above observations in the EPR measurements, the reactions were also investigated with mass spectrometry. We investigated the formation of both the mono- and the bis-nitrene species. High-resolution ESI-MS mass spectrometry proved to be a suitable method to detect the formation of both mono- and bis-nitrene species. However, since these species are neutral (or perhaps anionic, vide infra), only signals resulting from protonation, (one-electron) oxidation, and formation of Na+- adducts can be expected in positive mode UHR-ESI-MS.
A reaction mixture of 1P1 with nosyl azide 2Ns in C6D6/MeCN produced clear ESI-MS signals around m/z 872 characteristic for formation of the mono-nitrene species 3P1
(Scheme 3). The isotope distribution pattern and exact masses determined by ESI-MS match the theoretical values (Δm/z < 0.004 Da) for the species in its protonated form [3P1

amino ligand or the NO2PhSO2ND
amidine amine detected as the Na+ adduct of the amine in the ESI-MS measurements, in the first case directly and in the second case after HAT).
ESI-MS spectra recorded from a mixture of 1P1 and N-nosyl iminoiodane 4Ns revealed signals pointing to the presence of bis-nitrene species 5P1
Ns
(Scheme 4). This species was observed as the protonated form of its hydrogen atom abstraction (HAA) reaction product ([5P1
Na+-H+ + H+]), thus pointing to rapid HAA from the cosolvent MeCN (Figure 7b). Substantially weaker signals corresponding to the mono-nitrene species 3P0
Ns
were still detected ([3P0
Ns
+ H+]1), which likely resulted from incomplete conversion of 1P1 to 3P0
Ns
and/or fragmentation of 3P1
Ns
in the ionization chamber of the ESI-MS spectrometer.

Electronic Structures and UV–vis Spectra of Mono- and Bis-Nitrene Species. To gain additional insight into the electronic structures of the generated nitrene species, we performed DFT geometry optimizations at the b3-lyp/def2-TZVP level using the simplified models 3P0
Ns
and 3P1
Ns
without meso-phenyl substituents on the porphyrin ring P0 (Figure 8). According to these calculations, mono-nitrene species 3P1
Ns
formed from 1P1 and 2Ns is best described as a CoIII species with one 1e reduced nitrene moiety and a normal, non-oxidized (por2−) porphyrin ligand. Note again the experimental complex 3P1
Ns
needs not be five-coordinate. Coordination of an

additional ligand to the cobalt(III) center cannot be excluded (Scheme S5-5; Supporting Information) and even seems likely (vide infra). However, note that all six-coordinate analogs of CoIII(por) considered computationally have almost identical spin density distributions as the one shown for five-coordinate mono-nitrene complex 3P1Ns in Figure 8. In these calculations full atom models were optimized at the BP86/def2-TZVP/disp3 level (Turbomole), followed by single point calculations at the b3-llyp/def2-TZVP level (ORCA), considering several different (neutral and anionic) ligands bound trans to the nitrene radical moiety (see also Table S5-1; Supporting Information).

The bis-nitrene species 5P0Ns on the other hand, is a triple-radical containing two 1e-reduced nitrene-moieties and a 1e-oxidized porphyrin ring (from por2− to the por+ radical monoanion). As is clear from the positive and negative spin density distribution (Figure 8, right), two of the three unpaired electrons in 5P0Ns are antiferromagnetically coupled, thus effectively leading to a (net) doublet state (Stotal = 1/2). Both 3P1Ns and 5P0Ns were found to contain a low-spin d6 (SCo = 0) CoIII center. Hence, formation of 5 involves one-electron oxidation of CoII to CoIII upon formation of the first nitrene-radical (3) and a second intramolecular electron transfer from the porphyrin ring to the second nitrene moiety in the second step.

The DFT calculated electronic structures are qualitatively in agreement with UV−vis measurements, revealing the presence of a non-oxidized porphyrin ring in 3P1Ns and a “porphyrin radical” ligand in 5P1Ns (Figures 9 and 10).

![Figure 9](attachment:image_url)  
**Figure 9.** UV−vis spectra of a mixture of 1P1 and 2Ns, followed in time (after 40 min of sample preparation). Clear shifts in both the Q- and Soret-bands were observed corresponding to azide ligation to the cobalt(II) center.

![Figure 10](attachment:image_url)  
**Figure 10.** UV−vis spectral changes upon reaction of (left) complex 1P1 with azide 2Troc to give mono-nitrene species 3P2Troc formed after heating the solution overnight, and (right) reaction of complex 1P1 with iminoiodane 4Ns to give bis-nitrene species 5P1Ns within 1 h.

Metal- (not porphyrin-) centered oxidation of CoII(por) to CoIII(por) is known to produce characteristic red-shifts of both the Soret- and Q-bands.76,77 The same is also true for binding donor ligands, such as pyridine or bipyridyl ligands, to the central metal ion of cobalt(II) porphyrins.78,79 Such shifts were indeed observed upon measuring UV−vis spectra of a mixture of 1P1 and 2Ns immediately upon mixing. In Figure 9, the UV−vis spectrum of a mixture of 1P1 and 2Ns was followed in time (after 40 min of sample preparation). In these spectra, the observed shifts in the Q- and Soret-bands are due to formation of a simple azide adduct (mostly likely a monoazide adduct). Indeed, measuring EPR spectra of these same mixtures (again 40 min after mixing the reagents) without any additional heating revealed extremely weak EPR signals in the region around g = 2.0, corresponding to formation of only a tiny amount of nitrene radical species 3P1Ns.

On measuring the UV−vis spectra of these same solutions after heating them overnight at 45 °C (i.e., solutions that gave strong EPR signals characteristic for 3P1Ns) clearly revealed the presence of a new species in the UV−vis spectra (Figure S6-2, Supporting Information), concomitant with much higher EPR intensities corresponding to nitrene radical species 3P1Ns. Illustrative spectra comparing 1P1 and species 3P2Troc formed upon heating a solution of complex 1P1 in the presence of an excess of 2Troc are shown in Figure 10 (left).

Reaction of complex 1P1 with azide 2Troc resulted in red-shifts of the Soret band at 438 nm and shifting of the Q-band to 648 nm. In addition, a new peak at ∼753 nm was also observed (Figure 10, left). The shift in the Soret and the Q-band is indicative of oxidation of the metal from cobalt(II) to cobalt(III) and (or) ligation to the sixth coordination site, leaving the porphyrin ligand intact without oxidation upon formation of mono-nitrene radical species 3P2Troc. The additional band at ∼753 nm is likely a charge-transfer band (e.g., a MLCT or LMCT band involving the nitrene radical and the cobalt(III) center).

Formation of porphyrin-based ligand radicals is known to cause drastic changes in the UV−vis spectrum with appearance of red-shifted bands, disappearance of the Q-band and obvious shape changes of the Soret band compared to unmodified (i.e., non-reduced/nonoxidized) dianionic porphyrinato ligands (por2−).80,81 This is what was observed upon formation of bis-nitrene species 5P1Ns in the reaction of complex 1P1 with N-nosyl iminoiodane 4Ns (Figure 10, right). As mentioned before, when using iminoiodane 4Ns formation of the bis-nitrene species is comparatively faster than formation of the mononitrenes when using azide 2Ns. Accordingly, in the case on measuring the UV−vis spectra of a mixture of 1P1 and 4Ns, the disappearance and shape changes of the Q- and Soret-bands was observed within an hour of making these samples (Figure 10, right). As shown in Figure 10, the species exhibited characteristic, strongly red-shifted bands at 863 and 977 nm. Similar spectral changes have been reported for CoIII complexes with a 1e-oxidized octaethylporphyrin ligand.82,83 Hence, we assign these spectral changes to formation of the bis-nitrene species 5P1Ns. This is also in correspondence with the EPR measurements. Both the EPR and UV−vis signals characteristic for the nitrene radical species 5P1Ns were completely lost upon heating the mixture overnight at 45 °C.

In accordance with the EPR spectroscopic studies, once again the mono-nitrene species 3P2Troc was found to be more stable than bis-nitrene species 5P1Ns. UV−vis spectroscopy clearly indicated that solutions of 3P2Troc obtained from complex 1P1...
and 4$_{\text{Troc}}$ remained stable for even 2 days, while a significant amount of decomposition already occurred for 5$_{\text{Ns}}$ obtained from complex 1$_{\text{Ns}}$ and 4$_{\text{Ns}}$ within 2 h. This points to a higher intrinsic reactivity of bis-nitrene species 5$_{\text{Ns}}$ compared to mono-nitrene species 3$_{\text{Ns}}$. Indeed, DFT calculations (using 3$'$ and S$'$, which are simplified models of 3$_{\text{Ns}}$ and 5$_{\text{Ns}}$ without phenyl substituents on the porphyrin ring and having a N-SO$_2$Ph base nitrene instead of N-Ns) predict a ca. 1.3 kcal mol$^{-1}$ lower activation energy for HAA from ethylbenzene for 5$'$ ($\Delta G^\ddag = +30.4$ kcal mol$^{-1}$) than for 3$'$ ($\Delta G^\ddagger = +31.7$ kcal mol$^{-1}$).

**X-ray Absorption Spectroscopic (XAS) Studies.** To gain additional evidence for the coordination mode and the oxidation states of the two intermediates, i.e., the mono- and the bis-nitrene species, XAS measurements were performed. X-ray absorption near edge spectroscopic (XANES) studies were carried out at Co K-edge in order to directly probe the metal oxidation states in 3$_{\text{Ns}}$ 3P$_2$ 5P$_1$ and 5$_{\text{Ns}}$ (Figure 11A). The starting cobalt(II)-meso-tetraphenylporphyrin (TPP) complex 1$_{\text{p}}$ exhibited an edge inflection energy of ca. 7720.7 eV. A shoulder feature along the rising edge at 7715.4 eV corresponds to a 1s to 4p + LMCT shakedown transition, in accord with the observed four-coordinate square-planar structure of this complex. This transition is strongest in four-coordinate square-planar Co complexes, but is also observed in five-coordinate square-pyramidal geometries (it is not present in either T$_{2g}$ or O$_{3g}$ geometries). Finally, a broad 1s to 3d pre-edge peak was observed at 7708.9 eV, with preliminary peak fitting analysis indicating a peak area of approximately 8.1 units. The energies of the edge and 1s → 3d pre-edge transitions are in accord with the reported values for other cobalt(II) complexes.$^{10,81}$ XANES of 5$_{\text{Ns}}$ showed a +1.9 eV blue-shift of the edge inflection energy to 7722.56 eV, relative to complex 1$_{\text{p}}$, supporting metal-centered oxidation from cobalt(II) to cobalt(III). The 1s → 3d pre-edge transition was also blue-shifted by ~1.0 to 7710.2 eV and the pre-edge increased in intensity (peak-area of 12.0 units). Most notably, 5$_{\text{Ns}}$ lacks the diagnostic 1s → 4p shakedown transition shoulder on the rising edge, providing strong evidence for a six-coordinate O$_{6}$ cobalt site. Finally, the XANES data on 3$_{\text{Ns}}$ revealed the existence of edge and 1s → 3d pre-edge transitions at nearly identical positions (7722.8 and 7710.2 eV, respectively) relative to 5$_{\text{Ns}}$, thereby indicating that both mono-nitrene complex 3$_{\text{Ns}}$ and bis-nitrene complex 5$_{\text{Ns}}$ are cobalt(III) species.

Importantly, similar to the observations for complex 3$_{\text{Ns}}$, the absence of the 1s → 4p shakedown transition in the XAS data of 3$_{\text{Ns}}$ also points to the presence of a six-coordinate O$_{6}$ cobalt(III) center for this complex. XANES data were also obtained for complex 3$_{\text{Troc}}$ and compared with that for 3$_{\text{Ns}}$ and 5$_{\text{Ns}}$. Careful examination of the pre-edge of the XANES of different catalyst and oxidant combinations shows no distinct differences between the different generated intermediates (see Figure S3-1; Supporting Information). This indicates that six-coordinate O$_{6}$ species were formed in all cases. Extended X-ray absorption fine structure (EXAFS) analysis revealed further structural details (Figures 11B–C and S3-2, S3-3 and Tables 3, S3-1, S3-2, and S3-3). For complex 5$_{\text{Ns}}$, the first coordination sphere could be satisfactorily fitted by considering six N/O scatterers at a distance of 1.92 Å (Table 3). Although the additional outer-shell features could be satisfactorily accounted for by considering single scattering paths involving 8 carbons at 2.94 Å, 12 carbons at 3.35 Å, and 4 oxygen donors at 3.57 Å distance from cobalt, the fit could be significantly improved by introducing multiple-scattering pathways. The best fit for 5$_{\text{Ns}}$ is represented by fit 12 in Table S3-1 and Figure 11B. It is important to note that efforts were also made to include the effect of the sulfur scatterers originating from the two –NNS units. However, all fits (fits 9–11 in Table S3-1) including any kind of S-shell showed negative Debye–Waller factors in the fit parameters; and hence they were not considered in the fitting procedure.

Interestingly, consistent with the XANES data, our attempts to do a set of fits for a back transformation range limited to the first shell ($r = 0.8 – 2.1$ Å) for 3$_{\text{Ns}}$ also pointed to a six-

$^a$Details of the EXAFS simulation and DFT structures can be found in the Supporting Information.
coordinate geometry (fits 1–3; Table S3-2). This contrasts with previous assumptions considering mono-nitrene species $3^1\text{P}_\text{Ns}$ to be five-coordinate.\textsuperscript{4,42} The best fit to the data of the mono-nitrene species requires six N/O scatterers at $\sim 1.95$ Å distance from the cobalt(III) center, which is slightly longer (although almost identical within the error of measurements) than the Co–N distance of 1.92 Å obtained from the EXAFS data of bis-nitrene species $5^1\text{P}_\text{Ns}$.

With these results in hand, we set out to consider plausible ligands that could occupy the sixth coordination site for the mono-nitrene species $3^1\text{P}_\text{Ns}$. Initially, we considered coordination of a neutral unreacted nosyl azide ligand under the conditions of the EXAFS measurements. However, DFT geometry optimizations and calculation of the Co K-edge features of the optimized structures with DFT methods revealed that such nosyl azide species have too long Co–N distances to explain the experimental XAS data (Figures S8-2; Supporting Information). The same holds for the aqua adduct of $3^1\text{P}_\text{Ns}$. The Ns-NH$_2$ amine and ammonia (NH$_3$) adducts of $3^1\text{P}_\text{Ns}$ have shorter Co–N bond distances, which substantially decreases the calculated intensity of the pre-edge transitions in the Co K-edge region. However, the best agreement between the calculated and experimental pre-edge intensities is obtained for anionic ligand adducts of mono-nitrene $3^1\text{P}_\text{Ns}$. The optimized geometries of NsNH$_2^-$, NH$_3^-$, and OH$^-$ adducts of $3^1\text{P}_\text{Ns}$ species have comparable Co–N and Co–X distances for the nitrene radical ligand and the sixth ligand X (Figure 12), respectively. Hence, similar pre-edge intensities are also computed as obtained for bis-nitrene species $5^1\text{P}_\text{Ns}$ (Figure S8-2; Supporting Information). Considering the detection of the Na$^+$ adduct of NO$_2$PhSO$_2$NHD as mentioned earlier in the ESI-MS studies in combination with the above-mentioned calculated pre-edge intensities, the NsNH$_2^-$ amido ligand is perhaps the most probable candidate occupying the sixth coordination site of the mono-nitrene species. Notably, the DFT calculated geometrical parameters for $3^1\text{P}_\text{Ns}$ (NsNH$_2^-$) is in reasonable agreement with the EXAFS data (Table 3). This would mean, however, that $3^1\text{P}_\text{Ns}$ is anionic (perhaps containing an NsNH$_2^+$ counterion). Formation of such a charged species in benzene is unexpected, and as such we cannot exclude the sixth ligand being the neutral NsNH$_2$ amine donor (despite a better agreement between the calculated and experimental XAS pre-edge intensities for the NsNH$_2^+$ amido ligand). At this point, we cannot fully exclude formation of dinuclear complexes with ligand X being for example a bridging amido ligand. However, we consider this possibility less likely in view of the fact that similar XAS data were gathered for $3^3\text{P}_\text{Troc}$ which is based on the bulky porphyrin P2. No peak corresponding to a Co scatterer was observed in the EXAFS spectrum, which would be expected for a homodinuclear Co···Co species. It is further worth mentioning that the sixth ligand X (Figure 12) does not prevent conversion of mono-nitrene species $3^1\text{P}_\text{Ns}$ to bis-nitrene species $5^1\text{P}_\text{Ns}$ upon treatment with the strongly oxidizing N-nosyl iminoiodane 4$_\text{Ns}$. On adding an excess of 4$_\text{Ns}$ to a solution of previously formed mono-nitrene species $3^1\text{P}_\text{Ns}$ clear EPR signals corresponding to bis-nitrene species $5^1\text{P}_\text{Ns}$ appeared, once again displaying the strongly oxidizing nature of N-nosyl iminoiodane. Apparently, the ligand X can be replaced or converted to a nosyl nitrene radical moiety upon reaction of mono-nitrene $3^1\text{P}_\text{Ns}$ with iminoiodane 4$_\text{Ns}$.

### CONCLUSIONS

In conclusion, we have demonstrated that activation of both organic azides and iminoiodanes by cobalt(II) porphyrin complexes leads to formation of ‘cobalt(III)-nitrene radical’ complexes. Both species bear substantial spin density at the ‘nitrene-moiety’ and are key intermediates in cobalt-catalyzed nitrene transfer reactions. Notably, for the less bulky porphyrin complexes, the obtained species are markedly different. While organic azides generate predominantly mono-nitrene species, hypervalent iodine reagents such as iminoiodanes produce bis-nitrene species such as $5^1\text{P}_\text{Ns}$. This is the first report to demonstrate the formation of a bis-nitrene species of a cobalt porphyrin complex. The stronger oxidizing nature of the nitrene precursor 4$_\text{Ns}$ is considered important to generate such species. The bis-nitrene species $5^1\text{P}_\text{Ns}$ has a markedly different electronic structure from the mono-nitrene species $3^1\text{P}_\text{Ns}$ and $3^2\text{P}_\text{Troc}$ and also differs markedly from the electronic structure of the previously reported diamagnetic bis-imido Ru$^{II}$-porphyrin species (por)Ru$^{II}$((≡N≡R’)$_2$). Electronically, the mono- and the bis-nitrene species are markedly different; but XANES data for these species suggest that both are six-coordinate (O$_6$) complexes with similar averaged bond distances between cobalt(III) and the six N/O scatterers ($3^1\text{P}_\text{Ns}$: $\sim 1.95$ Å; $5^1\text{P}_\text{Ns}$: $\sim 1.92$ Å). The exact nature of the ligand X coordinated at the sixth available coordination site of the [Co(II)(por)(N≡R’)$_2$] nitrene radical species $3^1\text{P}_\text{Ns}$, $3^2\text{P}_\text{Troc}$ and $3^3\text{P}_\text{Troc}$ remains speculative. For $3^1\text{P}_\text{Ns}$, the most probable candidates (based on a comparison between the experimental and DFT calculated Co K-edge XAS pre-edge intensities, complementary mass data, and the previously detected NsNHD$^-$ radical) seem to be either the neutral NsNHD amine ligand or the anionic NsNND$^-$ amido ligand.

The revelation of the presence of a sixth ligand even in the mono-nitrene species implies that the use of additives in such catalytic nitrene transfer reactions should not have a positive effect on the catalytic reactions. This is indeed seen to be the case in the earlier reports from the Zhang group, where additives have only a detrimental effect on catalysis if any (except for ee enhancement in one case but in lower yields).\textsuperscript{39,40}

The two different types of catalytically relevant species detected are represented in Figure 12. Overall, these results signify the importance of the nature of nitrene sources in metal-catalyzed nitrene transfer processes. Depending on the nature of the nitrene precursor, the intermediates can be a result of a single oxidation of the catalyst at the metal center or a double oxidation where the second oxidation step occurs at the
porphyrin ring. In addition, the bis-nitrene species $3 P_{1N}$, though formed faster, lives shorter and is more reactive than the mono-nitrene species $3 P_{1N}$. Degradation of bis-nitrene species $5 P_{1N}$ occurs within hours after initial formation while decomposition of mono-nitrene species $3 P_{1N}$ is much slower (solutions of $3 P_{1N}$ in benzene-$d_6$ were stable for $>24$ h according to EPR and UV–vis). In addition, the studies described here clearly demonstrate the better performance of the nitrene moiety. The steric in stabilizing $e$ but also help in preserving them for longer periods by the not only give higher conversions to the nitrene-radical species and decomposition of mono-nitrene species $3 P_{1N}$, which do not only give higher conversions to the nitrene-radical species but also help in preserving them for longer periods by the stabilizing effects of H-bonding between the catalyst amide arms and the nitrene moiety. The steric influence of the bulk in complex $1 P_2$ also has an implication on the type of intermediates formed, as was shown for the reactions of $1 P_1$ and $1 P_2$ with N- nosyl iminoiodane $4 N$. Detailed studies of the differences in reactivity between the mono- bis-nitrene and bis-nitrene species and implications in catalysis between these ‘cobalt(III)-nitrene radical’ species are a topic of current investigation and should shed new light on the catalytic mechanisms of nitrene transfer processes catalyzed by cobalt(II) porphyrin complexes.
