Z boson production in $p + \text{Pb}$ collisions at $\sqrt{s_{\text{NN}}} = 5.02$ TeV measured with the ATLAS detector

G. Aad et al.*

(ATLAS Collaboration)

(Received 23 July 2015; revised manuscript received 23 September 2015; published 30 October 2015)

The ATLAS Collaboration measures the inclusive production of $Z$ bosons via their decays into electron and muon pairs in $p + \text{Pb}$ collisions at $\sqrt{s_{\text{NN}}} = 5.02$ TeV at the Large Hadron Collider. The measurements are made using data corresponding to integrated luminosities of 29.4 and 28.1 nb$^{-1}$ for $Z \rightarrow ee$ and $Z \rightarrow \mu\mu$, respectively. The results from the two channels are consistent and combined to obtain a cross section times the $Z \rightarrow \ell\ell$ branching ratio, integrated over the rapidity region $|y^Z| < 3.5$, of 139.8 ± 4.8 (statistical) ± 6.2 (systematic) ± 3.8 (luminosity) nb. Differential cross sections are presented as functions of the $Z$ boson rapidity and transverse momentum and compared with models based on parton distributions both with and without nuclear corrections. The centrality dependence of $Z$ boson production in $p + \text{Pb}$ collisions is measured and analyzed within the framework of a standard Glauber model and the model’s extension for fluctuations of the underlying nucleon-nucleon scattering cross section.

I. INTRODUCTION

The study of electroweak bosons in $p + \text{Pb}$ collisions at the Large Hadron Collider (LHC) at CERN has demonstrated that the production rate of non–strongly interacting particles scales with the number of nucleon-nucleon collisions, $N_{\text{coll}}$. This has been observed for photons [1], W bosons [2,3], and Z bosons [4,5]. The momentum and rapidity distributions of $Z$ boson yields are consistent with PYTHIA [6] simulations of $pp$ collisions multiplied by the average nuclear thickness function, $\langle T_{\text{AA}} \rangle$, which is equivalent to $\langle N_{\text{coll}} \rangle$ divided by the total nucleon-nucleon cross section [4]. $Z$ boson production in $p + \text{Pb}$ collisions was found to be consistent with next-to-leading-order perturbative quantum chromodynamics (NLO QCD) calculations that disregard nuclear modifications in the treatment of parton distribution functions (PDFs). However, nuclear modification is not excluded within the precision of the measurement [7]. The production of $Z$ bosons, examined as a function of centrality, was also found to scale with $\langle N_{\text{coll}} \rangle$.

To differentiate between initial- and final-state effects in heavy-ion collisions, the study of $p + \text{Pb}$ collisions is used at the LHC. One would expect that hot and dense QCD medium cannot be formed in such collisions, unlike in the $p + \text{Pb}$ case, and that modifications to final-state particles relative to nucleon-nucleon collisions should originate from the initial state of the nucleus. This assumption was challenged by the very first results from $p + \text{Pb}$ collisions at $\sqrt{s_{\text{NN}}} = 5.02$ TeV produced at the LHC in 2012. Results on multiparticle correlations, published for three LHC experiments [8–14], revealed collective behavior in $p + \text{Pb}$ collisions similar to that previously measured in heavy-ion collision systems. The yields of jets measured by ATLAS scale with $\langle N_{\text{coll}} \rangle$ when measured inclusively for all centralities but show significant deviations from binary scaling when considered in centrality selections [15]. The CMS Collaboration has measured dijet pseudorapidity distributions and found them to agree better with predictions that include nuclear PDF modifications than with predictions that do not include nuclear effects [16]. The CMS Collaboration has also recently measured the production of W bosons in $p + \text{Pb}$ collisions and observed hints of nuclear modifications of the PDF [17]. Collectively, these results have highlighted the need for a better understanding of the initial conditions of $p + \text{Pb}$ collisions.

Unlike symmetric $p + \text{Pb}$ collisions, in $p + \text{Pb}$ collisions nuclear modifications of the PDFs in the lead nucleus create an asymmetry in the rapidity-dependent cross section of $Z$ bosons; this presents an attractive observable for the study of initial-state nuclear conditions. The centrality-dependent yield of $Z$ bosons is a well-suited probe to test our understanding of $p + \text{Pb}$ collision geometry. The LHCb Collaboration has made a first exploratory measurement of $Z$ bosons at far forward and backward rapidities [18] based on an integrated luminosity of 1.6 nb$^{-1}$.

This paper presents the results of the measurement of $Z$ boson production in $p + \text{Pb}$ collisions at $\sqrt{s_{\text{NN}}} = 5.02$ TeV using the ATLAS detector. The yield of $Z$ bosons is measured as a function of their transverse momentum $p_T^Z$, rapidity in the center-of-mass frame ($y^Z$), and centrality. The leptonic decay

decays of the Z boson ($Z \rightarrow e e$ and $Z \rightarrow \mu \mu$) are used for its reconstruction. In the muon channel it is possible to reconstruct the Z boson in the rapidity range $-3 < \eta < 2$, while in the electron channel this range can be extended to $|\eta| < 3.5$. The larger acceptance in rapidity for $Z \rightarrow ee$ candidates is possible because of the larger acceptance of the ATLAS calorimeters compared to the muon spectrometer (MS, Secs. II and III B). The efficiency of Z boson reconstruction is calculated from detector simulations (Sec. III D). Backgrounds in each channel are estimated using simulations and data-driven methods (Sec. III E). Results measured in the dimuon and dielectron decay channels are combined after accounting for uncertainties and their correlations (Sec. III G). The measured cross sections and centrality-dependent yields are compared to models of proton-proton collisions (Secs. II and III B). The MS comprises separate trigger and high-precision tracking chambers that measure the deflection of muons in a magnetic field generated by superconducting air-core toroids. The ATLAS detector [19] at the LHC covers nearly the entire solid angle around the collision point. It consists of an inner tracking detector surrounded by a thin superconducting solenoid, electromagnetic and hadronic calorimeters, and an MS.

The inner detector (ID) system is immersed in a 2-T axial magnetic field and provides charged particle tracking in the pseudorapidity range $|\eta| < 2.5$. It comprises a high-granularity silicon pixel detector covering the collision region, surrounded by a silicon microstrip tracker and a transition radiation tracker.

The calorimeters cover the range $|\eta| < 4.9$. Within the region $|\eta| < 3.2$, electromagnetic calorimetry is provided by barrel and endcap high-granularity lead liquid-argon (LAr) calorimeters, with an additional thin LAr presampler covering $|\eta| < 1.8$. Behind the electromagnetic calorimeter there is a steel/scintillator sampling hadronic calorimeter covering $|\eta| < 1.7$, and LAr hadronic calorimeters extend the coverage to $|\eta| < 4.9$. Forward electromagnetic calorimeters (FCals) are located in the range $3.1 < |\eta| < 4.9$. Electrons may be reconstructed over the entire electromagnetic calorimeter system, $|\eta| < 4.9$.

The MS comprises separate trigger and high-precision tracking chambers that measure the deflection of muons in a magnetic field generated by superconducting air-core toroids. The precision chambers cover the region $|\eta| < 0.5$, with three layers of monitored drift tube chambers, complemented by cathode strip chambers in the innermost layer of the forward region. The muon trigger system covers the range $|\eta| < 2.4$, with resistive plate chambers in the barrel ($|\eta| < 1.05$) and thin gap chambers in the endcap regions ($1.05 < |\eta| < 2.4$).

The ATLAS detector has a three-level trigger system [20]: the hardware-based level 1 (L1) trigger and the software-based high-level trigger, which is subdivided into the level 2 (L2) trigger and the event filter. Single-electron and single-muon triggers are used to acquire the data analyzed in this paper. Minimum-bias events are selected based on signals in the minimum-bias trigger scintillators (MBTS) that detect charged particles in the range $2.1 < |\eta| < 3.9$.

## II. THE ATLAS DETECTOR

Electron candidates are first identified by the L1 trigger as a cluster of cells in the electromagnetic calorimeter, formed into $(\Delta \phi \times \Delta \eta) = 0.1 \times 0.1$ trigger towers, within the range $|\eta| < 2.5$ and with the cluster transverse energy exceeding 5 GeV. The high-level trigger then incorporates tracking information from the ID and imposes electron identification requirements on the electron candidates. A trigger for at least one electron candidate with $E_T > 15$ GeV and satisfying loose identification requirements is used to select events.

In the off-line analysis, electron candidates within $|\eta| < 4.9$ are selected using the ATLAS reconstruction algorithm [23]. Electrons with $|\eta| < 2.47$, referred to as midrapidity electrons, require the matching of a track to an energy cluster in the electromagnetic calorimeter. In addition to the reconstruction requirements, further electron identification selections based primarily on the shower shape in the electromagnetic calorimeter are made to reject background. Electron identification requirements used in previous ATLAS analyses [23] are used to provide quality classification of electrons based on the tightness of the identification criteria they satisfy. The triggering electron is required to have $E_T > 20$ GeV, to be outside the pseudorapidity interval $1.37 < |\eta| < 1.52$ (a transition region between the barrel and the endcap calorimeters which contains a relatively large amount of inactive material), and to satisfy tight identification quality requirements. If the other electron is within $|\eta| < 2.47$, it must have $E_T > 10$ GeV and satisfy looser quality requirements. Forward electrons are those reconstructed within the range $2.5 < |\eta| < 4.9$ based on energy deposited in the FCal [23]. There is no tracking...
in this region, so the electron candidate reconstruction and identification are derived solely from the calorimeter signal and do not have an associated charge. Forward electrons are required to have $E_T > 20$ GeV. Of $Z \rightarrow ee$ decays with $|y^Z| < 3.5$, approximately 82% fall into the fiducial acceptance defined by the electron $p_T$ and $\eta$ requirements.

Muon candidates are first identified at the L1 trigger, based on hits in either the resistive plate chamber or the thin gap chamber. The high-level trigger then reconstructs muon tracks in the vicinity of the detector region reported by the L1 trigger. The L2 trigger uses an algorithm to perform a fast reconstruction of muons, which is then refined in the event filter by incorporating the hits in the ID tracking as well as those in the MS tracking. Events containing at least one muon with $p_T$ greater than 8 GeV are accepted by the high-level trigger.

For the $Z \rightarrow \mu\mu$ analysis, muons are identified from candidates reconstructed in both the MS and the ID [24]. Muons are reconstructed separately in the MS and ID and a $x^2$-minimization procedure is used to obtain combined muon kinematic information. To reduce background from jets, each muon is required to pass a loose track-based isolation selection. Tracks are considered in a cone of size $\Delta R = \sqrt{(\Delta \eta)^2 + (\Delta \phi)^2} = 0.3$ around the direction of the muon. The muon is considered isolated if the scalar sum of the $p_T$ of these tracks, excluding the muon, is less than 50% of the muon $p_T$. The efficiency of this selection is greater than 99%. The triggering muon is required to have $p_T > 20$ GeV and be within $|\eta| < 2.4$. The second muon must be within $|\eta| < 2.47$ and have $p_T > 10$ GeV. Approximately 68% of $Z$ bosons with $-3 < y^Z < 2$ fall into the fiducial acceptance defined by the muon kinematic requirements.

**C. Centrality**

In addition to measuring the $Z$ boson cross section, the $Z$ boson yield per minimum-bias event is measured for different centrality selections. In order to characterize the $p + Pb$ collision geometry, each event is assigned a centrality based on the total transverse energy measured in the FCal on the Pb-going side ($-4.9 < \eta < -3.2$), $\Sigma E_T^{FCal}$ [22]. Collisions with more (fewer) participating nucleons are referred to as central (peripheral). As in Ref. [22], the standard Glauber model [25] approach is used to calculate the mean number of participating nucleons, $\langle N_{part} \rangle$. The mean number of inelastic nucleon-nucleon collisions, $\langle N_{coll} \rangle$, is $\langle N_{part} \rangle - 1$. Based on the observed centrality dependence of the charged particle multiplicity [22], a Glauber-Gribov color fluctuation (GGCF) model [26,27], an extension to the Glauber model which allows event-by-event fluctuations of the nucleon-nucleon cross section $\sigma(N + N \rightarrow X)$, is also considered. In this model the magnitude of the fluctuations is characterized by the parameter $\omega_{s}$, with $\omega_{s} = 0$ corresponding to the standard Glauber model. Following Ref. [22], two values of $\omega_{s}$, 0.11 and 0.2, based on the calculations in Refs. [26,27], are implemented and considered for this analysis.

Following Ref. [22], the centrality selections used for this analysis, in order from most central to most peripheral, are 0–5%, 5–10%, 10–20%, 20–30%, 30–40%, 40–60%, and 60–90%. For the study of the $y^Z$ distribution as a function of centrality (see Sec. IV B), larger bins are used: 0–10%, 10–40%, and 40–90%. For the most peripheral collisions, centrality greater than 90%, centrality modeling, and associated geometric quantities are not well constrained. Pileup events, those containing multiple $p + Pb$ interactions from the same bunch crossing, are removed by rejecting events in which more than one primary vertex is reconstructed. The fraction of candidate events which is removed from the centrality-selected $Z$ boson yield analysis due to pileup rejection is approximately 5%. Diffractive events are identified by a rapidity gap (defined by the absence of calorimeter energy clusters) of greater than two units on the Pb-going side of the detector and excluded. This leads to a rejection of less than 0.1% of $Z$ boson candidate events. The total number of minimum-bias events corresponding to the luminosity sampled by the trigger, $N_{evt}$, is used to define the $Z$ boson yield per event in each centrality selection.

Besides its sensitivity to the event geometry, the $\Sigma E_T^{FCal}$ for a fixed geometry may also be affected by the presence of a hard scattering process in the event. In particular, the calculation of centrality for $Z \rightarrow ee$ events in which there is a forward electron in the Pb-going-side FCal is biased by the energy of the electron. This is corrected by subtracting the transverse energy of the electron from $\Sigma E_T^{FCal}$. The subtraction procedure is found to effectively recover the correct centrality of minimum-bias events into which simulated $Z \rightarrow ee$ decays containing electrons in the Pb-going-side FCal were overlaid.

In addition to the case where there is a $Z$-decay electron in the Pb-going-side FCal, $\Sigma E_T^{FCal}$ may be more subtly biased in all $Z$ boson events. The presence of a $Z$ boson (or any hard process) is correlated with a higher transverse energy of the underlying event. Consequently, more energy may be deposited in the Pb-going-side FCal in events containing a hard scattering process than in those that do not contain one. This causes a bias in the centrality-dependent yield, as the $Z$ boson yield is enhanced in the more central events but depleted in the more peripheral ones. This effect, referred to as a centrality bias, has been noted for yields of hard processes in $d + Au$ collisions at $\sqrt{s_{NN}} = 200$ GeV by the PHENIX Collaboration [28] and in $p + Pb$ collisions at $\sqrt{s_{NN}} = 5.02$ TeV by the ALICE Collaboration [29].

A correction to the centrality-dependent yields of hard processes in $d + Au$ collisions at $\sqrt{s_{NN}} = 200$ GeV has been studied by the PHENIX Collaboration [28] (the correction is also calculated for $p + Pb$ at $\sqrt{s_{NN}} = 5.02$ TeV). The centrality-bias correction used by the PHENIX Collaboration is based on the modeling of an increase in the mean particle multiplicity produced by the specific $NN$ collision that undergoes a hard scattering. Recently, similar calculations of a centrality bias have been made in which all $NN$ collisions may contribute to an increase in the particle multiplicity [30]. The increase in multiplicity stemming from each $NN$ collision is taken to be proportional to the contribution from that collision to the $E_T$ in the event. This model is applied to the ATLAS $p + Pb$ centrality classification for the standard Glauber analysis as well as the GGCF models and, thus, used to calculate corrections to the hard process yield measured in a given centrality bin. Because the $N_{part}$ probability distribution varies

044915-3
Yields are applied as multiplicative factors to the centrality-dependent configurations, and bias correction factors derived from data (points) as explained in the text. The reciprocals of the correction factors are applied as multiplicative factors to the centrality-dependent Z boson yields.

less steeply in the GGCF models than in the standard Glauber model, the centrality bias corrections are closer to unity for the GGCF cases. The corrections from Ref. [30] are shown in Fig. 1. The reciprocals of the corrections are applied as multiplicative factors to the centrality-dependent Z boson yields measured in the present analysis.

Using Z bosons measured in ATLAS, data-driven centrality bias corrections may be calculated and compared with the results in Ref. [30]. To do so, the corrections are calculated by comparing the transverse energy deposited in the FCal in events selected by the minimum-bias trigger and in Z boson events from pp collisions (in which there is no centrality to consider). This effect is studied in pp collisions at \( \sqrt{s} = 2.76 \) TeV and \( \sqrt{s} = 7 \) TeV from the 2011 LHC run. At both energies a significant increase in the mean transverse energy deposited in the FCal is observed and, within the uncertainties of the measurement, found to be independent of the Z boson kinematics. A single value is interpolated from the \( \sqrt{s} = 2.76 \) TeV and \( \sqrt{s} = 7 \) TeV data for \( \sqrt{s_{NN}} = 5.02 \) TeV. The interpolation is performed using both logarithmic and linear expressions, and the difference between them contributes to the systematic uncertainty. A correction is made to account for the shifted center of mass in the \( p + Pb \) system, which changes the effective FCal acceptance in \( \eta \) compared to pp. From this procedure an additive shift to \( \Sigma E_T^{FCal} \) of 2.0 ± 0.5 GeV is calculated. In each \( p + Pb \) \( Z \to \ell \ell \) event this value is subtracted from \( \Sigma E_T^{FCal} \) and the resulting value used to determine a corrected centrality of the event. The centrality-dependent yield may be constructed, according to the method described in Sec. IIIE, using both the subtracted and the unsubtracted \( \Sigma E_T^{FCal} \) values and their ratio is then comparable to a centrality bias correction factor that may be compared to those calculated in Ref. [30]. As shown in Fig. 1, within the uncertainties this data-based method is compatible with the model calculations.

D. Monte Carlo (MC) simulation corrections

The trigger, reconstruction, and identification efficiencies of electrons and muons as well as the muon isolation efficiency are evaluated by an MC simulation complemented by data-driven estimates of these quantities. Using the POWHEG generator [31] (with the CT10 PDF [32]) interfaced to PYTHIA8 [6] for simulation of the parton shower, approximately 10 million \( Z \to ee \) and 4 million \( Z \to \mu \mu \) events were simulated. The Z bosons were generated from pp and pn collisions, which were added together with weights 82/208 and 126/208, respectively, corresponding to the numbers of protons and neutrons in the Pb ion. The response of the ATLAS detector to the generated particles was modeled using GEANT4 [33,34]. Due to the dependence of electron identification and reconstruction efficiency on the detector occupancy, simulated \( Z \to ee \) events were overlaid with data events selected with the minimum-bias trigger and then reconstructed.

To cross-check the efficiencies calculated in the MC simulation, a “tag-and-probe” technique is employed. The tag is defined as a fully reconstructed high-quality triggered lepton, whereas the probe is a lepton candidate to which triggering, reconstruction, or quality requirements are not applied. Using tag-and-probe pairs with an invariant mass \( m_{\ell\ell} \) consistent with selection of Z bosons, the efficiency of the probe with additional requirements is calculated. The mass window used depends on the background present in the probe sample and ranges from 80 < \( m_{\ell\ell} \) < 100 to 87 < \( m_{\ell\ell} \) < 95 GeV. For example, the electron trigger efficiency is measured from high-quality reconstructed electron probes selected without an \textit{a priori} trigger requirement, and the MS reconstruction efficiency is measured from charged-particle tracks in the ID without an \textit{a priori} MS signal requirement. The MC simulation is scaled to match the efficiencies determined with the data-driven tag-and-probe method. The factors used to scale the MC electron response are derived from the 2013 \( p + Pb \) data set. Muon reconstruction is insensitive to the differences between 2013 \( p + Pb \) and 2012 pp conditions and therefore the scale factors for muons are taken from \( Z \to \mu \mu \) events collected in the 2012 pp data set [24]. The scale factors for the \( Z \to ee \) (\( Z \to \mu \mu \)) MC events deviate from unity by less than 5% (1%).

The trigger efficiencies of electrons and muons depend on \( \eta \) and have average values of approximately 95% and 83%, respectively. The reconstruction and identification efficiency of the more stringently selected electrons is approximately 75%, whereas the reconstruction and identification efficiency for the looser-quality midrapidity electrons is approximately 88% and the forward-electron efficiency is about 65%. These values depend on \( \eta \) and \( p_T \). The muon reconstruction efficiency is approximately 95%, depending on \( \eta \).

Correction factors for the yields of \( Z \to ee \) and \( Z \to \mu \mu \) candidates are calculated from the MC simulations as functions of \( p_T^e, y^e, \) and \( p + Pb \) centrality. These corrections take into account the cumulative losses due to the trigger, reconstruction, and identification efficiency as well as the kinematic acceptance of decay leptons. The correction is defined relative to all generated Z bosons within the mass window 66 < \( m_{\ell\ell} \) < 116 GeV. The total efficiency for reconstructing a produced Z boson, including acceptance, is approximately 55% for

![FIG. 1. (Color online) Centrality bias correction factors and their uncertainties (bars), from Ref. [30], for the Glauber and GGCF model configurations, and bias correction factors derived from data (points) as explained in the text. The reciprocals of the correction factors are applied as multiplicative factors to the centrality-dependent Z boson yields.](image-url)
Z → ee and 65% for Z → μμ. Following the subtraction of background (see Sec. III E) and application of the correction factor, a corrected yield of Z bosons is obtained in each bin of \( p_T \) and \( \eta \). The uncertainty of the correction factor follows from the uncertainty of the data-driven tag-and-probe checks of the MC, primarily due to the relatively low number of tag-and-probe events in the data. The uncertainty associated with the lepton identification efficiency is the dominant uncertainty for probe events in the data. The uncertainty associated with the MC, primarily due to the relatively low number of tag-and-probe events, is approximately 10% for Z → ee (rising as high as 15% for pairs including a forward electron) and 1.5% for Z → μμ.

The sizable uncertainty for Z → ee is primarily driven by the limited size of the tag-and-probe 2013 p + Pb data set. The other uncertainties are typically less than 2% in both channels.

E. Yield extraction

To form Z → ee candidates, all electrons found in triggered events are paired with each other. When both electrons are at midrapidity (|\( \eta \) < 2.47), the unlike-sign charged pairs with an invariant mass satisfying 66 < \( m_{ee} \) < 116 GeV are accepted as signal Z boson candidates. The like-sign pairs in this window are used to estimate the combinatorial background, created primarily by jets. In total, 1647 unlike-sign pairs and 52 like-sign pairs are reconstructed. The like-sign pairs are composed of combinatorial background and Z → ee decays in which one of the electrons has misreconstructed charge. The contribution from pairs with misreconstructed charge is estimated, using the MC simulation, to be half of the like-sign pairs, and the remainder is taken as an estimate of the background. Pairs made of one midrapidity electron and one nontriggering forward electron have a larger contribution from background and so an invariant mass window of 80 < \( m_{ee} \) < 100 GeV is used to select Z boson candidates. To facilitate combination of all Z → ee candidates, an acceptance correction is made to account for the smaller mass window. No charge requirement is made for these candidates because the nontriggering electron is outside the acceptance of the ID and therefore does not have a reconstructed charge. There are 264 such candidates, of which an estimated 5% are background based on a fit of the invariant mass distribution. The fit is performed in the range 60 < \( m_{ee} \) < 120 GeV using a signal shape from the MC simulation and several background parametrizations assumed exponential or polynomial descriptions of the background. The mass distributions of Z → ee candidates are shown in Figs. 2(a) and 2(b), along with the reconstructed MC simulation of the same quantity. The estimated background is subtracted from the signal candidates differentially in rapidity, transverse momentum, and centrality.

A similar procedure is also followed to select Z → μμ candidates with an invariant mass of 66 < \( m_{μμ} \) < 116 GeV. This selection yields 2032 unlike-sign charged candidates and 4 like-sign pairs; their mass distribution is shown in Fig. 2(c).

The MC simulation describes the data well in both lepton channels. The slight shift of the mass peak visible between the data and the simulation for dielectron events has only a very small effect on the calculation of corrections based on the MC simulation and is incorporated into the systematic uncertainty associated with electron reconstruction.

F. Systematic uncertainties

The dominant source of uncertainty in the Z → ee measurement stems from imperfect knowledge of the efficiency.
TABLE I. Relative systematic uncertainties (in percent) associated with the measurement of $Z \rightarrow ee$. The uncertainties typically increase at the more forward rapidities. Background includes charge misreconstruction, and electron reconstruction includes resolution. The last two rows refer only to pairs where one of the electrons was reconstructed in the range $3.1 < |\eta| < 4.9$.

of the electron identification requirements. The uncertainty is driven by the limited number of events available for the tag-and-probe analysis, which had to rely on 2013 $p + $Pb collision data because the electron reconstruction performance changed due to detector conditions and occupancy compared to earlier $pp$ collision data. The uncertainty is larger in pairs involving a forward-electron, and the sample has a lower purity than the sample of midrapidity electrons. Other electron uncertainties are significantly smaller and are associated with the trigger efficiency, electron reconstruction efficiency and energy resolution, background subtraction (which becomes significant for forward electrons), and charge misreconstruction. In addition, a small uncertainty stems from possible differences between the simulated $y_Z^*$ distribution and the one measured in the data. The $Z \rightarrow ee$ systematic uncertainties depend on $p_T^Z$, $y_Z^*$, and $p + $Pb centrality and are summarized in Table I.

The conditions of muon reconstruction in the 2013 $p + $Pb collision data closely resemble those in $pp$ collisions described in Ref. [24]. The small uncertainties from the more abundant $pp$ data are used in this analysis. An uncertainty of 1%, based on the performance of the muon reconstruction in high-pileup $pp$ collisions, is associated with the scale factors to account for possible differences between the data sets. The uncertainties depend on $p_T^Z$ and $y_Z^*$. Table II summarizes the systematic uncertainties of the $Z \rightarrow \mu\mu$ measurement.

In addition to the $Z$ boson measurement uncertainties, a 2.7% uncertainty is associated with the luminosity calculation. For the centrality-dependent yields that are scaled by $\langle T_{AA} \rangle$, the uncertainties of the Glauber model calculations are taken

from Ref. [22]. The correction to centrality due to bias from the presence of a hard scattering, taken from Ref. [30], has uncertainties as shown in Fig. 1.

G. Lepton channel combination

The cross section in each leptonic decay channel is defined for the mass window $66 < m_Z < 116$ GeV, the rapidity ranges $|y_Z^*| < 3.5$ for $Z \rightarrow ee$ and $-3 < y_Z^* < 2$ for $Z \rightarrow \mu\mu$, and the full decay lepton kinematic phase space. The $Z \rightarrow ee$ and $Z \rightarrow \mu\mu$ yields, corrected for acceptance and efficiency, are used to calculate the cross section in each channel, and a good agreement between the two is observed as shown for the $y_Z^*$ distributions in Fig. 3.

The two decay channel results are combined to one set of $Z \rightarrow \ell\ell$ data using the method described in Refs. [35,36]. The technique uses a $\chi^2$ minimization procedure with a nuisance parameter formalism to combine the data sets coherently. The procedure distinguishes those systematic uncertainty sources that are uncorrelated bin to bin, uncorrelated across data sets, and fully correlated bin to bin and across data sets. In this way, combined points are calculated to optimize the overall agreement of the data sets, given the correlation of the uncertainties. This may result in differences in the combined $Z \rightarrow \ell\ell$ data points relative to the $Z \rightarrow ee$ data points in rapidity regions in which there are no $Z \rightarrow \mu\mu$ data points. Following this, an integrated cross section for the region $|y_Z^*| < 3.5$ is defined for the combined $Z \rightarrow \ell\ell$ points based on both the $Z \rightarrow ee$ and the $Z \rightarrow \mu\mu$ data even though the $Z \rightarrow \mu\mu$ data are limited to $-3 < y_Z^* < 2$. The systematic uncertainties associated with the combined results are fully correlated bin to bin in each distribution. They are
TABLE III. The measured integrated cross section (in nb) for several rapidity ranges, for $Z \to \mu\mu$, $Z \to ee$, and the combined $Z \to \ell\ell$. The first uncertainty listed is statistical, and the second systematic. There is an additional 2.7% luminosity uncertainty for each cross section. Cross sections predicted by the models (see text) are also listed. Uncertainties listed with the model calculations are the PDF and scale uncertainties added in quadrature.

approximately 3% at midrapidity and rise to about 10% at forward and backward rapidity.

IV. RESULTS

A. $Z \to \ell\ell$ cross section

From the combined $Z \to ee$ and $Z \to \mu\mu$ data a total cross section of $139.8 \pm 4.8$ (statistical) $\pm 6.2$ (systematic) $\pm 3.8$ (luminosity) nb is obtained in the $|y_\gamma^*| < 3.5$ acceptance. Based on the MC simulation (and the models discussed below) this acceptance covers approximately 99.5% of the total $Z \to \ell\ell$ cross section. Restricting the results to the smaller rapidity interval of $−3 < y_\gamma^* < 2$, the cross section is $119.3 \pm 2.2$ (statistical) $\pm 3.4$ (systematic) $\pm 3.2$ (luminosity) nb. Table III lists the integrated cross section in the larger and

FIG. 4. (Color online) (a) The $d\sigma/dy_\gamma^*$ distribution from $Z \to \ell\ell$, shown along with several model calculations in the upper panel. Bars indicate statistical uncertainty, and shaded boxes systematic uncertainty, of the data; uncertainties of model calculations are not shown. (b)–(d) Ratios of the data to the models. Uncertainties of the model calculations (scale and PDF uncertainties added in quadrature) are shown as bands around unity in each panel. An additional 2.7% luminosity uncertainty of the cross section is not shown.

FIG. 5. (Color online) (a) The differential cross section of $Z$ boson production multiplied by the Bjorken $x$ of the parton in the lead nucleus, $x_{pb}d\sigma/dx_{pb}$, as a function of $x_{pb}$ using $Z \to \ell\ell$ events shown along with several model calculations. Bars indicate statistical uncertainty, and shaded boxes systematic uncertainty, of the data; uncertainties of the model calculations are not shown. (b)–(d) Ratios of the data to the models. Uncertainties of the model calculations are shown as bands around unity in each panel. There is an additional 2.7% luminosity uncertainty of the cross section.
FIG. 6. (a), (c) Distributions of the differential cross section of $Z$ boson production as a function of the transverse momentum of the $Z$, $p_T^Z$, shown along with the CT10 model calculation. (b), (d) Ratio of the data to the model. (a), (b) For $-3 < y_Z^* < 2$; (c), (d) for $-2 < y_Z^* < 0$ and $0 < y_Z^* < 2$. Bars indicate statistical uncertainty; shaded boxes, systematic uncertainty. The leftmost bin represents the range $0–3$ GeV. An additional 2.7% luminosity uncertainty of the cross section is not shown.

smaller rapidity ranges as measured for each channel and their combination.

The measured cross section may be compared to a $p + Pb$ model prediction composed of a linear sum of the nucleon-nucleon cross sections: $82\sigma(pp \rightarrow Z + X) + 126\sigma(pn \rightarrow Z + X)$, corresponding to the numbers of protons and neutrons in the Pb ion. The value of $\sigma(pp \rightarrow Z + X)$ is 2% higher than that of $\sigma(pn \rightarrow Z + X)$ in all models discussed below. Calculating the baseline nucleon-nucleon cross sections using the CT10 PDF at NLO, as in the corresponding MC simulation, the model yields values of $132.2 \pm 3.3$ nb in the range $|y_Z^*| < 3.5$ and $110.8 \pm 2.9$ nb for $-3 < y_Z^* < 2$, where the uncertainties are the sums in quadrature of PDF and scale (renormalization and factorization) uncertainties. Using the MSTW2008 PDF, calculated with FEWZ [37] at next-to-next-to-leading order (NNLO), cross sections of $135.2^{+3.4}_{-2.7}$ nb are obtained for $|y_Z^*| < 3.5$ and $113.5^{+2.8}_{-2.4}$ nb for $-3 < y_Z^* < 2$. At NLO the results from MSTW2008 are very close to the CT10 results. In addition to the simple model of the $p + Pb Z$ boson cross section as a linear sum of nucleon-nucleon cross sections, calculations are performed incorporating nuclear corrections of the PDF. Including the EPS09 modifications [38] to the CT10 PDF results in cross sections of $127.4 \pm 3.6$ and $108.6 \pm 3.1$ nb, respectively.

For a more detailed understanding of $Z$ boson production, the measured cross section as a function of the $Z$ boson rapidity is presented in Fig. 4 and compared to model calculations. The data are seen to be strongly asymmetric about $y_Z^* = 0$. The CT10 + EPS09 calculations come closest to reproducing the shape of the measured $y_Z^*$ differential cross section. A $\chi^2$ test of compatibility between the data and the model shapes (irrespective of normalization) finds that the CT10 + EPS09 shape of the $y_Z^*$ distribution gives a $p$ value of 0.79. The unmodified CT10 calculation and MSTW2008 calculations have $p$ values of 0.07 and 0.01, respectively. A Kolmogorov-Smirnov test was also performed and resulted in probabilities of 0.96, 0.09, and 0.07 for CT10 + EPS09, CT10, and MSTW2008 model calculations. This is consistent with the preference for the observation of nuclear correction effects as in the $\chi^2$ test.

Nuclear modification of PDFs is fundamentally related to the Bjorken $x$ of the relevant parton. At leading order, $x_p$ in the proton and $x_{Pb}$ in the lead nucleus are related to the reconstructed $Z$ boson kinematics by

$$x_p = \frac{m_{\ell\ell}e^{y_Z^*}}{\sqrt{s_{NN}}}, \quad x_{Pb} = \frac{m_{\ell\ell}e^{-y_Z^*}}{\sqrt{s_{NN}}}. \quad (1)$$

The resulting $x_{Pb}$ distribution is shown in Fig. 5 and compared to model calculations.

Figure 6 shows the $p_T^2$ distributions for $-3 < y_Z^* < 2$ and, separately, for $-2 < y_Z^* < 0$ and $0 < y_Z^* < 2$. These are compared to the baseline CT10 model. The $p_T^2$ dependence is less sensitive to nuclear effects and a good agreement between the experimental measurement and the MC simulation shape is observed.

B. Centrality-dependent yield

Results are presented for the centrality-dependent $Z$ boson yield. If the rate of $Z$ boson production were consistent with geometric expectations, then the $Z$ boson yield divided by $\langle N_{\text{coll}} \rangle$ should be independent of centrality. To investigate
FIG. 7. (Color online) The yield of $Z$ bosons per event scaled by the mean number of nucleon-nucleon collisions ($N_{\text{coll}}$) as a function of the mean number of participating nucleons ($N_{\text{part}}$). Each panel uses a different Glauber model configuration in calculating ($N_{\text{coll}}$) and ($N_{\text{part}}$). Standard Glauber model (a) with no Glauber-Gribov color fluctuations (GGCFs) and $\omega_{\sigma}$ = 0.11 and (b) with GGCFs and $\omega_{\sigma}$ = 0.2. The data are compared to the CT10 model prediction plotted at ($N_{\text{part}}$) = 2. Bars indicate statistical uncertainty; shaded boxes, systematic uncertainty. Systematic uncertainties are correlated bin by bin. The ($N_{\text{coll}}$) uncertainty plotted does not include the bin-by-bin fully correlated uncertainty stemming from the uncertainty of $\sigma(N + N \rightarrow X)$, which is instead included in the CT10 prediction uncertainty. As a reference, data are plotted as they would be with no centrality bias correction in the open points.

In this, the yield of $Z$ bosons per event scaled by ($N_{\text{coll}}$), within $-3 < y_Z^* < 2$, is displayed as a function of ($N_{\text{part}}$) in Fig. 7. The yield is independent of centrality defined using the standard Glauber model. Using the GGCF centrality models increases ($N_{\text{coll}}$) in central events and reduces it in peripheral events; consequently, the yield divided by ($N_{\text{coll}}$) is reduced in central events and increased in peripheral events. Figure 7 also shows the yield without the application of the centrality bias corrections discussed in Sec. III C.

The ATLAS Collaboration has previously measured the inclusive charged-hadron multiplicity in $p + \text{Pb}$ collisions as a function of centrality [22], and the centrality dependence of that quantity is similar to that observed in the present measurement. In order to quantify the similarity, the ratio $(dN_Z/dy^*)/(dN_{ch}/d\eta)$ is plotted vs ($N_{\text{part}}$) in Fig. 8. The charged-particle yield is expected to scale with ($N_{\text{part}}$) and the $Z$ boson yield with ($N_{\text{coll}}$) = ($N_{\text{part}}$) - 1, and so the ratio is fit to a function with the form $a \cdot ((N_{\text{part}}) - 1)/N_{\text{part}}$. This

FIG. 8. (Color online) Ratio of the $Z$ boson multiplicity to the inclusive charged particle multiplicity, $(dN_Z/dy^*)/(dN_{ch}/d\eta)$, as a function of ($N_{\text{part}}$). A function of the form $a \cdot ((N_{\text{part}}) - 1)/N_{\text{part}}$ is also shown. The normalization $a$ is set based on the GGCF with $\omega_{\sigma}$ = 0.11 points. Statistical uncertainties are plotted as bars; systematic uncertainties, as shaded boxes.

FIG. 9. (Color online) (a) Rapidity differential $Z$ boson yields, scaled by ($N_{\text{coll}}$), for three centrality ranges compared with the CT10 model calculation. Bars indicate statistical uncertainty; shaded boxes, systematic uncertainty. The ($N_{\text{coll}}$) is defined with the standard Glauber model ($\omega_{\sigma}$ = 0). The scale uncertainty stemming from the centrality calculation for each bin is included in the systematic uncertainty. Uncertainty associated with the model is not plotted. (b) Ratios of the data to the model. The uncertainty of the model added in quadrature to the scale uncertainty due to uncertainty in the inclusive NN cross section is shown as a band around unity. (c) $R_{CP}$ (see text for details). The 0–10% and 40–90% centrality points are offset for visual clarity. Arrows in (b) and (c) indicate values outside the plotted axes.
function describes the data well for the GGCF cases, and less so for the standard Glauber model. 

To further investigate the behavior observed in the rapidity differential cross section, the \( y^* \) dependence of the Z boson yield in different centrality bins is also measured, as shown in Fig. 9. The differences between the data and the model are larger in central collisions. The \( \langle N_{\text{coll}} \rangle_{\text{scaled}} \) ratio of central to peripheral data, \( R_C \), defined as

\[
R_C(y^*_Z) = \frac{\langle N_{\text{coll}} \rangle_{\text{peripheral}}}{\langle N_{\text{coll}} \rangle_{\text{central}}} \times \frac{dN_Z^{\text{central}}/dy^*_Z}{dN_Z^{\text{peripheral}}/dy^*_Z},
\]

is used to observe changes in the rapidity distribution for different centrality bins in a model-independent way and is shown in Fig. 9. Events with 40–90% centrality define the peripheral event selection, and two central selections, 0–10% and 10–40%, are compared with it. A linear fit of the \( R_C (y^*_Z) \) for 0–10% centrality results in a slope of \( -0.11 \pm 0.04 \), which suggests that the \( y^*_Z \) distribution may be different in most central events compared to peripheral events. For 10–40% centrality, the slope is \( -0.05 \pm 0.03 \).

V. SUMMARY

The Z boson production cross section has been measured in \( p + Pb \) collisions at \( \sqrt{s_{NN}} = 5.02 \text{ TeV} \) with the ATLAS detector at the LHC, using \( Z \to ee \) (\( Z \to \mu\mu \)) decays in a 29.4-nb\(^{-1}\) (28.1-nb\(^{-1}\)) data sample. It is found to be slightly higher than predictions based on perturbative QCD calculations. Disregarding the difference in overall normalization, the shapes of the \( y^*_Z \) and \( x_F \)-dependent cross sections are somewhat better described by models that include nuclear modification of the lead nucleus PDF compared to those that do not, although models without nuclear modification are not excluded. Following the application of a centrality bias correction, the centrality-dependent yield is found to scale with \( \langle N_{\text{coll}} \rangle \). In addition, the centrality dependence of the \( y^*_Z \) distribution was studied, and the asymmetry in \( y^*_Z \) was found to be slightly larger in more central events. Integrated over \( y^*_Z \), the centrality dependence appears to be consistent with binary scaling and is similar to the production of inclusive charged particles.

ACKNOWLEDGMENTS

We thank CERN for the very successful operation of the LHC, as well as the support staff from our institutions, without whom ATLAS could not be operated efficiently. We acknowledge the support of ANPCyT, Argentina; YerPhI, Armenia; ARC, Australia; BMWFW and FWF, Austria; ANAS, Azerbaijan; SSTC, Belarus; CNPq and FAPESP, Brazil; NSERC, NRC, and CFI, Canada; CERN; CONICYT, Chile; CAS, MOST, and NSFC, China; COLCIENCIAS, Colombia; MSMT CR, MPO CR, and VSC CR, Czech Republic; DNov, DNRe, and Lundbeck Foundation, Denmark; EPLANET, ERC, and NSRF, European Union; IN2P3-CNRS, CEA-DSM/IRFU, France; GNSF, Georgia; BMBF, DFG, MPG, and AvH Foundation, Germany; GSRT and NSRF, Greece; RGC, Hong Kong SAR, China; ISF, MINERVA, GIF, I-CORE, and Benoziyo Center, Israel; INFN, Italy; MEXT and JSPS, Japan; CNRST, Morocco; FOM and NWO, The Netherlands; BRF and RCN, Norway; MNiSW and NCN, Poland; GRICES and FCT, Portugal; MINEFA, Romania; MES of Russia and NRC KI, Russian Federation; JINR; MSTD, Serbia; MSSR, Slovakia; ARRS and MIŽS, Slovenia; DST/NRF, South Africa; MINECO, Spain; SRC and Wallenberg Foundation, Sweden; SER, SNSF, and Cantons of Bern and Geneva, Switzerland; NSE, Taiwan; TAEK, Turkey; STFC, the Royal Society and Leverhulme Trust, United Kingdom; and DOE and NSF, United States of America. The crucial computing support from all WLCG partners is acknowledged gratefully, in particular, from CERN and the ATLAS Tier-1 facilities at TRIUMF (Canada), NDGF (Denmark, Norway, Sweden), CC-IN2P3 (France), KIT/GridKA (Germany), INFN-CNAF (Italy), NL-T1 (The Netherlands), PIC (Spain), ASGC (Taiwan), RAL (UK), and BNL (USA) and in the Tier-2 facilities worldwide.
