Left ventricular thrombus formation after acute myocardial infarction

Ronak Delewi, Felix Zijlstra, Jan J. Piek

*Heart.* 2012; 98: 1743-9
ABSTRACT

Left Ventricular (LV) thrombus formation after acute myocardial infarction is a serious complication, potentially leading to fatal stroke. Previous studies performed in the pre-thrombolytic and thrombolytic era reported varying data regarding the incidence of LV thrombus formation, ranging from 20-46%. Nowadays acute myocardial infarction patients are treated with primary PCI and the reported incidence is lower. This is probably due to more aggressive anticoagulation therapies in the acute phase, smaller infarct sizes and improved LV remodeling. However, when sensitive diagnostic modalities such as diffused weighed magnetic resonance imaging are used during the appropriate time-window, LV thrombus is found in about 10% of post-AMI patients, thus still constituting an important clinical challenge in the modern era of primary PCI.
INTRODUCTION

Cardiovascular disease remains the leading cause of death in Western society. Mortality from acute myocardial infarction (AMI) is decreasing since the introduction of primary percutaneous coronary intervention (PCI) that proved to be superior to thrombolytic therapy, showing lower mortality rates and reduced clinical adverse events. Nevertheless, post infarct complications still lead to morbidity and mortality in a large number of patients.

One of the most feared complications is the occurrence of thromboembolic events (mostly cerebrovascular accidents) due to left ventricular (LV) thrombus formation. The risk of LV thrombus formation is highest during the first 3 months following acute myocardial infarction, but the potential for cerebral emboli persists in the large population of patients with chronic LV dysfunction. Since these thromboembolic events are usually unheralded by warning signs of transient cerebral ischemia, the only truly satisfactory medical approach is adequate management of these high-risk groups. This article discuss the incidence, diagnosis and management of LV thrombus formation after an AMI.

Pathogenesis of LV thrombus

The combination of blood stasis, endothelial injury and hypercoagulability, often referred to as Virchow’s triad, is a prerequisite for in vivo thrombus formation. In the presence of LV thrombus formation after AMI the three components of this triad can also be recognized (Figure 1). LV regional wall akinesia and dyskinesia result in blood stasis, often recognized on two dimensional echocardiography by the occurrence of spontaneous LV contrast. Prolonged ischemia leads to subendocardial tissue injury with inflammatory changes. Finally, patients with an acute coronary syndrome display a hypercoagulable state with, for example, increased levels of protrombin, fibrinopeptide A and von Willebrand factor, and decreased levels of the enzyme responsible for cleaving von Willebrand factor (ADAMTS13). This triad can result in the formation of LV thrombus composed of fibrin, red blood cells, and platelets.

LV thrombus can occur within 24 hours after AMI. One study performing serial echocardiographic studies showed that about 90% of thrombi are formed at a maximum of two weeks after the index event. However, some patients develop a new LV thrombus after discharge, often in association with worsening LV systolic function. Spontaneous or anticoagulant induced resolution is relatively common in LV thrombus formation after AMI. Thrombus seems to disappear more often in patients with apical akinesia than those with apical aneurysm or dyskinesia.
It has been speculated that LV thrombus plays a positive role in the acutely infarcted myocardium, by offering mechanical support to the infarcted myocardium and therefore protecting against LV rupture.\textsuperscript{w4} The thrombus becomes firmly attached to its site of origin, enhancing the underlying myocardial scar, limiting potential infarct expansion and partially restoring the thickness of the myocardial wall. As a consequence, bulging is reduced, resulting in a more effective myocardial contraction. Often, however, expansion of the infarct zone occurs very early after infarction, before thrombus would have time to organize and is able to prevent formation of LV aneurysm and myocardial rupture.

**Incidence**

Early data from the prethrombolytic and thrombolytic eras suggest that in the setting of AMI, LV thrombus was present in 7-46\% of patients, most frequently in acute anterior or apical myocardial infarction.\textsuperscript{2,4, w3-w5} Differences in diagnostic techniques, timing of examination and use of antithrombotic treatment cause substantial variation in the reported frequency of LV thrombus from different series. In addition, it should be noted that the incidence as reported in autopsy studies is consistently higher as compared with clinical studies, probably due to better accuracy but also due to patient selection.
Nowadays the reported incidence is lower. This is probably due to (1) more aggressive anticoagulation therapies in the acute phase (e.g. the use of heparin, bivalirudin) (2) smaller infarctions and (3) improved LV remodeling. Although the use of angiotensin converting enzyme (ACE) inhibitors is also thought to be associated with improved LV remodeling, the GISSI-3 study found no difference in LV thrombus rates between patients who did and did not receive lisinopril.

There are limited data on the exact frequency of LV thrombus in PCI treated AMI patients. Two studies found LV thrombus formation in 5.4% and 7.1% of patients with acute anterior wall myocardial infarctions. However, these studies were retrospective, non-serial and only assessed LV thrombus formation at a single point in time and during the early phase of recovery after myocardial infarction.

In the latter study a follow-up echocardiography was performed at 1-3 months, showing LV thrombus in an additional 8% of the patients. Solheim et al., reported a similar incidence of 15% in the first 3 months in a selected group of AMI patients treated by primary PCI. So, the timing of LV thrombus assessment is crucial, as assessment too soon after the onset of myocardial infarction will probably lead to failure of detection of the thrombus in a significant percentage of patients.

**Clinical factors contributing to LV thrombus formation**

Risk factors for the development of LV thrombus are consistently irrespective of infarct treatment and include large infarct size, severe apical asynergy (i.e. akinesis or dyskinesis), LV aneurysm, and anterior MI. This is consistent with an increased contribution of at least two out of the three components of Virchow’s triad, namely a larger area of blood stasis as well as an increased area of injured subendocardium.

In a study with more than 8000 STEMI patients, LV thrombus was found in 427 patients (5.1%). This incidence is relatively low as compared to other studies, probably because of the exclusion of high risk patients with severe LV dysfunction. Patients with anterior AMI had a higher incidence of LV thrombus as compared to patients with AMI at other regions (11.5% vs. 2.3%, p <0.0001). The incidence of LV thrombus was also higher in patients with an ejection fraction ≤40% (10.5% vs 4%, p <0.0001). In patients with an anterior AMI and an ejection fraction ≤40% this percentage was as high as 17.8%.

Thrombus formation is not exclusively located apical; approximately 11% occurs at the septal wall and 3% at the inferoposterior wall. The prevalence of thrombus in non-anterior myocardial infarction increases when inferior necrosis extends towards the posterolateral wall. In such cases the prevalence is similar to that observed in anterior
The presence of thrombi is significantly related to the region of most severe functional impairment and/or the region with myocardial enhancement (ie infarction or scarring).\textsuperscript{7} LV thrombus appears earlier in the course of the disease when initial ejection fraction ≤40%, in the presence of multivessel coronary artery disease, or a high peak creatine kinase value.\textsuperscript{8}

There is conflicting evidence with respect to the influence of ß-blockers. Several studies have reported a higher frequency of thrombus development in patients treated with ß-blockers which could be related to negative inotropic action of these drugs and thus increased blood stasis. In particular, in a randomised study, Johannessen \textit{et al} reported an increased occurrence of thrombus in patients with anterior AMI after oral ß-blocker therapy.\textsuperscript{9} Turpie \textit{et al} reported similar results after treatment with ß-blockers in a large population of patients with AMI.\textsuperscript{9} The GISSI-2 study, however, observed the same rate of LV thrombi in patients with or without atenolol.\textsuperscript{10}

It has been demonstrated that mitral regurgitation prevents thrombus formation in patients with dilated cardiomyopathy.\textsuperscript{10} The protective effect of mitral regurgitation may be the consequence of augmented early diastolic flow velocities at the mitral annulus level, as well through the entire length of the left ventricle, protecting the LV cavity from a stagnant, thrombogenic blood flow pattern. In addition, studies suggest abnormal flow profiles are associated with the presence of an LV thrombus.\textsuperscript{11,11} However, to date no studies have demonstrated the same association in patients with AMI.

There have been few studies performed on the use of biomarkers in the setting of LV thrombus formation. It could be postulated that factors involved in the coagulation cascade could serve as biomarkers to identify patients at increased risk for LV thrombus development. Data presented at the European Society of Cardiology in 2011 demonstrated higher soluble tissue factor and d-dimer concentrations in patients with LV thrombus formation.\textsuperscript{12} Another study observed mildly elevated anticardiolipin antibody levels in patients with LV thrombus formation after AMI.\textsuperscript{13} Whether these factors are indeed capable of predicting LV thrombus formation needs to be evaluated.

**Diagnostic modalities to detect LV thrombus**

**Radionuclide based techniques**

In 39 series using radionuclide ventriculography a so-called “square left ventricle” was reported to be associated with LV thrombus.\textsuperscript{14} The use of indium-111 labeled platelets is much better documented. It provides excellent specificity (95%) in identifying LV
thrombus, and its sensitivity was reported to be 70% compared with transthoracic echocardiography (TTE). It is not applied widely though because it is time consuming, expensive, not universally available and involves radiation exposure. Furthermore, this scintigraphic technique is ineffective in identifying relatively small thrombi, and it has good specificity and sensitivity only if there is active platelet aggregation on the surface of the LV mural thrombus at the time of imaging. In patients with an elevated left hemidiaphragm, indium-111 activity in the spleen may be confused with that from the LV apex. Finally, in patients with a large LV aneurysm but no LV thrombus, a large amount of relatively static blood within the LV aneurysm may increase indium-111 activity.

Echocardiography

Two dimensional TTE is the technique used most often for assessing the presence, shape and size of a LV mural thrombus. When the thoracic anatomy of the patient allows sufficient visualization of the heart, two dimensional echocardiography provides excellent specificity (85-90%) and sensitivity (95%) in detecting LV thrombus. LV thrombus on echocardiography is defined as a discrete echodense mass in the left ventricle with defined margins that are distinct from the endocardium and seen throughout systole and diastole. It should be located adjacent to an area of the LV wall which is hypokinetic or akinetic and seen from at least two views (usually apical and short axis). Care must be taken to exclude false tendons and trabeculae and to rule out artefacts (reverberations, side lobe, or near field artifacts), which constitute the most common cause for a false diagnosis of a thrombus. Another source of false-positive studies, result from tangentially-cut left ventricular wall. Varying gain settings and depth of field, as well as using transducers with different carrier frequencies in multiple positions and orientations are helpful to minimize such false-positive studies.

In addition, often the LV apex cannot be clearly defined and the presence or absence of a thrombus may be very difficult to establish leading to an estimated 10-46% of echocardiograms that are inconclusive. Intravenous echo contrast during TTE may improve the diagnostic assessment of LV thrombus. However, in Europe the use of most compounds is contraindicated by the European Medicines Agency in cardiac patients with acute coronary syndromes, recent PCI, acute or chronic severe heart failure or severe cardiac arrhythmias. Also non-protruding and small mural LV thrombi may still go undetected.

Transoesophageal echocardiography (TOE) has little to offer in the detection of LV thrombus. Although it is the technique of choice for detecting atrial masses and thrombi in the left atrial appendage, its value for diagnosis of LV thrombus is limited because the
apex is most often not well visualized. Nevertheless, some data suggest that TOE is superior to TTE in providing optimal visualization of small LV apical thrombi.

**Computed tomography**

Computed tomography scanning provides about the same specificity and sensitivity as two dimensional TTE in the identification of LV thrombus. This technique is not used in daily practice since it requires the intravenous injection of radiographic contrast material and exposes the patient to ionising radiation.

**Magnetic resonance imaging**

Cardiac magnetic resonance imaging (CMR) with contrast (delayed enhancement, [DE]) has significantly better accuracy than TTE and TOE for the diagnosis of LV thrombus (table 1 and figure 2). A study by Srichai et al compared CMR and late gadolinium enhancement with echocardiography in a cohort of patients undergoing LV reconstruction surgery in whom surgical and/or post-mortem verification of thrombus was performed. This study reported that the sensitivity of TTE was 40%, compared with 88% for CMR. Another study reported an echo sensitivity and specificity of 33% and 91% in a heterogeneous population of patients with LV systolic dysfunction. These studies report lower sensitivity for detection of LV thrombus than previously described, probably due to exclusion of suboptimal echocardiographic examinations in the previously mentioned studies. Also, echocardiographic examinations were often reinterpreted with emphasis on LV thrombus detection and led to different findings when the presence or absence of LV thrombus was based on routine clinical echocardiographic reading as part of the patient’s evaluation.

DE-CMR allows for a relatively rapid assessment of thrombus presence, size, and location and is nowadays considered the gold standard. The intravenous administration of gadolinium chelates greatly enhances the ability to detect and characterize LV thrombi. Immediately after contrast administration, the homogeneous, strong enhancement of the LV cavity allows easy detection of abnormal intraventricular structures (dark), which frequently occur adjacent to scarred myocardium (bright hyperenhanced).

Cine-CMR (without a contrast agent such as gadolinium) seems to be less suitable for LV thrombus detection. Thrombus was missed in 44-50% of the cases as detected by DE-CMR. The ability of DE-CMR to identify thrombus based on tissue characteristics rather than anatomical appearance alone may explain why it provides improved thrombus imaging compared with cine-CMR. It should be mentioned that the criteria to differentiate no-reflow zones from mural thrombi are not definite, and thus differentiation may not always be straightforward. Also, further research and histopathological correlation is needed to evaluate the role of DE-CMR to differentiating subacute from organised clots.

Bouma, Department of Cardiology, Academic Medical Center, Amsterdam, the Netherlands.

Embolic complications

In the prethrombolytic era, embolic complications were reported in approximately 10% of the cases, whereas in the thrombolytic era, embolic complications occurred in 2-3% of patients. There are poor data regarding embolic complications in LV thrombus patients treated by primary PCI. Also, exact percentages regarding the site of embolization are not available.

Several studies have suggested that LV thrombi that protrude into the ventricular cavity or that exhibit independent mobility are associated with a higher rate of embolization than thrombi without these features (figure 3). A thrombus is considered as
protruding when it projects predominantly into the LV cavity and as mural when it appears flat and parallel to the endocardial surface. Echocardiographic studies analyzing mainly retrospective and non-serial data have indicated a positive relationship between the embolic potential of LV thrombi and their protruding shape and/or intracavitary motion. However, spontaneous time-course variation in the morphologic aspects, such as shape and mobility pattern, are common. By performing serial echocardiography on 59 untreated patients, Domenicucci et al found that these morphological features demonstrated pronounced spontaneous variability in the first several months after acute infarction, and therefore suggested that the assessment of these features was not helpful. They noted that 41% of 59 thrombi had significant changes in shape and 29% had changes in mobility. Also, it has been reported that up to 40% of embolism episodes occur in patients whose thrombi are neither protuberant nor mobile.

Other thrombus characteristics, such as thrombus size, central echolucency, or hyperkinesia of the myocardial segments adjacent to the thrombus, were found in some
studies to be associated with an increased risk of embolism, but were not confirmed by others.

Other conditions that increase the risk of systemic embolization are (1) severe congestive heart failure, (2) diffuse LV dilatation and systolic dysfunction, (3) previous embolization, (4) atrial fibrillation, and (5) advanced patient age. It has been thought that the risk of embolization is lower in patients with LV aneurysm, since the absence of LV contraction near the site of the thrombus makes dislodgement unlikely. 

**Pharmacological management**

If indeed systemic embolization is the highest risk of LV thrombus, the central question arises as to how these patients should be treated to prevent embolization. In the past, if recurrent systemic emboli developed despite anticoagulant therapy, surgical removal of the thrombus was considered necessary. Nowadays antithrombotic therapy is thought to prevent embolic complications of LV thrombus.

**Thrombolysis**

Vaitkus and Barnathan pooled the data from six studies consisting of a total of 390 patients and assessed incidence of LV thrombus formation in those patients treated with thrombolysis versus those without thrombolytic therapy. They were not able to demonstrate a statistical difference in the incidence of LV thrombus formation, only a trend in favor of thrombolysis. These studies were not randomized but often utilised patients seen 3 hours after symptom onset as a control group. Data from the Gissi-3 database, including more than 8000 patients, showed no reduced incidence of thrombus formation in patients who received either thrombolytic therapy or heparin.

Intravenous thrombolyis has also been used for treatment of documented LV thrombus. In a report of 16 patients with LV thrombus on echocardiography, urokinase was infused intravenously at a rate of 60,000 U/h for 2 to 8 days in combination with intravenous heparin (200 units/kg x 12 h). LV thrombi were successfully lysed in 10 of 16 patients. None of the patients suffered from clinical embolism, and therapy had to be discontinued in only patient due to haematuria. In a later study, four patients with mobile LV thrombus were treated with intravenous urokinase or streptokinase. In the first two cases, lysis of thrombus was achieved without complication. In the latter two cases, however, systemic embolism occurred, with transient diplopia in one and stroke followed by death in the other. It was concluded that fibrinolytic agents are capable of lysing ventricular thrombi but that the risks of this therapy are too high.
**Heparin**

Data regarding the benefit of heparin treatment in patients with documented LV thrombus on echocardiography during the first 2 weeks are somewhat conflicting, leading us to believe that there may be a benefit, at least in the short term. In a randomized controlled trial, AMI survivors who were treated with high dose heparin (12500 units subcutaneously every 12 hours) showed a lower incidence of LV thrombus formation than those administered a low dose (5000 units subcutaneously every 12 hours) (11% vs 32%, p<0.001) during a 10 day period. Results from the SCATI study showed a similar reduction in LV thrombus formation for the group that was treated with calcium-heparin compared to the control group in patients undergoing thrombolysis. In the GISSI-2-connected study, however, high dose heparin did not prevent thrombus formation (27% vs 30%, P=NS). In a study with 23 consecutive patients with mobile and protruding thrombi, high dose heparin was given intravenously over a period of 14-22 days (mean 14 ±4). In all 23 patients LV thrombi decreased in size, with disappearance of the high risk features. No embolic events were detected during treatment, and the only complication was an upper gastrointestinal haemorrhage. Dalteparin however, a low-molecular-weight heparin, reduced the incidence of LV mural thrombus formation but had no influence on the risk of systemic embolization, and its use was associated with an increased risk of haemorrhage.

**Vitamin K antagonist**

Observational studies conducted in prethrombolytic and thrombolytic eras, provided support for the hypothesis that anticoagulation reduces the risk of embolization. A 1993 meta-analysis included 11 studies of 856 patients who had an anterior myocardial infarction; the odds ratio (OR) for an embolic event was 5.5 (95% CI 3.0-9.8). The meta-analysis included seven studies with 270 patients that included data on the relationship between anticoagulation for six months and embolisation. Although all seven studies presented data suggesting that systemic anticoagulation reduces embolic complications, this trend reached significance only in three trials. When pooling the data, anticoagulation compared to no anticoagulation was associated with a reduction in the rate of embolisation (odds ratio 0.14, 95% CI 0.04-0.52).

Based on these data, both current European Society of Cardiology and American College of Cardiology/American Heart Association guidelines recommend vitamin K antagonist therapy in patients with an LV thrombus after myocardial infarction.

However, vitamin K antagonists do not appear to affect the likelihood of resolution of the thrombus and, unfortunately, no large randomized trials have been performed to evaluate the efficacy of long term anticoagulation to prevent embolization in patients with LV thrombus. Therefore the effects of long term anticoagulants on the risk of
embolization are the subject of debate. Among the many questions left unanswered is when to withdraw anticoagulant medication when thrombus is identified since the risk of embolization decreases over time, likely as a result of organization of thrombus, which include thrombus neovascularization. However, retrospective studies documented ongoing embolic risk in LV thrombus patients.\textsuperscript{42} In indium 111 platelet imaging studies most thrombi, regardless of age, have been observed to have externally detectable ongoing platelet accumulation, indicating continued surface activity.\textsuperscript{20} The European guidelines recommend vitamin K antagonist for at least 3-6 months, while the American guidelines recommend indefinite treatment in patients without increased risk of bleeding.

Although there are limited data regarding the appropriate follow-up and timing of cessation of vitamin K antagonists in these patients, the following approach seems appropriate for most patients:

- Assess LV thrombus within the first month after AMI, preferably with CMR in high risk patients and start vitamin K antagonist when LV thrombus is present and no contra-indication exists
- Re-evaluate LV thrombus formation after 6 months since data show that LV thrombus resolution in the first months is very common, also in patients treated with vitamin K antagonists\textsuperscript{43}
- When LV thrombus is not present and there is no other indication for vitamin K antagonists, assess bleeding risk and consider stopping therapy

Newer anticoagulants are presently being developed and some of them are already registered.\textsuperscript{44-46} It can be envisioned that in the longer term these new anticoagulants will replace vitamin K antagonist. However, at present vitamin K antagonist is still the standard of care for the treatment of LV thrombus. More importantly, the newer anticoagulants also have the risk of fatal and non-fatal bleedings and their role in LV thrombus patients should be further assessed.

\textit{Antiplatelet therapy and triple therapy in the PCI era}

Another issue is that nowadays, STEMI patients are treated by primary PCI and receive long term dual anti-platelet therapy (including aspirin and a P2Y\textsubscript{12} inhibitor). Consequently, patients with LV thrombus or at increased risk of LV thrombus after a myocardial infarction are frequently being treated with vitamin K antagonist in addition to dual antiplatelet therapy (triple antithrombotic therapy) and therefore subjected to an increased bleeding risk. It is unclear, however, if long term anticoagulation is still necessary in STEMI patients treated by primary PCI and subsequent dual antiplatelet therapy.
Large prospective studies show a yearly incidence of bleeding of approximately 3.7% for dual antiplatelet therapy and 12% for triple antithrombotic therapy.\textsuperscript{47} The most common site of bleeding is the gastrointestinal tract (30-40%) and cerebrum (9-10%), with 25% of episodes in the latter site proving fatal. Furthermore, non-fatal bleedings are an important predictor of mortality post-PCI at follow-up.\textsuperscript{48} Also, in regard to hospitalization after emergency department visits in the United States for adverse drug events in patients above 65 years, 33.3% of the 99,628 hospitalizations concerned warfarin.\textsuperscript{49} Moreover, in the general STEMI population treated with primary PCI and dual antiplatelet therapy but no anticoagulation therapy, symptomatic cerebral infarction is rare, occurring in 0.75-1.2% of all STEMI patients.\textsuperscript{50} Thus, the potential benefit of vitamin K antagonist treatment on top of dual anti-platelet therapy may not outweigh against the increased bleeding risk. This calls for a randomised trial to be conducted to determine whether anticoagulation treatment prevents embolic complications in AMI patients treated with primary PCI.
