I. INTRODUCTION

Experiments show that neutrinos have much smaller masses than charged leptons (see Ref. [1] and references therein). While in the Standard Model (SM) the charged fermions acquire masses by coupling to the Higgs ($H$) boson, the neutrinos may become massive via new physics beyond the SM, e.g. via the introduction of Majorana mass fermionic fields with zero hypercharge in the adjoint representation of SU(2)$_L$. These masses could be small due to the seesaw mechanism [3,4], which relies on new massive states that couple to a charged lepton and the Higgs field. Among different models for the seesaw mechanism, the type-III model [2,5] introduces at least two extra triplets of fermionic fields with zero hypercharge in the adjoint representation of SU(2)$_L$ that generate neutrino masses and couple to gauge bosons. This model predicts new charged and neutral heavy leptons that could be produced in proton-proton collisions at the LHC.

A search by the CMS experiment [6] excluded the type-III seesaw heavy leptons with masses in the range of 100–210 GeV, depending on theoretical assumptions. A recent search by ATLAS [7] also sets complementary limits on heavy leptons using the three-lepton final state. Similar searches have also been done by the L3 experiment [8] ruling out charged heavy leptons with masses below 100 GeV.

In this paper, a search for heavy leptons predicted by the type-III seesaw mechanism is presented. The search explores the mass region above 100 GeV. A minimal type-III seesaw model [9] is used to optimize the analysis strategy and interpret the search results. The model introduces a triplet with one neutral and two oppositely charged leptons denoted by $N^0$ and $L^\pm$, respectively. The heavy leptons decay into a SM lepton and a $W$, $Z$, or Higgs boson. The heavy leptons are assumed to be degenerate in mass. This assumption does not affect the result because in the case of a small mass splitting due to radiative corrections, the decays within the heavy leptons are highly suppressed [10]. The dominant production mechanism for type-III seesaw heavy leptons in pp collisions is pair production through the weak coupling to the W boson propagator, $pp \rightarrow W^* \rightarrow N^0L^\pm$, and the largest branching fraction is the one with two $W$ bosons in the final state, $N^0 \rightarrow W^+L^-$, where $L^\pm \rightarrow W^\pm\nu$, $W^\pm \rightarrow \ell^\pm/\ell^\pm + \nu$, and $\ell^\pm \rightarrow e^\pm/\mu^\pm + \nu$. The production cross section does not depend on the mixing angles between the SM leptons and the new heavy lepton states $V_{a\ell}$, which enter only in the expressions for the $L$ and $N$ decay widths. The fraction of $L$ and $N$ decays to lepton flavor $\alpha$ is proportional to $b_\alpha = |V_{a\ell}|^2/\left(|V_{e\ell}|^2 + |V_{\mu\ell}|^2 + |V_{\tau\ell}|^2\right)$. The limits obtained may be interpreted in terms of a range of mixing angles and Yukawa couplings [9], allowing tests of a range of models with different couplings to gauge bosons and cross section predictions [11,12].

In the type-III seesaw model considered here, a benchmark point is defined by setting $V_\ell$ to zero, so that $b_e$ and $b_\mu$ are determined only by the ratio $V_e/V_\mu$, taken to be 0.87 based on the separately allowed maximum values of $V_e$ and $V_\mu$ in Refs. [13–15]. This choice results in values of $b_e=0.53$, $b_\mu=0.43$, and $b_\tau=0$. The search is performed for the process $pp \rightarrow N^0L^\pm \rightarrow W^\pm\ell^\mp W^\pm\nu$, where one $W$ boson decays leptonically and the other $W$ boson decays hadronically, resulting in a lepton pair in the final state with either the same charge [same sign (SS)] or with the opposite charge [opposite sign (OS)].

II. DATA SAMPLE AND MONTE CARLO SIMULATION

The analysis uses data from $\sqrt{s} = 8$ TeV pp collisions at the LHC that were recorded by the ATLAS detector.
samples are processed through the GEANT4-based detector simulation [33,34] or a fast simulation using a parametrization of the performance of the calorimeter and GEANT4 for the other parts of the detector [35]. The standard ATLAS reconstruction software is used for both simulated and collision data.

### III. OBJECT DEFINITIONS

The reconstructed objects used in this analysis are electrons, muons, jets, and missing transverse momentum. Electrons are reconstructed from clusters of energy depositions in the calorimeter that match a track reconstructed in the inner detector (ID) and satisfy the “tight” criteria defined in Ref. [36]. The electrons are required to have $p_T > 25$ GeV and pseudorapidity $|\eta| < 2.47$ [37], excluding the transition region between the barrel and end caps in the liquid argon calorimeter ($1.37 < |\eta| < 1.52$). Muons are reconstructed by combining ID and muon spectrometer tracks that are spatially matched and have consistent curvatures. The muon tracks are required to have $p_T > 25$ GeV and $|\eta| < 2.5$. In addition, leptons are required to be isolated from other tracks and calorimetric activity [38]. To ensure that leptons originate from the interaction point, requirements of $|d_0|/\sigma_{d_0} < 3$ and $|z_0\sin\theta| < 0.5$ mm are imposed on the electrons and muons, where $d_0$ ($z_0$) is the transverse (longitudinal) impact parameter of the lepton and $\sigma_{d_0}$ is the uncertainty on the measured $d_0$. The lepton impact parameters are measured with respect to the event primary vertex.

Jets are reconstructed from three-dimensional topological clusters of energy depositions in the calorimeter using the anti-$k_t$ algorithm [39] with a radius parameter of $R = 0.4$. The energies of jets are calibrated to the hadronic energy scale by correcting for energy losses in passive material, the noncompensating response of the calorimeter, and extra energy due to multiple $pp$ interactions [40]. The jets are required to have $p_T > 30$ GeV and $|\eta| < 2.8$. For jets with $p_T < 50$ GeV and $|\eta| < 2.4$, the summed scalar $p_T$ of associated tracks from the reconstructed primary vertex is required to be at least 25% of the summed scalar $p_T$ of all tracks associated with the jet. In the pseudorapidity range $|\eta| < 2.5$, jets containing $b$-hadrons are identified using a $b$-tagging algorithm [41] with an efficiency of 70% and with a misidentification rate for selecting light-quark or gluon jets of less than 1%. The identification efficiency of the algorithm for jets containing $c$-hadrons is 20%. The efficiencies and misidentification rates are determined from $t\bar{t}$ MC events.

The missing transverse momentum vector (with its magnitude $E_T^{\text{miss}}$) is derived using the calorimeter cell energies within $|\eta| < 4.9$ and corrected on the basis of dedicated calibrations of the associated physics objects including muons [42]. Calorimeter cells containing energy depositions above noise and not associated with high-$p_T$ physics objects are also included.
IV. EVENT SELECTION

Events that contain exactly two reconstructed leptons (electrons or muons), at least two jets, and no $b$-tagged jets are selected. One of these leptons is required to match the object upon which the event was triggered. Different sets of optimized selection criteria are used for the events in the OS and SS final states. The optimization is done using simulated heavy lepton pair-production events at a benchmark mass of 300 GeV. For the OS (SS) final state, the leading and next-to-leading lepton candidates are required to have $p_T$ greater than 100 (70) GeV and 25 (40) GeV, respectively. The invariant mass of the two lepton candidates is required to be larger than 130 (90) GeV in order to suppress background from the production of $Z + j$. The hadronically decaying $W$ candidate is formed by combining the two jets with highest $p_T$, and the $p_T$ of the first and second leading jets are, respectively, required to be larger than 60 (40) and 30 (25) GeV, for the OS (SS) final state. The invariant mass of the $W$ candidate, $m_{jj}$, is required to be between 60 and 100 GeV. Events selected in the OS (SS) final state are required to have a $E_T^{miss}$ of at least 110 (100) GeV and, for OS events, an angular separation $\Delta R_{jj} = \sqrt{\Delta \eta^2 + \Delta \phi^2} < 2$ between the two jets with highest $p_T$, where $\Delta \eta$ and $\Delta \phi$ are defined as the differences in pseudorapidity and azimuthal angle between the jets.

V. BACKGROUND ESTIMATE

The background in this search can be classified into two categories based on the origin of the charged lepton candidates. The first category of backgrounds consists of events in which two leptons are produced via the decays of $W$ or $Z$ bosons and are correctly reconstructed. This category of backgrounds includes the production of $Z + j$, $t\bar{t}$, $Wt$ single-top-quark and diboson events. Smaller contributions originate from $t\bar{t} + W/Z$ events. Contributions from triboson events, such as $WWW$ and events containing a Higgs boson, are negligible. The number of events from this background category is estimated using the simulated samples described previously.

The second category corresponds to all other sources, such as events containing at least one particle that is incorrectly identified as a lepton, or a lepton which originates from secondary interactions and decays, which are together denoted as "fakes," and events with a lepton whose charge is incorrectly determined. Fake electrons originate primarily from jets that have a large electromagnetic energy fraction passing the electron selection requirements, photon conversions, and electrons from semileptonic decays of charm or bottom hadrons. Fake muons include muons arising from semileptonic decays of charm or bottom hadrons, in-flight decays of pions or kaons, or energetic particles that reach the muon spectrometer.

For the OS final state, the background contribution is dominated by events from the first category. For the SS final state, the expected background is very small and is also primarily from the first category. Events from $Z + j$ production can mimic the SS signal if the charge of one of the electrons is incorrectly determined. The background events from this contribution are modeled by simulation, with correction factors derived using $Z \to ee$ events in data. The probability of misidentifying the muon charge is negligible.

The background contribution in the second category (i.e., fake leptons) is estimated using an in situ technique that relies minimally on simulation. This is done by reweighting a complementary set of events, selected by changing the electron identification criterion from tight to “loose” and by loosening the muon $|d_0|/\sigma_d$ and the electron and muon isolation requirements, while keeping the event selection otherwise identical. The reweighting factors are defined as the ratio of the number of events containing a lepton that satisfies the nominal criteria to the number of events containing a lepton that only fulfills the relaxed criteria. These factors are measured as a function of the candidate $p_T$ and $\eta$ in data samples that are enriched in fake leptons. Corrections to the factors due to true leptons from vector boson decay in the background-enriched samples are taken from MC simulation.

Figure 1 shows a comparison of the missing transverse momentum distribution of data, expected backgrounds, and signal predictions when all the selection requirements, except for the missing transverse momentum requirement, are applied. The shape and the rate of the background estimate is in good agreement with the data.

The background estimates are validated by comparing the predicted numbers of events in simulation to those observed in the data in several control regions that have event selection criteria similar to those for the signal region. The control region for top-quark pairs is defined by selecting events with two $b$-tagged jets. In this region, according to MC simulation, all the events are from top-quark pair and single-top-quark production with a negligible contribution from other sources. MC simulation predicts $26 \pm 3$ (stat.) events, and in the data 32 events are observed. The scale factor, the ratio of the observed and predicted event yields, is found to be consistent with unity.

The diboson control region is obtained using a $WZ$-enriched sample of events containing three leptons without a requirement on the missing transverse momentum. In this control region, according to MC simulation, all the events are from diboson production with a negligible contribution from other sources. MC simulation predicts $11 \pm 1$ events, and in the data nine events are observed. The scale factor is found to be consistent with unity.

VI. SYSTEMATIC UNCERTAINTIES

The uncertainties on the rate of top-quark and diboson backgrounds due to potential differences between the data and MC simulation are evaluated using the statistical
uncertainties of the measured scale factors in the control samples. They are the dominant systematic uncertainties (∼35%) on the background estimates. For top-quark production, an additional systematic uncertainty is considered to account for a potential difference between scale factors in the control region and the signal region. This is done by comparing the nominal \( t\bar{t} \) sample to alternative \( t\bar{t} \) MC samples. These samples include events that are generated using POWHEG-BOX 1.0 (patch 4) [44–46] and the leading-order, multileg generator ALPGEN v2.13 [47]. The POWHEG-BOX generator is interfaced to the Pythia 6.426 showering routines with either CT10 or HeraPDF [48] PDF sets and with the POWHEG \( P_{\text{damp}} \) parameter set to either the mass of the top quark or infinity [49]. ALPGEN is interfaced to HERWIG 6.520 and used to simulate top pair events with up to four additional partons in the matrix element. The uncertainties due to QCD ISR and FSR modeling are estimated with samples generated with ACERMC v3.8 interfaced to Pythia 6.426 in which the parton shower parameters are varied in a range consistent with a measurement of additional hadronic activity in \( t\bar{t} \) events [50]. The differences observed in the signal region by using different MC simulations are about 35%.

For the \( Z + n \)-jets (\( n \geq 2 \)) background estimate, the dominant systematic uncertainty in the OS final state is from the uncertainty on its production cross section (∼50%) [51]. For the SS final state, the systematic uncertainty is dominated by the statistical uncertainty on the measured electron charge misidentification rate.

Uncertainties on the background estimate due to fake leptons are determined in dedicated studies using a combination of simulation and data. They account for potential biases in the method used to extract the reweighting factors and for the dependency of the reweighting factors on the event topology.

For both the predicted signal and background event yields, uncertainties resulting from detector effects from jet energy scale and resolution [40], lepton reconstruction and identification efficiencies [36,52], lepton momentum scales and resolutions [52,53], and missing transverse momentum [42] are considered. They are typically small (1%–5%). The theoretical uncertainties on the signal production cross section and acceptance, such as PDF choice and ISR and FSR modeling, are found to be negligible.

The background estimates and their uncertainties are tested in two other regions: a \( Z + \text{jets} \) control region and a \( Z + n \)-jets control region.

| TABLE I. Event yields for opposite-sign (OS) and same-sign (SS) selection for predicted backgrounds, data, and type-III seesaw lepton pair production with masses of 150 and 300 GeV. The reported errors include both the statistical and systematic uncertainties. |
|---|---|---|---|
| | OS | SS |
| Fake leptons | 1.4 ± 0.9 | 0.67 ± 0.42 |
| \( Z + \text{jets} \) | 2.4 ± 1.2 | 0.06 ± 0.23 |
| WW/\( WZ/ZZ \) | 9.2 ± 2.9 | 1.95 ± 0.58 |
| \( t\bar{t} (W/Z) \) and single top | 17.9 ± 6.9 | 0.47 ± 0.25 |
| Total | 31.0 ± 7.7 | 3.15 ± 0.80 |
| Data | 25 | |
| Signal \( m_{L/N} = 150 \) GeV | 9.5 ± 1.6 | 20.3 ± 2.3 |

SEARCH FOR TYPE-III SEESAW HEAVY LEPTONS IN ...

PHYSICAL REVIEW D 92, 032001 (2015)

FIG. 2 (color online). Event yields for opposite-sign (OS) and same-sign (SS) selection for $ee$, $\mu\mu$, and $e\mu$ predicted backgrounds, data, and signal events featuring type-III seesaw lepton pair production with masses 150 and 300 GeV. The reported uncertainties include both the statistical and systematic uncertainties.

the hadronic $W$ sidebands. The $Z +$ jets control region is selected by requiring the invariant mass of the oppositely charged lepton pair to be consistent with the $Z$ boson mass. In this region, approximately 70% of the events are from a $Z$ boson produced in association with jets. The predicted number of events is $34 \pm 4$, where the error includes both the statistical and systematic uncertainties, and 32 events are observed in the data. For the hadronic $W$ sidebands, the analysis was repeated using the same event selection but requiring the invariant mass of the hadronically decaying $W$ candidate to be $35 < m_{jj} < 60$ GeV or $100 < m_{jj} < 125$ GeV. This selection provides samples dominated by background events with kinematic properties similar to those of the signal candidates. In this region the predicted number of events is $34 \pm 7$ events, where the error includes both the statistical and systematic uncertainties, and in the data 18 events are observed. The data are in agreement with the predictions within 1.9 standard deviations.

VII. RESULTS AND INTERPRETATION

Table I shows the predicted numbers of signal and background events and the observed data events in the signal region. The data agree with the background-only hypothesis. Figure 2 shows the flavor composition of the simulated signal and background events and of the observed events in data. In the absence of any significant data excess, upper limits on the production rate of $pp \to N^0L^\pm \to W^\pm \ell^\mp W^\pm \nu$ at the 95% confidence level (C.L.) are derived as a function of the heavy lepton mass using the CLs method [54]. The results of limit calculations combining the observations in the OS and SS final states are shown in Figs. 3 and 4. With the default mixing angles considered here, heavy leptons with masses less than 335 GeV are excluded by the analysis, while masses less than 475 GeV are excluded in the scenario in which heavy leptons can only decay to the $W\ell$ or $W\nu$ final states. For comparison, upper limits are also calculated for different theoretical assumptions, such as exclusive coupling between the heavy leptons and muons ($b_e = 0, b_\mu = 1$) or electrons ($b_e = 1, b_\mu = 0$). In the limit calculations for exclusive couplings, events in the two-muon (two-electron) final state

FIG. 3 (color online). Left: Observed (solid line) and expected (dashed line) 95% C.L. upper limits on the type-III seesaw heavy lepton cross section as a function of the heavy lepton $L$ or $N$ mass assuming $b_e = 0.43$, $b_\mu = 0.57$, and $b_{\tau} = 0$. The bands surrounding the expected limit correspond to one and two standard deviations on the expected limit. The large-dashed (dot-dashed) line shows the theoretical prediction for $m_{L/N}$-dependent (maximal) branching fraction for decays to a $W$ boson. Right: The expected (large-dashed line) and observed (shaded region) upper limits at the 95% C.L. on the $\text{BR}(L^\pm \to W\ell) \times \text{BR}(N^0 \to W^\pm \ell^\mp)$ vs $m_{L/N}$. The dashed line corresponds to one standard deviation around the expected limit. The dotted line shows the nominal mass-dependent branching ratio of the type-III seesaw model.
A search for the pair production of heavy leptons predicted by the type-III seesaw model is presented. The analysis is performed using a final state that contains two leptons, two jets from a hadronically decaying W boson, and a large missing transverse momentum. The data used in the search correspond to an integrated luminosity of 20.3 fb$^{-1}$ of $pp$ collisions at $\sqrt{s} = 8$ TeV collected by the ATLAS detector at the LHC. No evidence of heavy lepton production is observed. Heavy leptons with masses below 325–540 GeV are excluded at the 95% confidence level, depending on the considered theoretical scenarios.

VIII. CONCLUSIONS

A search for the pair production of heavy leptons predicted by the type-III seesaw model is presented. The analysis is performed using a final state that contains two leptons, two jets from a hadronically decaying W boson, and a large missing transverse momentum. The data used in the search correspond to an integrated luminosity of 20.3 fb$^{-1}$ of $pp$ collisions at $\sqrt{s} = 8$ TeV collected by the ATLAS detector at the LHC. No evidence of heavy lepton production is observed. Heavy leptons with masses below 325–540 GeV are excluded at the 95% confidence level, depending on the considered theoretical scenarios.

ACKNOWLEDGMENTS

We thank CERN for the very successful operation of the LHC, as well as the support staff from our institutions without whom ATLAS could not be operated efficiently. We acknowledge the support of ANPCyT, Argentina; YerPhI, Armenia; ARC, Australia; BMWFW and FWF, Austria; ANAS, Azerbaijan; SSTC, Belarus; CNPq and FAPESP, Brazil; NSERC, NRC, and CFI, Canada; CERN; CONICYT, Chile; CAS, MOST, and NSFC, China; COLCIENCIAS, Colombia; MSMT CR, MPO CR, and VSC CR, Czech Republic; DNRF, DNSRC, and Lundbeck Foundation, Denmark; EPLANET, ERC, and NSRF, European Union; IN2P3-CNRS and CEA-DSM/IRFU, France; GNSF, Georgia; BMBF, DFG, HGF, MPG, and AvH Foundation, Germany; GSRT and NSRF, Greece; RGC, Hong Kong SAR, China; ISF, MINERVA, GIF, I-CORE, and Benoziyo Center, Israel; ININF, Italy; MEXT and JSPS, Japan; CNRST, Morocco; FOM and NWO, Netherlands; BRF and RCN, Norway; MNiSW and NCN, Poland; GRICES and FCT, Portugal; MNE/IFA, Romania; MES of Russia and NRC KI, Russian Federation; JINR; MSTD, Serbia; MSSR, Slovakia; ARRS and MIZŠ, Slovenia; DST/NRF, South Africa; MINECO, Spain; SRC and Wallenberg Foundation, Sweden; SER, SNSF, and Cantons of Bern and Geneva, Switzerland; NSC, Taiwan; TAEK, Turkey; STFC, the Royal Society, and Leverhulme Trust, United Kingdom; DOE and NSF, United States of America. The crucial computing support from all WLCG partners is acknowledged gratefully, in particular from CERN and the ATLAS Tier-1 facilities at TRIUMF (Canada), NDGF (Denmark, Norway, and Sweden), CC-IN2P3 (France), KIT/GridKA (Germany), INFN-CNAF (Italy), NL-T1 (Netherlands), PIC (Spain), ASGC (Taiwan), RAL (U.K.) and BNL (USA) and in the Tier-2 facilities worldwide.

SEARCH FOR TYPE-III SEESAW HEAVY LEPTONS IN ...

[26] Production mechanisms involving weak interactions at the Born level (of order $\alpha_{EW}^2$ without considering the boson decay, where $\alpha_{EW}$ is the electroweak coupling constant) are referred to as electroweak production [55]. Production mechanisms involving both the strong and electroweak interactions at Born level (of order $\alpha_s^2\alpha_{EW}^2$, where $\alpha_s$ is the strong coupling constant) are referred to as strong production.

ATLAS uses a right-handed coordinate system with its origin at the nominal interaction point (IP) in the center of the detector and the z axis along the beam pipe. The x axis points from the IP to the center of the LHC ring, and the y axis points upward. Cylindrical coordinates $(r, \phi)$ are used in the transverse plane, $\phi$ being the azimuthal angle around the beam pipe. The pseudorapidity is defined in terms of the polar angle $\theta$ as $\eta = -\ln(\tan(\theta/2))$. ATLAS Collaboration, arXiv:1411.2921.
