Future cosmic microwave background experiments have the potential to probe the density of relativistic species at the subpercent level. This sensitivity allows light thermal relics to be detected up to arbitrarily high decoupling temperatures. Conversely, the absence of a detection would require extra light species never to have been in equilibrium with the Standard Model. In this Letter, we exploit this feature to demonstrate the sensitivity of future cosmological observations to the couplings of axions to photons, gluons, and charged fermions. In many cases, the constraints achievable from cosmology will surpass existing bounds from laboratory experiments and astrophysical observations by orders of magnitude.

DOI: 10.1103/PhysRevLett.117.171301

Introduction.—Most of what we know about the history of the Universe comes from the observations of light emitted at or after recombination. To learn about earlier times we rely either on theoretical extrapolations or the observations of relics that are left over from an earlier period. One of the most remarkable results of the Planck satellite is the detection of free-streaming cosmic neutrinos [1–3], with an energy density that is consistent with the predicted freeze-out abundance created one second after the Big Bang. Probing even earlier times requires detecting new particles that are more weakly coupled than neutrinos. Such particles arise naturally in many extensions of the Standard Model (SM) [4,5]. Particularly well-motivated are Goldstone bosons created by the spontaneous breaking of additional global symmetries.

Goldstone bosons are either massless (if the broken symmetry was exact) or naturally light (if it was approximate). Examples of light pseudo-Nambu-Goldstone bosons (pNGBs) are axions [6–8], familons [9–11], and majorons [12,13], associated with spontaneously broken Peccei-Quinn, family, and lepton-number symmetry, respectively. Below the scale of the spontaneous symmetry breaking, the couplings of the Goldstone bosons φ to the SM degrees of freedom can be characterized through a set of effective interactions

\[ \frac{O_\phi O_{\text{SM}}}{\Lambda^2}, \]

(1)

where \( \Lambda \) is related to the symmetry breaking scale. Axion, familon, and majoron models are characterized by different couplings in Eq. (1). These couplings are constrained by laboratory experiments [5,14], by astrophysics [15,16], and by cosmology [17,18]. While laboratory constraints have the advantage of being direct measurements, their main drawback is that they are usually rather model specific and sensitive only to narrow windows of pNGB masses. Astrophysical and cosmological constraints are complimentary since they are relatively insensitive to the detailed form of the couplings to the SM and span a wide range of masses. The main astrophysical constraints on new light particles come from the SM. In this Letter, we will show that cosmology is remarkably sensitive to extra light particles. This is because interactions like Eq. (1) can bring these particles into equilibrium with the SM particles. Moreover, thermal equilibrium is democratic. Any new light field that was in thermal equilibrium in the past will have a number density that is comparable to that of photons. This is why neutrinos have been detected with high significance in the CMB [1–3] despite their weak coupling. Like astrophysical constraints, cosmology therefore requires any new light particles to be more weakly coupled than neutrinos. Given the Moore’s law-like improvements in CMB detector sensitivity [19,20], cosmology will push the sensitivity to new light particles beyond the strength of weak scale interactions and has the potential to explore a fundamentally new territory of physics beyond the SM.

Preliminaries.—The total energy density in relativistic species is often defined as

\[ \rho_r = \left[ 1 + \frac{7}{8} \left( \frac{4}{11} \right)^{4/3} N_{\text{eff}} \right] \rho_\gamma, \]

(2)

where \( \rho_r \) is the energy density of photons and the parameter \( N_{\text{eff}} \) is called the effective number of neutrinos, although there may be contributions that have nothing to do with neutrinos (see, e.g., Ref. [21]). The SM predicts...
that the sensitivity to
sensitivity in future experiments.

Equation (1) holds up to
description of the pNGBs with interactions of the form of
axions arises independently of a possible cold population.

Note that these constraints make no assumption about the
nature of dark matter because the thermal population of
relics is below the would-be freeze-out temper-

Figure 1 shows the extra contribution to the radiation density of a
thermally decoupled Goldstone boson as a function of its
freeze-out temperature $T_F$. We see that particles that
decoupled after the QCD phase transition are effectively
ruled out by the observations of the Planck satellite\[17\].

On the other hand, the effect of particles that decoupled
before the QCD phase transition is suppressed by an order of
magnitude, $0.05 \geq \Delta N_{\text{eff}} \geq 0.027$. Although Planck is
blind to these particles, this regime is within reach of future
experiments. In particular, the planned CMB Stage IV
(CMB-S4) experiments have the potential to constrain (or
detect) extra relativistic species at the level of $\sigma(N_{\text{eff}}) \sim
0.01$ [3,19,20]. To simplify the narrative, we will assume
that the sensitivity to $\Delta N_{\text{eff}} = 0.027$ will be reached with
CMB-S4, either on its own or in conjunction with other
data [23,24]. Alternatively, our arguments could be viewed
as strong motivation for reaching this critical level of
sensitivity in future experiments.

Future CMB constraints.—Even the absence of a detection
would be very informative, because it would strongly constrain the couplings between the extra light relics and the SM degrees of freedom. This is because a thermal abundance can be avoided if the reheating temperature of the Universe, $T_R$, is below the would-be freeze-out temperature, i.e., $T_R < T_F$. In that case, the extra particles have never been in thermal equilibrium and their densities therefore do not have to be detectable. In the absence of a detection, requiring $T_F(\Lambda) > T_R$ would place very strong bounds on the scale(s) in Equation (1), i.e., $\Lambda > T_F^{-1}(T_R)$. We note that these constraints make no assumption about the nature of dark matter because the thermal population of axions arises independently of a possible cold population. On the other hand, we have to assume that the effective description of the pNGBs with interactions of the form of Equation (1) holds up to $T_F \ll \Lambda$. This is equivalent to assuming
\[ \Lambda_\pi > \left( \frac{\pi^2}{90} g_{\pi R} \right)^{-1/4} \sqrt{\gamma_{n R} T_R M_{\text{pl}}}, \]  

(6)

where \( \gamma_{n R} \equiv \gamma_n(T_R) \).

The operator that has been most actively investigated experimentally is the coupling to photons. Photons are easily produced in large numbers in both the laboratory and in many astrophysical settings which makes this coupling a particularly fruitful target for axion searches. The electroweak couplings in the high-energy theory prior to EWSB are related to the photon coupling \( \Lambda_\gamma \) through the Weinberg mixing angle. In [33], we show in detail how the constraints (6) on the couplings to the electroweak gauge bosons map into a constraint on the coupling to photons. This constraint is a function of the relative size of the couplings to the \( SU(2)_L \) and \( U(1)_Y \) sectors. To be conservative, we will here present the weakest constraint which arises when the axion only couples to the \( U(1)_Y \) gauge field. A specific axion model is likely to also couple to the \( SU(2)_L \) sector and the constraint on \( \Lambda_\gamma \) would then be stronger (as can be seen explicitly in [33]). Using \( \gamma_{\gamma R} \approx \sigma_{\gamma}(10^{10} \text{ GeV}) = 0.029 \) and \( g_{\pi R} = 106.75 + 1 \), we find

\[ \Lambda_\gamma > 1.4 \times 10^{13} \text{ GeV} \sqrt{T_{R,10}}. \]  

(7)

where \( T_{R,10} \equiv T_R/10^{10} \text{ GeV} \). For a reheating temperature of about \( 10^{10} \text{ GeV} \), the bound in (7) is three orders of magnitude stronger than the best current constraints (cf. Fig. 2). Even for a reheating temperature as low as \( 10^4 \text{ GeV} \) the bound from the CMB would still marginally improve over existing constraints.

Massive axions are unstable to decay mediated by the operator \( \phi F \tilde{F} \). However, for couplings compatible with the stellar cooling constraint, \( \Lambda_\gamma > 1.3 \times 10^{10} \text{ GeV} \) [35], and masses \( m_\alpha \lesssim 10 \text{ keV} \), these decays occur after recombination and, hence, the axions are effectively stable [33]. The regime \( 10 \text{ keV} < m_\alpha < 1 \text{ MeV} \) (where the axion decays between neutrino decoupling and recombination) is constrained by effects on the CMB and on big bang nucleosynthesis (BBN) [36–38].

The coupling to gluons is especially interesting for the QCD axion since it has to be in present order to solve the strong CP problem. The axion production rate associated with the gluon interaction in Eq. (3) is

\[ \Gamma_\gamma = \frac{417T^3}{\Lambda_\gamma^2} \]  

[28]. As before, we have dropped a weakly temperature-dependent prefactor, but account for it in Ref. [33]. The bound (6) then implies

\[ \Lambda_\gamma > 5.4 \times 10^{13} \text{ GeV} \sqrt{T_{R,10}}. \]  

(8)

Laboratory constraints on the axion-gluon coupling are usually phrased in terms of the induced electric dipole moment (EDM) of nucleons: \( d_n = g_d q_0 \), where \( q_0 \) is the value of the local axion field. The coupling \( g_d \) is given for the QCD axion by

\[ g_d \approx \frac{2\pi}{\alpha_s} \frac{3.8 \times 10^{-3} \text{ GeV}^{-1}}{\Lambda_\gamma}. \]  

(9)

Constraints on \( g_d \) (and hence \( \Lambda_\phi \)) are shown in Fig. 3. We see that future CMB-S4 observations will improve over existing constraints on \( \Lambda_\gamma \) by up to six orders of magnitude if \( T_R = O(10^{10} \text{ GeV}) \). Even if the reheating temperature is as low as \( 10^4 \text{ GeV} \), the future CMB constraints will be tighter by three orders of magnitude.

Constraints on familons.—Spontaneously broken global symmetries have also been invoked to explain the approximate \( U(3)^5 \) flavor symmetry of the Standard Model. The associated pNGBs—called familons [9–11]—couple to the SM through Yukawa couplings,

\[ L_{\phi \psi} = \frac{\partial_\mu \psi}{\Lambda_\phi} \gamma^\mu (g_{ij} + g_{ij}^I \gamma^5) \psi_j \]

\[ + \frac{\phi}{\Lambda_\phi} \left( iH_\psi L^{(i)} \left( \sum_{x=V,A} \left( \lambda_i \mp \lambda_j \right) g_{ij}^x \psi_{R,j} + \text{H.c.} \right) \right), \]

(10)

where \( H \) is the Higgs doublet and \( \psi_{L,R} = \frac{1}{2} (1 \mp \gamma^5) \psi \). The \( SU(2)_L \) and \( SU(3)_c \) structures in Eq. (10) take the same form as for the SM Yukawa couplings [43], but this has been left implicit to avoid clutter. In the second line we have integrated by parts and used the equations of motion. The subscripts \( V \) and \( A \) denote the couplings to the vector and axial-vector currents, respectively, and \( \lambda_i \equiv \sqrt{2}m_i/v \) are the Yukawa couplings, with \( v = 246 \text{ GeV} \) being the Higgs vacuum expectation value. We note that the diagonal couplings, \( i = j \), are only to the axial part, as expected from vector current conservation. In Table I, we have collected accelerator and astrophysics constraints on the effective couplings \( \Lambda_{ij} \equiv \Lambda_{\phi \psi} g_{ij}^V \) and \( \Lambda_{ij} \equiv \Lambda_{\phi \psi} / [(g_{ij}^V)^2 + (g_{ij}^A)^2]^{1/2} \). We see that current data typically constrain the couplings to the first generation fermions much more than those to the
The total production rate is \[ \frac{33}{33} \] bounds, in contrast, do not depend on \[ \Lambda \] second and third generations. We wish to compare these processes:

\[ \Delta \] the following processes:

\[ \Delta \] in contributions associated with the different couplings, and assume weaker than that of the Hubble expansion rate, leading to a recoupling (i.e., freeze-in) of the pNGBs at low temperatures. To avoid a large density of pNGBs requires that the freeze-in temperature \[ T_f \] is smaller than the mass of the fermions participating in the interactions, \[ T_f < m_\psi \], so that the interaction rate becomes Boltzmann suppressed before freeze-in can occur. Again, this constraint can be expressed as a bound on the scales that couple the pNGBs to the SM fermions.

For the diagonal couplings in Eq. (10), the production rate is dominated by a Compton-like process, \[ \{ \gamma, g \} \rightarrow \psi_i \rightarrow \psi_i + \phi \], and by fermion-antifermion annihilation, \[ \psi_i + \psi_j \rightarrow \{ \gamma, g \} + \phi \], where \[ \{ \gamma, g \} \] is either a photon or gluon depending on whether the fermion is a lepton or quark. Since freeze-in occurs at low temperatures, the quark production becomes sensitive to strong coupling effects. We therefore only present bounds for the lepton couplings. Above the lepton mass, the production rate is \[ \Gamma_{ii} = \frac{35a}{44} \bar{\epsilon}_{ii}^2 / (8\pi)T \], where \[ \bar{\epsilon}_{ii} = 2m_i / \Lambda_{ii} \]. Deriving the freeze-in temperature and imposing \[ T_f < m_\psi \], we find

\[ \Lambda_{ii} > \frac{9.5 \times 10^7}{\left( \frac{g_{\nu,\psi}}{g_{\nu,\psi}} \right)^{1/4} \left( \frac{\alpha_i}{\alpha_i} \right)^{1/2}} \text{GeV}, \]

where \[ N_\psi = 1 \] for charged leptons and \[ N_\psi = 3 \] for quarks. The “−” and “+” signs apply to \( I = V \) and \( I = A \), respectively. Deriving the freeze-out temperature and imposing \[ T_F > T_R \], we find

\[ \Lambda_{ij} > \frac{m_j}{m_i} \sqrt{T_{R,10}} \left( \frac{1}{10^{11}} \text{GeV}, \frac{1.8 \times 10^{13}}{\text{GeV}} \right), \]

where the first line applies to charged leptons with \( m_i \approx 1.8 \text{ GeV} \) and the second to quarks with \( m_i \approx 173 \text{ GeV} \).

We use Table I, we show how these bounds compare to current laboratory and astrophysics constraints for a fiducial reheating temperature of \( 10^{10} \text{ GeV} \). Except for the coupling to electrons, the constraints from future CMB experiments are orders of magnitude stronger than existing constraints. For lower reheating temperatures the constraints would weaken proportional to \( \sqrt{T_R} \). We note that, except for the top quark, laboratory and astrophysical constraints are considerably weaker for second and third generation particles because of kinematics, while the cosmological constraints are strengthened for the higher mass fermions due to the larger effective strength of the interactions.

Below the EWSB scale, the leading coupling of the familon to fermions becomes marginal after replacing the Higgs in Eq. (10) with its vacuum expectation value. The temperature dependence of the interaction rate is then weaker than that of the Hubble expansion rate, leading to a recoupling (i.e., freeze-in) of the pNGBs at low temperatures. To avoid a large density of pNGBs requires that the freeze-in temperature \( T_f \) is smaller than the mass of the fermions participating in the interactions, \( T_f < m_\psi \), so that the interaction rate becomes Boltzmann suppressed before freeze-in can occur. Again, this constraint can be expressed as a bound on the scales that couple the pNGBs to the SM fermions.

For the diagonal couplings in Eq. (10), the production rate is dominated by a Compton-like process, \[ \{ \gamma, g \} \rightarrow \psi_i \rightarrow \psi_i + \phi \], and by fermion-antifermion annihilation, \[ \psi_i + \psi_j \rightarrow \{ \gamma, g \} + \phi \], where \[ \{ \gamma, g \} \] is either a photon or gluon depending on whether the fermion is a lepton or quark. Since freeze-in occurs at low temperatures, the quark production becomes sensitive to strong coupling effects. We therefore only present bounds for the lepton couplings. Above the lepton mass, the production rate is \[ \Gamma_{ii} = \frac{5.3a}{44} \bar{\epsilon}_{ii}^2 / (8\pi)T \], where \[ \bar{\epsilon}_{ii} = 2m_i / \Lambda_{ii} \]. Deriving the freeze-in temperature and imposing \( T_f < m_\psi \), we find

\[ \Lambda_{ii} > \frac{9.5 \times 10^7}{\left( \frac{g_{\nu,\psi}}{g_{\nu,\psi}} \right)^{1/4} \left( \frac{\alpha_i}{\alpha_i} \right)^{1/2}} \text{GeV}, \]
the production rate associated with this process is $\tilde{\Gamma}_{ij} = 0.31N_{\nu}E_{ij}/(8\pi)m_{j}T^2$ [33], where $\tilde{E}_{ij} \approx m_{j}/\Lambda_{jj}$. Requiring the corresponding freeze-in temperature to be below the mass of the heavier fermion, $T_{\tilde{f}} < m_{i}$, we get

$$\Lambda_{jj} > \left(\frac{g_{s,z/z}}{g_{s,y}}\right)^{1/4} \left(\frac{m_{i}}{m_{y}}\right)^{1/2} \left\{ 1.3 \times 10^{8} \text{ GeV}, \quad 2.1 \times 10^{9} \text{ GeV} \right\} (14)$$

where the first line applies to charged leptons and the second to quarks. We see that this improves over existing constraints for the third generation leptons and for the second and third generation quarks (except the top).

**Conclusions.**—In closing, we would like to re-emphasize that $\Delta N_{\text{eff}} = 0.027$ is an important theoretical threshold (see Refs. [17,28,46,47] for related discussions). Remarkably, this is within reach of future cosmological observations [23], including the planned CMB-S4 mission [19]. These observations therefore have the potential to probe for light thermal relics up to arbitrarily high decoupling temperatures. We consider this to be a unique opportunity to detect new particles, or place very strong constraints on their couplings to the Standard Model.
