Search for photonic signatures of gauge-mediated supersymmetry in 8 TeV $pp$ collisions with the ATLAS detector

G. Aad et al.*
(ATLAS Collaboration)
(Received 21 July 2015; published 6 October 2015)

A search is presented for photonic signatures motivated by generalized models of gauge-mediated supersymmetry breaking. This search makes use of 20.3 fb$^{-1}$ of proton-proton collision data at $\sqrt{s} = 8$ TeV recorded by the ATLAS detector at the Large Hadron Collider (LHC) in 2012. For the first of the four classes, two isolated energetic photons are required (“diphoton” events), while for the remaining classes only a single isolated photon is required. For the second and third classes, the isolated photon is required to appear in combination with a “$b$-jet” identified as having arisen from the production of a bottom ($b$) quark (“photon + $b$” events) or an isolated electron or muon (“photon + $\ell$” events), respectively. For the fourth class of events the isolated photon is required to appear in combination with multiple jets selected without regard to the flavor of the underlying parton (“photon + jet” events).

The results are interpreted in the context of a broad range of general models of gauge-mediated supersymmetry breaking (GGM) [1–3] that include the production of supersymmetric partners of strongly coupled Standard Model (SM) particles as well as SM partners possessing only electroweak charge. In all models of GGM, the lightest supersymmetric particle (LSP) is the gravitino $\tilde{G}$ (the partner of the hypothetical quantum of the gravitational field), with a mass significantly less than 1 GeV. In the GGM models considered here, the decay of the supersymmetric states produced in LHC collisions would proceed through the next-to-lightest supersymmetric particle (NLSP), which would then decay to the $\tilde{G}$ LSP and one or more SM particles, with a high probability of decay into $\gamma + \tilde{G}$. In this study, several different possibilities for the nature of the NLSP are considered, providing separate motivation for the four different and complementary experimental signatures that are explored. In all models considered, all supersymmetric states with the exception of the $\tilde{G}$ are short lived, leading to prompt production of SM particles that are observed in the ATLAS detector.

The results based on the diphoton and photon + $b$ signatures extend and supplant studies (Refs. [4] and [5], respectively) that made use of 4.8 fb$^{-1}$ of $pp$ collision data at $\sqrt{s} = 7$ TeV; the analyses based on the photon + jet and photon + $\ell$ signatures are new and have only been performed with the 8 TeV data. Making use of 19.7 fb$^{-1}$ of $pp$ collision data at $\sqrt{s} = 8$ TeV, a search [6] for events similar in nature to those of the diphoton and photon + jet signatures mentioned above has performed by the CMS Collaboration, and used to set limits on the masses of strongly coupled supersymmetric particles in several GGM scenarios.

II. GAUGE-MEDIATED SUPERSYMMETRY PHENOMENOLOGY

Supersymmetry (SUSY) [7–15] introduces a symmetry between fermions and bosons, resulting in a SUSY partner (sparticle) with identical quantum numbers except a difference by half a unit of spin for each SM particle. As none of these sparticles have been observed, SUSY must be a broken symmetry if realized in nature. Assuming $R$-parity conservation [16–20], sparticles are produced in pairs. These would then decay through cascades involving other sparticles until the stable, weakly interacting LSP is produced, leading to a final state with significant $E_T^{\text{miss}}$.

Experimental signatures of gauge-mediated SUSY breaking models [21–26] are largely determined by the nature of the NLSP. For GGM, the NLSP is often formed from an admixture of any of the SUSY partners of the electroweak gauge and Higgs boson states. In this study, three cases are assumed for the composition of the NLSP. For the first case, the NLSP is assumed to be purely bino-like [the SUSY partner of the SM U(1) gauge boson]. For the second case, the NLSP is assumed to be an admixture of bino and neutral higgsino states. For the final case, the NLSP is assumed to be a degenerate triplet of wino states [the SUSY partners of the SM SU(2) gauge bosons]. In this paper, the neutral NLSP is denoted $\tilde{\chi}_1^0$ irrespective of its composition. For the case that the NLSP is a degenerate triplet, the charged NLSP states are denoted $\tilde{\chi}_1^\pm$. The properties of the GGM models used to represent these possibilities are discussed below and summarized in Table I.

For the case that the NLSP is a bino, the final decay in each of the two cascades in a GGM event would be predominantly $\tilde{\chi}_1^0 \rightarrow \gamma + \tilde{G}$, leading to final states with $\gamma \gamma + E_T^{miss}$. For the case that the NLSP is a mixture of bino and higgsino, both the possibilities that the higgsino mass parameter $\mu$ is less than or greater than zero are explored. For the $\mu < 0$ possibility, the final decay in the cascade would include a significant contribution from $\tilde{\chi}_1^0 \rightarrow b + \tilde{G}$ with the subsequent decay $h \rightarrow b\bar{b}$, leading to final states with a photon, multiple $b$-jets, and $E_T^{miss}$. The latter ($\mu > 0$) possibility can produce scenarios for which the final decay in the cascade can be relatively evenly split between $\tilde{\chi}_1^0 \rightarrow \gamma + \tilde{G}$ and $\tilde{\chi}_1^0 \rightarrow Z + \tilde{G}$, leading to final states with a photon, multiple jets (including two from the hadronic decay of the Z boson) that most often do not arise from $b$-quarks, and $E_T^{miss}$. For the case that the NLSP is a degenerate set of three wino states, the final step in the cascade includes charged as well as neutral wino decays. Charged wino decays tend to produce isolated leptons, while neutral wino decays produce photons with a wino-to-photon branching fraction that is no less than $\sin^2 \theta_W$ for any value of the wino mass. Overall, these two wino-NLSP contributions lead to a significant number of events with an isolated photon accompanied by an isolated lepton. Of the five GGM models considered here, two (the “gluino-bino” and “wino-bino” models, where the gluino is the SUSY partner of the gluon) incorporate a purely bino-like NLSP, two (the “higgsino-bino” models) incorporate a NLSP that is a higgsino-bino admixture, and one (the “wino-NLSP” model) incorporates a wino-like set of NLSPs; in all cases the mass of the NLSP state is considered to be a free parameter of the model.

For the case that the NLSP is a mixture of bino and neutral higgsino, both the possibilities that the higgsino mass parameter $\mu$ is less than or greater than zero are explored. For the $\mu < 0$ possibility, the final decay in the cascade would include a significant contribution from $\tilde{\chi}_1^0 \rightarrow \gamma + \tilde{G}$, leading to final states with $\gamma \gamma + E_T^{miss}$. For the case that the NLSP is a degenerate triplet of wino states [the SUSY partners of the SM SU(2) gauge bosons], the final decay in the cascade can be relatively evenly split between $\tilde{\chi}_1^0 \rightarrow \gamma + \tilde{G}$ and $\tilde{\chi}_1^0 \rightarrow Z + \tilde{G}$, leading to final states with a photon, multiple $b$-jets, and $E_T^{miss}$. For the latter ($\mu > 0$) possibility can produce scenarios for which the final decay in the cascade can be relatively evenly split between $\tilde{\chi}_1^0 \rightarrow \gamma + \tilde{G}$ and $\tilde{\chi}_1^0 \rightarrow Z + \tilde{G}$, leading to final states with a photon, multiple jets (including two from the hadronic decay of the Z boson) that most often do not arise from $b$-quarks, and $E_T^{miss}$. For the case that the NLSP is a degenerate set of three wino states, the final step in the cascade includes charged as well as neutral wino decays. Charged wino decays tend to produce isolated leptons, while neutral wino decays produce photons with a wino-to-photon branching fraction that is no less than $\sin^2 \theta_W$ for any value of the wino mass. Overall, these two wino-NLSP contributions lead to a significant number of events with an isolated photon accompanied by an isolated lepton. Of the five GGM models considered here, two (the “gluino-bino” and “wino-bino” models, where the gluino is the SUSY partner of the gluon) incorporate a purely bino-like NLSP, two (the “higgsino-bino” models) incorporate a NLSP that is a higgsino-bino admixture, and one (the “wino-NLSP” model) incorporates a wino-like set of NLSPs; in all cases the mass of the NLSP state is considered to be a free parameter of the model.

For the case that the NLSP is a bino, the final decay in each of the two cascades in a GGM event would be predominantly $\tilde{\chi}_1^0 \rightarrow \gamma + \tilde{G}$, leading to final states with $\gamma \gamma + E_T^{miss}$. For the case that the NLSP is a mixture of bino and higgsino, both the possibilities that the higgsino mass parameter $\mu$ is less than or greater than zero are explored. For the $\mu < 0$ possibility, the final decay in the cascade would include a significant contribution from $\tilde{\chi}_1^0 \rightarrow b + \tilde{G}$ with the subsequent decay $h \rightarrow b\bar{b}$, leading to final states with a photon, multiple $b$-jets, and $E_T^{miss}$. The latter ($\mu > 0$) possibility can produce scenarios for which the final decay in the cascade can be relatively evenly split between $\tilde{\chi}_1^0 \rightarrow \gamma + \tilde{G}$ and $\tilde{\chi}_1^0 \rightarrow Z + \tilde{G}$, leading to final states with a photon, multiple jets (including two from the hadronic decay of the Z boson) that most often do not arise from $b$-quarks, and $E_T^{miss}$. For the case that the NLSP is a degenerate set of three wino states, the final step in the cascade includes charged as well as neutral wino decays. Charged wino decays tend to produce isolated leptons, while neutral wino decays produce photons with a wino-to-photon branching fraction that is no less than $\sin^2 \theta_W$ for any value of the wino mass. Overall, these two wino-NLSP contributions lead to a significant number of events with an isolated photon accompanied by an isolated lepton. Of the five GGM models considered here, two (the “gluino-bino” and “wino-bino” models, where the gluino is the SUSY partner of the gluon) incorporate a purely bino-like NLSP, two (the “higgsino-bino” models) incorporate a NLSP that is a higgsino-bino admixture, and one (the “wino-NLSP” model) incorporates a wino-like set of NLSPs; in all cases the mass of the NLSP state is considered to be a free parameter of the model.
the branching fraction of $\tilde{\chi}_1^0 \to h + \tilde{G}$ to that of $\tilde{\chi}_1^0 \to \gamma + \tilde{G}$ is maintained at approximately 1.7:1 over the full range of NLSP masses. The photon + $b$ analysis was found to provide the greatest advantage relative to the diphoton analysis for this ratio of branching fractions. In the limit that $m_{\tilde{\chi}_1^0} \gg m_{\tilde{\chi}_2^0}$, the NLSP branching fractions to $h + \tilde{G}$, $\gamma + \tilde{G}$, and $Z + \tilde{G}$ approach 56%, 33%, and 11%, respectively. The GGM SU(3) mass parameter $M_3$ bears a direct relation to the gluino mass, and is taken to be a free parameter in this $\mu < 0$ higgsino-bino model, with all squark states decoupled. The GGM SU(2) mass parameter $M_2$ is set to a value of 2.5 TeV. Four other electroweak gaugino states typically lie within 25 GeV of the $\tilde{\chi}_1^0$ NLSP: the two lightest charginos $\tilde{\chi}_1^\pm$ and $\tilde{\chi}_2^\pm$, and two additional neutralinos $\tilde{\chi}_2^0$ and $\tilde{\chi}_3^0$. The pair production of gluinos or any of these four additional gaugino states leads to decays to the $\tilde{\chi}_1^0$ via cascades involving SM particles.

For the second of the higgsino-bino models, which is the focus of the photon + $j$ analysis, the $\mu$ parameter is chosen to be positive, which suppresses the $h + \tilde{G}$ decay mode of the higgsino. As in the models described above, the NLSP mass is taken to be a free parameter. The $M_1$ and $\mu$ parameters are adjusted so that the branching fractions of the $\tilde{\chi}_1^0$ to $\gamma + \tilde{G}$, $Z + \tilde{G}$ and $h + \tilde{G}$ are maintained close to 50%, 49% and 1% for most values of the $\tilde{\chi}_1^0$ and gluino masses. In this model, the production of gluino pairs can be followed by decays to both a single photon and a hadronically decaying $Z$ boson, producing events with a single isolated high-energy photon accompanied by two jets. In the case that the gluino mass is substantially larger than the $\tilde{\chi}_1^0$ mass, additional jets can be produced in the cascade. Three additional electroweak gaugino states lie close in mass to the $\tilde{\chi}_1^0$, allowing for the possibility of SUSY production through pairs of these states. Such events tend to produce fewer jets than those that proceed through gluino production, but in certain regions of the model space can provide a significant contribution to data samples selected to isolate the photon-plus-jets signature. As in the $\mu < 0$ higgsino-bino model, the value of $M_3$, which is directly related to the gluino mass, is taken to be a free parameter, $M_2$ is set to a value of 2.5 TeV, and all squark states are decoupled. Typical production and decay-chain processes for the two models for which the NLSP is a higgsino-bino admixture are shown in Fig. 2.

Finally, the wino-NLSP model, which is the focus of the photon + $e$ analysis, incorporates a set of three degenerate winolike NLSPs. This set includes the neutral $\tilde{W}_0^0$, which as the lightest neutral gaugino is also referred to as the $\tilde{\chi}_1^0$, as well as the two charged wino states, which form the $\tilde{\chi}_1^\pm$ states. Production proceeds through the direct production of pairs of NLSP states; such events usually contain at least one $\tilde{W}_0^0$ NLSP. Although the $\tilde{W}_0^0$ couples preferentially to the $Z$ boson relative to the photon, the $\tilde{W}_0^0$ decays into a photon + gravitino final state with unit branching fraction for wino mass below that of the $Z$ boson. The $\tilde{W}_0^0$ branching fraction to photon + gravitino approaches $\sin^2 \theta_W$ for wino masses far above that of the $Z$ boson. Leptons can be produced either through the decays of charged wino states, or through the decays of $Z$ bosons that arise from $\tilde{W}_0^0$ decay, leading to a significant probability that the overall final state would contain both a photon and a lepton. In this model, a common wino mass scale is taken as a free parameter, with all other GGM mass parameters set to a value of 2.5 TeV, except the squark masses, which are set to infinity. A production and decay diagram typical for this model is shown in Fig. 3.

For all five models considered here, the mass of the gravitino is chosen so that the NLSP decay length is never greater than 1 mm. This ensures that all particles arising from the decay of the NLSP are prompt, and in particular that the relationship between the point and direction of impact of photons from NLSP decay upon the face of the

FIG. 1 (color online). Typical production and decay-chain processes for the gluino-production (left) and electroweak-production (right) instances of the GGM model for which the NLSP is a binolike neutralino, referred to in the text as the gluino-bino and wino-bino models, respectively.

FIG. 2 (color online). Typical production and decay-chain processes for the gluino-production instance of the GGM model for which the NLSP is a higgsino-bino neutralino admixture, referred to in the text as the higgsino-bino model. For the model with $\mu < 0$ (left), the final step of the cascade (the $\tilde{\chi}_1^0$ decay) would have a probability of order 50% of producing a Higgs boson rather than a photon or $Z$ boson; for the model with $\mu > 0$ (right), the $\tilde{\chi}_1^0$ decay would have a probability of order 50% of producing a $Z$ boson rather than a photon. For both of these models, production can also proceed through gaugino and neutralino states, which can dominate the production cross section for high values of gluino mass.
detector is consistent with that of a prompt photon (a separate analysis [27] searches for GGM models with a longer-lived binolike NLSP, leading to signatures with nonprompt photons). In addition, the ratio $\tan\beta$ of the two SUSY Higgs-doublet vacuum-expectation values is set to a value of 1.5; for all five models, the phenomenology relevant to this search is only weakly dependent on the value of $\tan\beta$.

III. SAMPLES OF SIMULATED PROCESSES

For the GGM models under study, the SUSY mass spectra and branching ratios are calculated using SUSPECT 2.41 [28] and SDECAY 1.3b [29], respectively, inside the package SUSY-HIT 1.3 [30]. The Monte Carlo (MC) SUSY signal samples are produced using HERWIG++ 2.5.2 [31] with CTEQ6L1 parton distribution functions (PDFs) [32]. Signal cross sections are calculated to next-to-leading order (NLO) in the strong coupling constant, including, for the case of strong production, the resummation of soft gluon emission at next-to-leading-logarithmic accuracy (NLO + NLL) [33–37]. The nominal cross section and its uncertainty are taken from an envelope of cross-section predictions using different PDF sets and factorization and renormalization scales [38]. At fixed center-of-mass energy, SUSY production cross sections decrease rapidly with increasing SUSY partner mass. At $\sqrt{s} = 8$ TeV, the gluino-production cross section is approximately 24 fb for a gluino mass of 1000 GeV and falls to below 1 fb for a gluino mass of 1400 GeV. The wino production cross section is approximately 15 fb for a wino mass of 500 GeV, and falls to approximately 1 fb for a wino mass of 750 GeV.

While most of the backgrounds to the GGM models under examination are estimated through the use of control samples selected from data, as described below, the extrapolation from control regions (CRs) to signal regions (SRs) depends on simulated samples, as do the optimization studies. The simulation of $W$ and $Z$ boson production, including events with up to five accompanying partons, is calculated by two different generators. The ALPGEN 2.14 [39] Monte Carlo generator is interfaced to HERWIG 6.520 for showering and fragmentation and to JIMMY [40] for simulation of the underlying event. Parton distributions are provided by the CTEQ6L1 functions. Similar samples are produced with the SHERPA 1.4.1 generator [41] with CT10 [42] PDFs, for up to four accompanying partons.

$W\gamma$ production is also simulated via ALPGEN interfaced to HERWIG and JIMMY, but makes use of the CT10 PDFs. Other $W\gamma$ samples are generated, as is the $Z\gamma$ process, by using SHERPA with the CT10 PDFs. The $t\bar{t}\gamma$ process is simulated at leading order (LO) using MADGRAPH 5.1.5.11 [43] and CTEQ6L1, interfaced to the PYTHIA 6.427 parton shower generator [44]. The $t\bar{t}$ process is simulated not only with the POWHEG generator interfaced to PYTHIA and the CTEQ6L1 PDFs, but also with the MC@NLO 4.06 generator [45,46] and the CT10 PDFs, including full NLO QCD corrections. This contribution is rescaled to match the $t\bar{t}$ cross section at NNLO with NNLL soft gluon terms, as calculated with top $++ 2.0$ [47–52]. The $t\gamma$ and $\bar{t}\gamma$ processes are simulated with the WHIZARD 2.1.1 [53,54] generator, with four-flavor/five-flavor matching provided using HOPPET [55]. Additional photon radiation is added with PHOTOS [56], with parton showering and fragmentation again simulated with PYTHIA. Other $t$ and $\bar{t}$ samples are generated with POWHEG.

The $\gamma + \text{jet}(s)$ process is simulated in a similar manner to the $W^{\pm}$ or $Z$ samples using ALPGEN interfaced to HERWIG and JIMMY and the CTEQ6L1 PDFs. A generator-level requirement of 35 GeV is applied to the photon transverse momentum $p_T^\gamma$, and the sample is generated in exclusive bins of $p_T^\gamma$ to produce a more statistically significant sample at higher values of $p_T^\gamma$. Additional $\gamma + \text{jet}(s)$ samples are used, simulated with SHERPA and the CT10 PDFs. The prompt diphoton sample is generated with PYTHIA 6.423, which includes the subprocesses $gg \rightarrow \gamma\gamma$ and $q\bar{q} \rightarrow \gamma\gamma$, with the requirement that there be at least two prompt photons with generated transverse momentum greater than 20 GeV. Parton densities are modeled according to the MRST 2007 LO* [57] functions.

The background from $Z(\rightarrow \ell\ell) + \gamma\gamma$ production is simulated using the SHERPA MC generator, normalized to a cross section calculated at LO using MADGRAPH 5 and the CTEQ6L1 PDF, and then corrected by a $K$-factor of 2.0 $\pm$ 1.0 [58]. The background from $W(\rightarrow c\ell) + \gamma\gamma$ production is simulated using the ALPGEN MC generator, although the overall normalization is set via a study making use of data events containing two photons and a charged lepton (to be discussed below). Diboson production, for the case that each boson is a $W$ or $Z$, is simulated with POWHEG.

All MC samples are processed with the GEANT4-based simulation [59] of the ATLAS detector [60], or, where appropriate, a simulation of the ATLAS detector based on parametrized shower shapes in the calorimeter, and GEANT4 elsewhere. Corrections are applied to the simulated samples to account for differences between data and simulation for the lepton and photon trigger, identification, and reconstruction efficiencies, as well as for the efficiency and misidentification rate of the algorithm used to identify
jets containing $b$-hadrons ($b$-tagging). The variation of the number of $pp$ interactions per bunch crossing (“pileup”) as a function of the instantaneous luminosity is taken into account by overlaying simulated minimum-bias events according to the observed distribution of the number of pileup interactions in data, with an average of 21 interactions per event.

IV. ATLAS DETECTOR

The ATLAS experiment makes use of a multipurpose detector [61] with a forward-backward symmetric cylindrical geometry and nearly $4\pi$ solid angle coverage.\footnote{ATLAS uses a right-handed coordinate system with its origin at the nominal interaction point (IP) in the center of the detector and the $z$ axis along the beam pipe. The $x$ axis points from the IP to the center of the LHC ring, and the $y$ axis points upwards. Cylindrical coordinates $(r, \phi)$ are used in the transverse plane, $\phi$ being the azimuthal angle around the beam pipe. The pseudorapidity is defined in terms of the polar angle $\theta$ as $\eta = -\ln[\tan(\theta/2)]$. Angular distance is measured in units of $\Delta R \equiv \sqrt{(\Delta \eta)^2 + (\Delta \phi)^2}$.} Closest to the beam line are solid-state tracking devices comprising layers of silicon-based pixel and strip detectors covering $|\eta| < 2.5$ and straw-tube detectors covering $|\eta| < 2.0$, located inside a thin superconducting solenoid that provides a 2 T magnetic field. Outside the solenoid, fine-grained lead/liquid-argon electromagnetic (EM) calorimeters provide coverage over $|\eta| < 3.2$ for the measurement of the energy and position of electrons and photons. A presampler, covering $|\eta| < 1.8$, is used to correct for energy lost upstream of the EM calorimeter. An iron/scintillator-tile hadronic calorimeter covers the region $|\eta| < 1.7$, while a copper/liquid-argon medium is used for hadronic calorimeters in the end cap region $1.5 < |\eta| < 3.2$. In the forward region $3.2 < |\eta| < 4.9$ liquid-argon calorimeters with copper and tungsten absorbers measure the electromagnetic and hadronic energy. A muon spectrometer consisting of three superconducting toroidal magnet systems, each comprising eight toroidal coils, tracking chambers, and detectors for triggering, surrounds the calorimeter system. The muon system reconstructs penetrating tracks over a range $|\eta| < 2.7$ and provides input to the trigger system over a range $|\eta| < 2.4$. A three-level trigger system is used to select events. The first-level trigger is implemented in hardware and uses a subset of the detector information to reduce the accepted rate to at most 75 kHz. This is followed by two software-based trigger levels that together reduce the accepted event rate to 400 Hz on average depending on the data-taking conditions during 2012.

V. RECONSTRUCTION OF CANDIDATES AND OBSERVABLES

Primary vertices are formed from sets of two or more tracks, each with transverse momentum $p_T^\text{track} > 400$ MeV, that are mutually consistent with having originated at the same three-dimensional space point within the luminous region of the colliding proton beams. When more than one such primary vertex is found, the vertex with the largest scalar sum of the squared transverse momenta of the associated tracks is chosen. To further ensure the event resulted from a beam collision, the primary vertex of the event is required to have at least five associated tracks.

Electron candidates are reconstructed from EM calorimeter energy clusters consistent with having arisen from the impact of an electromagnetic particle (electron or photon) upon the face of the calorimeter. For the object to be considered an electron, it is required to match a track identified by a reconstruction algorithm optimized for recognizing charged particles with a high probability of bremsstrahlung. In addition, the matched track is required to include information from at least seven layers of the solid-state tracking system; a track within the acceptance of the tracking system typically traverses eleven layers of the solid-state tracking system. The energy of the electron candidate is determined from the EM cluster, while its pseudorapidity is determined from the associated reconstructed track. Further details of the reconstruction of electrons can be found in Refs. [62] and [63]. Electron candidates used by these analyses are further required to have $p_T > 20$ GeV and $|\eta| < 2.47$. For the photon + $\ell$ analysis, signal electrons are not allowed to be within the transition region $1.37 < |\eta| < 1.52$ between the barrel and end cap calorimeters. A track-based isolation requirement is imposed, with the scalar sum of the transverse momenta of tracks within a cone of size $\Delta R = 0.3$ required to be less than 16% of the electron $p_T$. Finally, the electron track is required to be consistent with coming from the primary vertex in the $r$–$z$ plane.

Electromagnetic clusters are classified as photon candidates provided that they either have no matched track or have one or more matched tracks consistent with coming from a photon conversion vertex. Based on the characteristics of the longitudinal and transverse shower development in the EM calorimeter, photons are classified as “loose” or “tight.” Further details of the reconstruction of photons can be found in Ref. [64]. In the case that an EM calorimeter deposition is identified as both a photon and an electron, the photon candidate is discarded and the electron candidate retained. Photon candidates used by these analyses are required to be within $|\eta| < 2.37$, and to be outside the transition region $1.37 < |\eta| < 1.52$. Finally, an isolation requirement is imposed. After correcting for contributions from pileup and the deposition ascribed to the photon itself, loose and tight isolation criteria are defined, with the tight criterion requiring less than 4 GeV of transverse “isolation energy” in a cone of size $\Delta R = 0.4$ surrounding the energy deposition in the calorimeter associated with the photon. For the loose isolation criterion, no more than 5 GeV of isolation energy is allowed within a cone of size $\Delta R = 0.2$. 
The tight criterion is used for the diphoton analysis, while the loose criterion is used for the remaining three signatures (photon + b, photon + j, photon + ℓ).

Muons are required to either “combined,” for which the muon is reconstructed independently in both the muon spectrometer and the tracking system and then combined, or “segment tagged,” for which the muon spectrometer is used to tag tracks as muons, without requiring a fully reconstructed candidate in the muon spectrometer. Signal muons are required to have $p_T > 20$ GeV and $|\eta| < 2.4$. Track-based as well as calorimeter-based isolation requirements are imposed, with the scalar sum of the transverse momenta of tracks within a cone of size $\Delta R = 0.3$ required to be less than 12% of the muon $p_T$, and the energy in the calorimeter projected in the transverse plane within a cone of size $\Delta R = 0.3$, corrected for pileup, also required to be less than 12% of the muon $p_T$. Finally, the muon track is required to be consistent with coming from the primary vertex in both the $r-z$ and $r-\phi$ planes.

Jets are reconstructed from three-dimensional calorimeter energy clusters using the anti-$k_T$ algorithm [66] with a radius parameter $R = 0.4$. Jets arising from detector noise, cosmic rays or other noncollision sources are rejected, as described in Ref. [67]. Each cluster is classified, prior to the jet reconstruction, as coming from an electromagnetic or hadronic shower on the basis of its shape [68]. Each cluster energy is then corrected by weighting electromagnetic and hadronic energy deposits with correction factors derived from Monte Carlo simulation. A correction is applied to subtract the expected contamination from pileup, calculated as the product of the jet area in $\eta-\phi$ space and the average energy density of the event [69]. A further calibration, relating the response of the calorimeter to in situ jet-energy measurements [69] is then applied. Once calibrated, jets are required to have $p_T > 20$ GeV and $|\eta| < 2.8$. Jets containing $b$-hadrons are identified using the MV1c $b$-tagging algorithm [70]. This neural network algorithm combines the information from various algorithms based on track impact-parameter significance or explicit reconstruction of $b$- and $c$-hadron decay vertices. The analyses presented in this paper use an operating point corresponding to 70% efficiency for jets originating from the fragmentation of a $b$-quark in simulated $t\bar{t}$ events, selecting approximately 0.7% of light-quark and gluon-induced jets and 20% of $c$-quark-induced jets.

In the case that two reconstructed objects are in close enough proximity to one another to raise a concern that they are a single detector object reconstructed as more than one particle or jet candidate, an overlap-removal procedure is followed. To reduce the rate of electrons misidentified as photons, if the angular distance $\Delta R$ between a reconstructed electron and photon is less than 0.01, the object is classified as an electron.

To avoid ambiguity that arises when an electron or photon is also reconstructed as a jet, if a jet and an electron or photon are reconstructed within an angular distance $\Delta R = 0.2$ of one another, the electron or photon is retained and the jet is discarded; if $0.2 < \Delta R < 0.4$ then the jet is retained and the electron or photon is discarded. Finally, in order to suppress the reconstruction of muons arising from showers induced by jets, if a jet and a muon are found with $\Delta R < 0.4$ the jet is retained and the muon is discarded.

The vector momentum imbalance in the transverse plane is obtained from the negative vector sum of the reconstructed and calibrated physics objects and is referred to as missing transverse momentum $E_T^{\text{miss}}$ [71]. Calorimeter energy deposits are associated with a reconstructed and identified high-$p_T$ object in a specific order: electrons with $p_T > 10$ GeV, photons with $p_T > 10$ GeV, and jets with $p_T > 20$ GeV. Deposits not associated with any such objects are also taken into account in the $E_T^{\text{miss}}$ determination, as are muons with $p_T > 10$ GeV.

The transverse mass $M_T$ of a system of two massless particles with four-vectors $p_1$ and $p_2$ is given by

$$M_T = \sqrt{2p_{T,1}p_{T,2}(1 - \cos \Delta \phi_{1,2})},$$

where $\Delta \phi_{1,2}$ is the angular separation between the two vectors projected into the transverse plane. The analyses presented here make use of the transverse mass of both the photon-$E_T^{\text{miss}}$ $(M_T^{\gamma,E_T^{\text{miss}}})$ and lepton-$E_T^{\text{miss}}$ $(M_T^{\ell,E_T^{\text{miss}}})$ systems, where the lepton is taken to be massless in the transverse-mass determination.

Several additional observables are defined to help in the discrimination of SM backgrounds from potential GGM signals. The total visible transverse energy $H_T$ is calculated as the scalar sum of the transverse momenta of the selected photons and any additional leptons and jets in the event; a similar observable based only on the momenta of jets in the events is referred to as $H_T^{\text{jets}}$. The “effective mass” $m_{\text{eff}}$ is defined as the scalar sum of $H_T$ and $E_T^{\text{miss}}$. The photon-$E_T^{\text{miss}}$ separation $\Delta \phi(\gamma, E_T^{\text{miss}})$ is defined as the azimuthal angle between the missing transverse momentum vector and the selected photon. In the case of the diphoton analysis, $\Delta \phi_{\text{min}}(\gamma, E_T^{\text{miss}})$ is defined to be the minimum value of $\Delta \phi(\gamma, E_T^{\text{miss}})$ of the two selected photons. The minimum-jet-$E_T^{\text{miss}}$ separation $\Delta \phi_{\text{min}}(\text{jet}, E_T^{\text{miss}})$ is defined as the minimum azimuthal angle between the missing transverse momentum vector and the leading (highest-$p_T$) jets in the event. The number of leading jets used differs depending on the signature under study and is shown in Tables II and III. For the diphoton analysis, leading jets are required to have $p_T > 75$ GeV, and if no such jet is found, no requirement is placed on the observable. The quantity $\Delta \phi_{\text{min}}(\text{jet}, \gamma)$ is defined as the minimum separation between the selected photon and each of the two leading jets in the event. The quantity $\Delta R(\ell, \gamma)$ is defined as the distance in

VI. EVENT SELECTION

The data sample is selected by a trigger requiring the presence of one loose photon with energy projected into the plane transverse to the beam pipe \((E_T)\) of greater than 120 GeV for the photon \(+ b\), photon \(+ j\) and photon \(+ \ell\) analyses, or two loose photons with \(E_T > 40\) GeV for the diphoton analysis. Events are removed from the data sample if they contain jets likely to be produced by beam backgrounds, cosmic rays or detector noise, as described in Ref. [67]. After applying data-quality requirements related to the beam and detector conditions, the total available integrated luminosity is 20.3 fb\(^{-1}\). The uncertainty on the integrated luminosity is \(\pm 2.8\%\), estimated via the methodology of Ref. [72].

For the diphoton analysis, geared towards the exploration of the gluino-bino and wino-bino GGM models incorporating a purely binolike \(\tilde{\chi}_1^0\), two separate SR selection strategies were developed: a “\(SR_{S}^{\gamma}\)” selection geared towards the production of higher-mass strongly coupled SUSY states (gluinos and squarks) and a “\(SR_{W}^{\gamma}\)” selection geared towards the production of lower-mass weakly coupled SUSY states (winos). For each of these approaches, two SRs are defined: the first (\(SR_{S-L}^{\gamma}\), \(SR_{W-L}^{\gamma}\)) optimized for the case of a lower-mass \(\tilde{\chi}_1^0\) and the second (\(SR_{S-H}^{\gamma}\), \(SR_{W-H}^{\gamma}\)) for a higher-mass \(\tilde{\chi}_1^0\).

For the photon \(+ b\) analysis, geared towards the higgsino-bino GGM model with a negative value of the \(\mu\) parameter, two SRs (\(SR_{L}^{\gamma b}\), \(SR_{H}^{\gamma b}\)) are defined. The SRs are again distinguished by their optimization for low- and high-\(\tilde{\chi}_1^0\) mass, respectively. In particular, the \(SR_{L}^{\gamma b}\) selection is designed to have a high acceptance for events that arise through the production of pairs of weakly coupled SUSY partners, which can have a significant cross section for the low-\(\tilde{\chi}_1^0\)-mass reaches of the higgsino-bino GGM model explored here. For the photon \(+ j\) analysis, geared towards the higgsino-bino GGM model with a positive value of the \(\mu\) parameter, a further set of two SRs are defined (\(SR_{L}^{\gamma j}\), \(SR_{H}^{\gamma j}\)). These two SRs are once again distinguished by their optimization for low and high \(\tilde{\chi}_1^0\) mass, respectively.

A final “\(SR_{e/\mu}^{\gamma}\)” signal region was developed to search for photon \(+ \ell\) events arising from the GGM model with a winolike set of NLSPs. This SR is divided into two subsets—\(SR_{e/\mu}^{\gamma e}\) and \(SR_{e/\mu}^{\gamma \mu}\)—depending on the flavor of the leading lepton (electron or muon).

All four diphoton SRs require two tight, isolated photons with \(E_T > 75\) GeV, while the \(SR_{L}^{\gamma b}\) and \(SR_{H}^{\gamma b}\) signal regions require a single tight, isolated photon with \(E_T > 125\) GeV.

\(\eta-\phi\) space between the leading photon and lepton. Finally, the quantity \(R_{ij}\) is defined as the scalar sum of the transverse momentum of the four highest-\(p_T\) jets in the event divided by the sum of the transverse momentum of all jets in the event.

\(^a\)For \(SR_{L}^{\gamma j}\) and \(SR_{H}^{\gamma j}\), the two leading jets are required to have \(p_T > 100\) and \(p_T > 40\) GeV, respectively.
and $E_T > 150$ GeV, respectively, and the SR$^{i,j}_\gamma$ and SR$^{i,j}_H$ signal regions require a single tight, isolated photon with $E_T > 125$ GeV and $E_T > 300$ GeV, respectively. The SR$^{e/\mu}_T$ signal region requires a single tight, isolated photon with $E_T > 125$ GeV. Along with $E_T^{miss}$, leptonically, and (b-) jet activity, requirements are made on a number of additional observables, with values chosen to optimize the sensitivity to the GGM signal of interest for each SR. To ensure that the $E_T^{miss}$ observable is accurately measured, minimum requirements on $\Delta \phi_{min}(\gamma, E_T^{miss})$ and $\Delta \phi_{min}(jet, E_T^{miss})$ are considered for each SR. For the SR$^{i,j}_H$ signal region of the photon $+ j$ analysis, rejecting events with jets misidentified as photons by placing a requirement on $\Delta \phi_{min}(jet, \gamma)$ is found to improve the sensitivity of the analysis.

To exploit the high-energy scale associated with SUSY production at masses close to the expected limit of sensitivity of the various SRs, several SRs include minimum requirements on one of the two total-transverse-energy observables $H_T$ or $m_{eff}$. As an illustration, Fig. 4 (left) shows the $m_{eff}$ distribution of selected diphoton events as well as that expected from several SM sources and from characteristic strong-production points of the binolike NLSP GGM model. For electrons from $W$ boson decay that are misreconstructed as photons, the transverse mass $M_T^{\gamma, E_T^{miss}}$ of the photon-$E_T^{miss}$ system tends to be less than that of the $W$ boson; because of this, the photon $+ b$ analysis is found to benefit from a minimum requirement on $M_T^{\gamma, E_T^{miss}}$. The SR$^{e/\mu}_H$ analysis also benefits from a requirement that the invariant mass $M_{bb}$ of the system formed by the two most energetic $b$-jets be close to the Higgs boson mass. A minimum requirement on the transverse mass $M_T^{\gamma, E_T^{miss}}$ of the lepton-$E_T^{miss}$ system is similarly found to be effective in rejecting backgrounds from $W$ boson and semileptonic $t\bar{t}$ decay for the photon $+ \ell$ analysis. A further requirement that the electron-photon system invariant mass not be close to the $Z$ boson mass helps to reject $Z$ boson backgrounds to the photon $+ \ell$ analysis. A requirement that SR$^{e/\mu}_T$ signal events have no identified charged leptons helps to reduce the background from semileptonic $t\bar{t}$ events, while a requirement that SR$^{i,j}_H$ signal events have $R_T^4 < 0.85$ helps reduce the background from SM events, which tend to have fewer and softer jets than do signal events; as an illustration, see Fig. 4 (right). Finally, a requirement that the total transverse energy from jets with $p_T > 40$ GeV ($H_T^{jets}$) be less than 100 GeV helps reduce the backgrounds to SR$^{e/\mu}_T$ due to top quark production.

A summary of the selection requirements specific to each of the diphoton SRs is presented in Table II, to SR$^{e/\mu}_H$, SR$^{i,j}_H$,

![Figure 4](image_url)  
**FIG. 4** (color online). (Left) Distribution of $m_{eff}$, the sum of the total visible transverse energy and $E_T^{miss}$, for selected diphoton events, after requiring $\Delta \phi_{min}(jet, E_T^{miss}) > 0.5$ but before application of a requirement on $E_T^{miss}$ and $\Delta \phi_{min}(\gamma, E_T^{miss})$. Also shown are the expected contributions of SM processes, estimated as described in Sec. VII, as well as the expected $m_{eff}$ distributions for the $(m_\gamma, m_\mu) =$ (1300, 150) GeV and $(m_\gamma, m_\mu) =$ (1300, 1050) GeV gluino-bino GGM models. (Right) Distribution of $R_T^4$, the scalar sum of the transverse momentum of the four highest-$p_T$ jets in the event divided by the sum of the transverse momentum of all jets in the event, for the sample surviving all SR$^{i,j}_H$ selection criteria except the $R_T^4$ requirement itself. Also shown are the expected contributions of SM processes, estimated as described in Sec. VII, as well as the signal expectation for the two points in the $M_{\mu-\mu}$ parameter space characteristic of the $\mu > 0$ GGM model relevant to the photon $+ j$ analysis. For both figures, the lower plot shows the ratio of observed data to the combined SM expectation, with the inner band representing the range of statistical uncertainty and the outer band (visible only in the highest $R_T^4$ bin in the right-hand figure) the combined statistical and systematic uncertainty. Events outside the range of the displayed region are included in the highest-valued bin.

SR$_r$ and SR$_H$ in Table III, and to the two photon + $\ell$ SRs in Table IV. After all selection requirements, the numbers of events remaining in the various signal regions are 0 (SR$_{\gamma L}$, SR$_{S-H}$), 5 (SR$_{W-L}$), 1 (SR$_{W-H}$), 12 (SR$_{H, S R}$), 2 (SR$_{H, L}$, SR$_{H}$), 16 (SR$_{\tau}$) and 10 (SR$_{\mu}$).

VII. BACKGROUND ESTIMATION

Backgrounds to the various SRs arise from a number of sources, including processes such as radiative vector boson production that generate real photons in combination with energetic neutrinos, as well as events in which one or more energetic jets or electrons are misidentified as a photon. While these sources contribute generically to all four signatures explored in this study, the differing definitions of each of the associated SRs lead to, in many cases, significant differences in the manner in which the contributions of these various background sources are estimated. In the following, the methodology of the background estimation for each of the four experimental signatures is discussed, and the resulting background estimates, broken down by source, are tabulated. For the estimation of background contributions that rely upon MC simulation, either directly or through the estimation of “transfer factors” relating the background content of control regions to that of corresponding SRs, the effect of MC modeling uncertainties have been considered; in general, these uncertainties are found not to be dominant contributions to the overall uncertainty in the background estimates. Background models are confirmed in validation regions (VRs) with selection criteria closely related to those of the corresponding SR, but with one or more selection criteria modified to suppress the contribution of possible GGM signal to the VR.

A. Backgrounds to the diphoton analysis

Backgrounds from SM contributions to the four diphoton SRs are grouped into three primary components. The first of these, referred to as “QCD background,” arises from a mixture of processes that include $\gamma\gamma$ production as well as $\gamma + \text{jet}$ and multijet events with at least one jet misreconstructed as a photon. The second background component, referred to as “EW background,” is due to $W + X$ (here “$X$” can be any number of jets, accompanied by no more than one photon; the two-photon case is treated separately) and $t\bar{t}$ events, with a smaller contribution arising from $Z + X$ events. These events tend to include final-state neutrinos that produce significant $E_T^{\text{miss}}$. In both cases, EW background events entering the signal regions generally have at least one electron misreconstructed as a photon. The QCD and EW background are estimated through the use of dedicated control samples of data events.

The third background component, referred to as “irreducible,” consists of $W$ and $Z$ bosons produced in association with two real photons, with a subsequent decay into one or more neutrinos. For this background, the $W(\rightarrow \ell\nu) + \gamma\gamma$ component dominates, and requires corrections to its LO contribution that are both large and rapidly varying across the phase space of the $W(\rightarrow \ell\nu) + \gamma\gamma$ (plus possible additional jets) process [73]. Thus a data-driven approach was developed to constrain the $W(\rightarrow \ell\nu) + \gamma\gamma$ contribution to the four SRs. The $Z(\rightarrow \nu\bar{\nu}) + \gamma\gamma$ contribution is estimated directly from the MC simulation.

The QCD background to SR$_{S-L}$, SR$_{S-H}$, SR$_{W-L}$, and SR$_{W-H}$ is expected to arise from events with two real, isolated photons (diphoton QCD events) unaccompanied by any additional electroweak bosons, and from events with a single real, isolated photon and a jet whose fragmentation fluctuates in such a manner as to cause it to be misidentified as a second isolated photon (“photon + jet” QCD events). A contribution from dijet QCD events is found to be small and largely incorporated into the photon + jet background estimate. To estimate the photon + jet contribution a “QCD control sample” is identified within the diphoton-trigger data sample by selecting events for which one photon candidate satisfies the tight selection criterion, while the other satisfies the loose but not the tight photon criterion. QCD control sample events containing electrons are vetoed to reduce contamination from $W \rightarrow e\nu$ decays. Studies with MC simulated samples as well as $E_T^{\text{miss}}$ and $H_T$ sideband data suggest that the $E_T^{\text{miss}}$ distribution of this control sample adequately reproduces the $E_T^{\text{miss}}$ distribution of the QCD background in the high-$E_T^{\text{miss}}$ region used for the signal selection. A diphoton MC sample is used for the estimation of the diphoton contribution to the QCD background.

The $H_T, m_{\text{eff}}, \Delta \phi_{\text{min}}(\text{jet}, E_T^{\text{miss}})$ and $\Delta \phi_{\text{min}}(\gamma, E_T^{\text{miss}})$ requirements associated with each of the four SRs are applied to the QCD control and diphoton MC samples, and the resulting samples are scaled so that the combination of the two samples exactly reproduces the number of observed diphoton events (for the given SR) in the region $0 < E_T^{\text{miss}} < 60$ GeV, and with the diphoton MC sample providing a specified fraction of the total event count in this region. As suggested by the independent ATLAS $H \rightarrow \gamma\gamma$ [74] and isolated photon pair cross-section [75] analyses, this fraction is set to 75%, although in this analysis a range
between 50% and 100% is adopted to reflect the degree of uncertainty in this fraction. The resulting QCD-background estimate, for each of the four binolike SRs, is then obtained by summing the scaled number of combined QCD control and diphoton MC events with $E_T^{\text{miss}}$ above the minimum requirement for the given SR. Additional sources of systematic uncertainty on the QCD-background estimate include its dependence on the low-$E_T^{\text{miss}}$ region used to scale the diphoton MC and QCD control samples, and the effect of possible mismodeling of the $\Delta\phi_{\text{min}}(\text{jet}, E_T^{\text{miss}})$ and $\Delta\phi_{\text{min}}(\gamma, E_T^{\text{miss}})$ distributions of the QCD background by the QCD control sample. Including both systematic uncertainty and the statistical uncertainty associated with the limited number of events in the QCD control and diphoton MC samples, the result for the QCD background and its overall uncertainty is shown in Table V.

The QCD-background model is validated by comparing the observed numbers of events to the total expected SM background in bins of 300 GeV in $H_T$ for the sideband region $100 < E_T^{\text{miss}} < 150$ GeV, for which event rates are expected to be dominated by the QCD background. The observed event rate tends to be somewhat lower than that predicted by the overall background model, although it is within 1 standard deviation of the overall background model uncertainty for all $H_T$ bins.

The EW background, arising predominantly from $W + X$ and $\bar{t} t$ events, is estimated via an “electron-photon” control sample composed of events with at least one isolated tight photon and one isolated electron, each with $E_T > 75$ GeV, and scaled by the probability for such an electron to be misreconstructed as a tight photon, as estimated from a “tag-and-probe” study of the Z boson in the $ee$ and $e\gamma$ sample. The electron-to-photon scale factor varies between 1.9% ($0 < |\eta| < 0.6$) and 3.7% ($1.52 < |\eta| < 1.81$), since it depends on the amount of material in front of the calorimeter. Events with two or more tight photons are vetoed from the control sample to preserve its orthogonality to the signal sample. In the case of more than one electron, the one with the highest $p_T$ is used. Including systematic uncertainties of $\pm 25\%$ each, associated with a possible $p_T$ dependence of the scale factor and a possible overlap between the QCD and EW background estimates, leads to the estimates for the EW background to the four diphoton SRs shown in Table V.

The irreducible background is composed of two distinct components: diphoton production in association with either a $W$ or $Z$ boson. The latter contribution is relatively small and is sufficiently well understood to allow the use of the MC simulation, with a total cross section scaled to that of Ref. [58], to directly estimate the $Z(\rightarrow \nu\bar{\nu}) + \gamma\gamma$ contribution to the four SRs. The value of this estimate is shown in Table V; the uncertainty is dominated by a $\pm 50\%$ uncertainty on the $Z(\rightarrow \nu\bar{\nu}) + \gamma\gamma$ cross section of Ref. [58] that arises from the variation of the factorization and renormalization scales used to quantify the uncertainty due to missing higher-order processes.

The $W(\rightarrow \ell\nu) + \gamma\gamma$ background to the four SRs is estimated using a lepton-diphoton ($\ell\gamma\gamma$) CR. To enhance the contribution of $W(\rightarrow \ell\nu) + \gamma\gamma$ and ensure that the $\ell\gamma\gamma$ CR is exclusive of the four SRs, the photon $p_T$ requirement is lowered to 50 GeV and a requirement of $50 < E_T^{\text{miss}} < 150$ GeV is imposed. To ensure that the CR sample arises from the same region of the $W(\rightarrow \ell\nu) + \gamma\gamma$ process phase space as the expected background, a further requirement that the transverse momentum of the $\ell\gamma\gamma$ system be greater than 100 GeV is imposed. A total of seven events is observed in the CR, for which MC simulation suggests that 2.2 are expected to arise from SM sources other than $W(\rightarrow \ell\nu) + \gamma\gamma$. When setting limits on contributions from new physics in the four SRs, a simultaneous fit to the CR and the signal region under study is performed, allowing both the signal and $W(\rightarrow \ell\nu) + \gamma\gamma$ contributions to float to their best-fit values. When setting model-dependent limits, the fit also takes into account a possible signal contribution to the $\ell\gamma\gamma$ CR, which can be significant for the electroweak-production models in the case that the $\gamma_1$ mass is light. In the limit that no GGM signal contributes to the $\ell\gamma\gamma$ control region, an enhancement factor of 2.3 must be applied to the $W(\rightarrow \ell\nu) + \gamma\gamma$ MC sample to achieve agreement between the MC simulation and data in the $\ell\gamma\gamma$ control region. The resulting $W(\rightarrow \ell\nu) + \gamma\gamma$-background estimate in each of the four SRs, under the assumption that there is no signal contribution to the $\ell\gamma\gamma$ CR, is shown in Table V; the uncertainty is dominated by that of the limited number of events in the $\ell\gamma\gamma$ CR. Also shown is the combined expected and observed numbers of events for the four diphoton signal regions. The quoted errors are the combined statistical and systematic uncertainties.

background estimation. Including all SM sources, a total of 14.5 (58.0) events are expected in the CR_{lep}^{Higgs} (CR_{lep}^{Higgs}) control regions, to be compared to an observation of 18 (61) events. Scaling the combined SM MC samples by these ratios of data to expectation, after having subtracted the contributions estimated by other techniques, yields the SR background estimates shown in Table VI. It is found that the data-to-expected scale factor is somewhat dependent upon the requirements used to define the lepton-enriched CRs; these variations are included in the systematic error on the resulting SR background prediction.

The QCD background is estimated via the definition of a two-dimensional signal- and control-sample grid (the "ABCD" method). For the SR_{lep}^{L} analysis, three control samples are defined by requiring only a single tagged b-jet, by requiring that \( E_{\text{miss}}^{\text{miss}} < 75 \) GeV, or by requiring both of these SR modifications. For the SR_{lep}^{H} analysis, three similar control samples are defined by requiring that no jet be identified as a b-jet, by requiring that \( E_{\text{miss}}^{\text{miss}} < 150 \) GeV, or by requiring both of these SR modifications. A transfer factor is calculated by taking the ratio of the number of events with only the \( E_{\text{miss}}^{\text{miss}} \) requirement changed to the number of events with both the \( E_{\text{miss}}^{\text{miss}} \) and b-jet requirements changed. Assuming that the relaxation of the b-jet requirement is uncorrelated with the relaxation of the \( E_{\text{miss}}^{\text{miss}} \) requirement, the number of QCD-background events in the SR can then be estimated by scaling, by this transfer factor, the number of events with only the b-tag requirement changed. This scaling is done only after subtracting the number of events expected to come from sources other than those that produce QCD-background events from each of the control samples. To avoid the biasing effects of possible correlations between the relaxation of the b-jet requirement and the \( E_{\text{miss}}^{\text{miss}} \) requirement, for the SR_{lep}^{L} (SR_{lep}^{H}) analysis events are binned in \( E_{\text{miss}}^{\text{miss}} \) and weighted bin by bin in the ratio of the number of events in the 2-tag (1-tag) region to the number of events in the 1-tag (0-tag) region in the \( \gamma + \text{jet} \) MC sample. The resulting estimate of the small expected QCD background in the two SRs is shown in Table VI, with the systematic uncertainty dominated by the limited number of events to which the scale factor is applied.

An additional background due to the production of a Z boson that decays into two neutrinos, in association with a photon and a b-jet, is estimated directly from the MC simulation, and is tabulated in Table VI. For this final contribution, a 50% scale error is assumed for the overall rate of production for this process. The combined background from all expected sources is also shown in Table VI.

For both photon + b SRs, the background model is validated in four VRs, defined for SR_{lep}^{L} by requiring \( 75 < E_{\text{miss}}^{\text{miss}} < 100 \) GeV, by reversing the \( M_{bb} \) requirement, by requiring \( M_{T,\text{miss}}^{\text{miss}} < 90 \) GeV, or by requiring

\[
\begin{array}{l}
\text{Signal Regions} \quad \text{SR}_{L}^{\text{lep}} \quad \text{SR}_{H}^{\text{lep}} \\
\hline
\text{Expected background events} & 18.8 \pm 5.3 & 3.82 \pm 1.25 \\
\text{W(\( \rightarrow \ell \nu \))} & 3.2 \pm 0.4 & 0.18 \pm 0.08 \\
\text{QCD} & 12.6 \pm 4.9 & 3.35 \pm 1.05 \\
\text{Z} \rightarrow \nu \nu & 2.3 \pm 2.1 & 0.00 \pm 0.65 \\
\text{Observed events} & 0.8 \pm 0.4 & 0.29 \pm 0.15 \\
\end{array}
\]
Δφ_{min}(jet, E_T^{miss}) < 0.3, respectively. Since no $M_{bb}$ requirement is made for SR_{H}^{jH}, the second validation region is instead defined by changing the $H_T$ requirement to 500 < $H_T$ < 1000 GeV. The observed numbers of events in the VRs are consistent with the predictions of the overall background model.

C. Backgrounds to the photon + $j$ analysis

Backgrounds to the photon + $j$ analysis are expected to arise both from events with real photons as well as events for which an electron or a jet is misidentified as a photon. The former source is expected to receive contributions from events for which a $W/Z$ boson, a single-top quark, or a $t\bar{t}$ pair is produced in association with a real photon, with neutrinos in the subsequent weak decays of these produced states providing significant $E_T^{miss}$ ($W\gamma$, $Z\gamma$ and $t\bar{t}\gamma$ background). Events with real photons can also contribute to the background to the photon + $j$ analysis when significant $E_T^{miss}$ arises from instrumental sources (QCD background). The $W\gamma$, $t\bar{t}\gamma$ and QCD backgrounds are estimated by scaling a corresponding MC sample to match the observed event count in a corresponding CR enriched in the given background process but otherwise kinematically similar to the corresponding SR. The MC simulation is then used to provide an estimate of the expected background in the SR_{L}^{jL} and SR_{H}^{jH} SRs. Smaller contributions from single-top + $\gamma$ and $Z\gamma$ are estimated directly from the MC simulation.

The QCD-background CR is defined by changing the SR_{L}^{jL} and SR_{H}^{jH} $E_T^{miss}$ requirements to instead select events with $E_T^{miss} < 50$ GeV, but leaving all other selection requirements unchanged, providing a region dominated by real photons arising from radiative QCD processes. The $W\gamma$-background CR is defined by requiring, in addition to the other SR_{L}^{jL} and SR_{H}^{jH} requirements, that there be a single identified isolated lepton (electron or muon) and no $b$-jet in the event. The $t\bar{t}\gamma$-background CR is defined similarly, but requires instead at least one $b$-jet. In both cases, in order to increase the number of events in the CR the $E_T^{miss}$ requirement is changed to 100 < $E_T^{miss}$ < 200 GeV. The event counts in the resulting QCD, $W\gamma$ and $t\bar{t}\gamma$ CRs are used to scale the $\gamma + j$, $W\gamma$ and $t\bar{t}\gamma$ MC samples, respectively, after applying a selection identical to that of the corresponding CR. The scale factors are determined in a simultaneous fit to all CRs, taking into account mutual cross contamination between the different backgrounds. Estimates for the contributions of all three of the real-photon backgrounds are shown in Table VII. Systematic uncertainty on the scale factor is dominated by the theoretical uncertainties on the relevant MC samples, related in turn to the PDF choice and the renormalization and factorization scales.

As in the other analyses, backgrounds from events for which electrons are misidentified as photons are estimated by identifying a control sample of events through the application of a set of selection requirements that are identical to those of the given SR, but with a requirement that the event have an electron that replaces the required photon. The estimate of the background in the SR (SR_{L}^{jL} or SR_{H}^{jH}) is then, as in the other analyses, derived by scaling each event in the control sample by an $\eta$-dependent electron-to-photon misidentification factor. The resulting background estimates are displayed in Table VII.

Finally, the contribution of a background due to events for which the selected photon arises from the misidentification of a jet is estimated by determining the jet-to-photon misidentification rate from the observed isolation-energy distribution of energy in a cone of size $\Delta R = 0.2$ surrounding the energy deposition in the calorimeter associated with the photon. The isolation-energy distribution for real photons is modeled with electrons from $Z$ boson decays, while that of misidentified jets is modeled with a sample of events for which there is a “pseudophoton.” A pseudophoton is defined to be an object that passed all loose photon selection requirements, as well as all tight photon selection requirements except one or more from a set of four that relate to the shape of the deposition in the finely granulated front portion of the EM calorimeter. The fraction of misidentified jets within the tight, isolated photon sample is determined with a control sample composed of events with tight, isolated photons with $p_T > 125$ GeV, as well as a relaxed $E_T^{miss}$ requirement of 50 < $E_T^{miss}$ < 150 GeV and an intermediate requirement of $H_T > 600$ GeV. The photon isolation-energy distribution of this control sample is fit to establish the relative amounts of these two sources (real photons and misidentified jets), with the misidentification fraction taken to be the relative integrals of the isolation-energy distributions of the misidentified and total contributions in the region for which the isolation energy is less than 5 GeV. The estimation of the jet-misidentification background in each signal region and control sample (as well as for the validation regions described below) is then obtained by scaling the observed number of events in each

region or sample by the jet-misidentification factor. The number of misidentified jets is then parametrized as a function of $E_{\text{miss}}^{\text{jet}}$ by fitting the $E_{\text{miss}}^{\text{jet}}$ dependence of the estimated misidentified-jet contribution in the range $E_T^{\text{miss}} < 200$ GeV. The estimates in the SR$_{\ell}$ and SR$_{t}$ signal regions are then extracted by integrating the fit function over the relevant $E_T^{\text{miss}}$ range. The result for the contribution of the jet-misidentification backgrounds for each SR is shown in Table VII. Systematic uncertainties arise due to the uncertainties in the combined fit used to derive the misidentification factor, for which the parameters of the signal and background templates are allowed to vary within their uncertainties, and from the uncertainties of the extrapolation fit used for the estimation of the SR contamination.

The background model is validated by comparing expected and observed event rates in several VRs. For SR$_{\ell}$, this includes three VRs for which the $\Delta \phi_{\text{min}}(\text{jet}, E_T^{\text{miss}})$ is reversed, $E_T^{\text{miss}}$ is required to be within an intermediate range of $75 < E_T^{\text{miss}} < 150$ GeV, and for which the $E_T^{\text{miss}}$ requirement is reversed. For SR$_{t}$ two VRs are made use of, including one for which $\Delta \phi_{\text{min}}(\text{jet}, E_T^{\text{miss}})$ is reversed and another that requires that $400 < H_T < 800$ GeV. Good agreement is observed between the number of expected and observed events in all five VRs.

**D. Backgrounds to the photon + $\ell$ analysis**

Backgrounds to the photon + $\ell$ analysis (SR$_{e}$ and SR$_{\mu}$) are expected to arise primarily from events with hard photons produced in association with electroweak bosons ($W\gamma$ or $Z\gamma$) and top quarks ($t\bar{t}\gamma$), and events containing $W$ bosons or semileptonically decaying top quarks for which an accompanying jet is misidentified as a photon (jet-to-photon events). Lesser contributions are expected to arise from $t\bar{t}$ events and events containing two electroweak bosons that produce two final-state leptons, one of which is an electron that is subsequently misidentified as a photon. As in the other analyses, data-driven techniques making use of CRs similar to but exclusive of the SRs, or control samples appropriate for assessing jet-to-photon and electron-to-photon misidentification rates, are used to estimate or constrain the primary backgrounds, while lesser backgrounds are estimated directly from MC simulation.

The most prevalent background in the photon + $\ell$ sample is expected to arise from $W\gamma$ events. A $W\gamma$ CR is defined by requiring an isolated electron or muon, and by requiring in addition that $45 < E_T^{\text{miss}} < 100$ GeV and $35 < M_T^{\gamma,E_T^{\text{miss}}} < 90$ GeV, but otherwise requiring that the sample satisfy the SR$_{e}$ and SR$_{\mu}$ criteria. Transfer factors relating the number of events observed in the $W\gamma$ CR to the number of $W\gamma$ events expected in the SRs are estimated, separately for the electron and muon contributions, from the $W\gamma$ MC simulation. Systematic uncertainties on the resulting $W\gamma$-background estimate for the two SRs arise from the scale and PDF uncertainties associated with the transfer factors. A somewhat lesser contribution from $t\bar{t}\gamma$ events is estimated directly from the MC simulation, with uncertainties arising from imprecise knowledge of the strong-interaction scale and the rate of final-state photon production into the acceptance of the SRs. A smaller background contribution from $Z\gamma$ events is estimated directly from the MC simulation, with an uncertainty of ±50% assumed for the production rate into the region of the $Z\gamma$ phase space that populates the photon + $\ell$ SRs.

As in the other analyses, a potentially sizable contribution to the photon + $\ell$ sample arises from jet-to-photon misidentification. The contribution of SR events arising from jet-to-photon misidentification is estimated by exploring the isolation-energy distribution of events in an extended $W\gamma$ control sample for which the requirement on isolation energy has been removed. Isolation-energy distribution templates for true photons and for jets misidentified as photons are developed in the manner described for the photon + $j$ analysis. A fit is then performed on the isolation-energy distribution of the extended $W\gamma$ control sample to estimate the number of events in the isolated (isolation energy less than 5 GeV) $W\gamma$ CR that arise from jets misidentified as photons. A scale factor is defined as the ratio of the estimated number of events in the isolated $W\gamma$ CR arising from misidentified jets to that expected from the $W + j$ and semileptonic $t\bar{t}$ MC simulations. A data-driven estimate of the number of events arising from misidentified jets in SR$_{e}$ and SR$_{\mu}$ is then derived by multiplying the number of such events expected from the combination of the $W + j$ and semileptonic $t\bar{t}$ MC simulations by this scale factor. Because the MC simulation is relied upon to propagate the background estimate from the control sample into the SR, uncertainties on the jet-to-photon misidentification background arise due to imprecise knowledge of the proton PDFs and strong-interaction scale. An additional uncertainty is assigned based on the difference between the scale factors determined for the separate electron and muon samples.

A final significant source of background is expected to arise from $t\bar{t}$ events, single-top events, and events containing two electroweak bosons that produce two final-state leptons, one of which is an electron that is subsequently misidentified as a photon. The contribution from these backgrounds is estimated from MC simulation, applying a correction based on the relative electron-to-photon misidentification rate between data and MC simulation. This correction is determined from $Z\to e^+e^-$ events as described above for other analyses. In addition to the uncertainty in the measurement of the misidentification rate, uncertainties in the estimate arise from PDF and scale uncertainty in the $t\bar{t}$ production process as well as an
TABLE VIII. The expected and observed numbers of events for the two photon + $\ell$ signal regions. The quoted errors are the combined statistical and systematic uncertainties. The contribution from the $Z\gamma$ process arises from events for which one of the leptons from the $Z \rightarrow \ell^+\ell^-$ decay is either missed or badly mismeasured. The likelihood of this occurring is significantly greater for muons than electrons.

The product of acceptance times efficiency tends to be greatest (10%–25%) when the masses of both the produced and the NLSP states are largest, leading to large amounts of both visible energy and missing transverse momentum that would clearly distinguish signal from background events. However, for the lower accessible mass scales associated with electroweak production, and particularly for the case of a low-mass NLSP, the product of acceptance times efficiency can be significantly smaller. For example, for the region relevant to establishing limits at low values of $\mu$, the efficiency of the $SR_L^\gamma$ analysis is less than 0.1%, leading to a relatively modest lower limit on the mass of produced SUSY states.

Making use of a bootstrap method \cite{77}, the efficiencies of both the single photon and diphoton triggers are determined to be greater than 99%, with an uncertainty of less than 1%.

The reconstruction efficiency for tight, isolated photons is estimated with complementary data-driven methods \cite{78}. Photons identified kinematically as having come from radiative decays of a $Z$ boson ($Z \rightarrow \ell^+\ell^-\gamma$) are used to study the photon reconstruction efficiency as a function of $p_T$ and $\eta$. Independent measurements making use of a tag-and-probe approach with $Z\rightarrow ee$ events, with one of the electrons used to probe the calorimeter response to electromagnetic depositions, also provide information about the photon reconstruction efficiency. For photons with $E_T > 75$ GeV, the identification efficiency in the range $0 < \eta < 1.81$ is greater than 95%; for the range $1.81 < \eta < 2.37$ the efficiency is approximately 90%. The uncertainty in the efficiency also varies with $|\eta|$, and lies between $(-1-2)\%$.

The isolated electron efficiency is also estimated using tag-and-probe methods, making use of samples of $Z \rightarrow ee$ and $J/\psi \rightarrow ee$ events as described in Refs. \cite{62,63}. The efficiency and its uncertainty are estimated as a function of electron $p_T$ and $\eta$, leading to an overall uncertainty of $\pm 1.0\%$ on the efficiency of the photon + $\ell$ analysis, the only analysis that explicitly requires an electron. The muon identification uncertainty, estimated as described in Ref. \cite{65}, is found to contribute an uncertainty of only $0.4\%$ on the efficiency of the photon + $\ell$ analysis.

In portions of the GGM parameter space, uncertainties that vary across the parameter space dominate the systematic uncertainty on the signal acceptance times efficiency. These model-dependent uncertainties include those due to uncertainties in the photon, electron and jet-energy scales, the $b$-jet tagging efficiency, and the “pileup” uncertainty arising from the modeling of additional interactions in the same or nearby bunch crossings.

The electron and photon energy scale is determined using samples of $Z \rightarrow ee$ and $J/\psi \rightarrow ee$ events \cite{79}, both of whose masses are known precisely and thus provide an accurate calibration signal for determination of the electromagnetic calorimeter response. Uncertainties arise from
imprecise knowledge of the material burden between the IP and the face of the EM calorimeter. The muon energy scale and uncertainty are similarly estimated with calibration samples of $Z \rightarrow \mu\mu$, $T \rightarrow \mu\mu$ and $J/\psi \rightarrow \mu\mu$ events [65].

The jet-energy scale is established via the propagation of single-particle test-beam measurements of the calorimeter response through simulations of jets arising from $pp$ collisions [67,80]. The jet-energy scale uncertainty is constrained by the study of momentum imbalance in dijet events [81], as well as from an assessment of the effect of uncertainties in the modeling of jet properties with MC simulations, and from uncertainties in the modeling of the varying response to differing jet flavor composition.

Uncertainties in the values of whole-event observables, such as $E_T^{miss}$ and $H_T$, arise from uncertainties on the energy of the underlying objects from which they are constructed. In addition, the $E_T^{miss}$ observable receives a contribution from calorimetric energy deposits not associated with any of the reconstructed objects in the event. Uncertainties on the energy scale of these unassigned contributions are found to contribute negligibly to the overall uncertainty on the value of the $E_T^{miss}$ observable.

The uncertainty due to pileup is estimated by varying the distribution of the number of interactions per bunch crossing overlaid in the simulation by $\pm 10\%$. The uncertainty on the $b$-tagging efficiency in the MC simulation is estimated from measurements of dedicated heavy-flavor calibration data samples.

In the regions of GGM parameter space relevant for establishing the exclusion limits discussed below, and excepting MC statistical uncertainty, the quadrature sum of the individual sources of systematic uncertainty on the signal reconstruction efficiency for the diphoton, photon + $b$ and photon + $\ell$ analyses is of order 10%. For the photon + $j$ analysis the systematic uncertainty is somewhat larger—approximately 20%—due to an increased sensitivity to the jet-energy scale and resolution associated with the multiple-jet requirement.

IX. RESULTS

An accounting of events observed in each SR is shown in Table IX, along with the size of the expected SM background. Comparisons of the $E_T^{miss}$ distribution between signal and expected background is shown for several different SRs in Figs. 5–7. No evidence for physics beyond the SM is observed in any of the SRs. The largest excess relative to the expected background is observed for the $\gamma\gamma$ SR analysis; considering both statistical and systematic uncertainty, and assuming that all observed events are from SM sources, an observation of five or more events over an expected background of $2.04^{+0.82}_{-0.75}$ represents an upward fluctuation with a probability of occurrence of approximately 6%.

### Table IX. Summary of the number of events expected from SM sources ($N_{SM}$), and the observed number of events ($N_{obs}$), for each of the ten SRs. Also shown is the derived model-independent 95% CL limit ($S_9^{obs}$) on the number of possible events from new physics, as well as both the observed ($\langle \sigma \epsilon \rangle^{95}_{obs}$) and expected ($\langle \sigma \epsilon \rangle^{95}_{exp}$) 95% CL limit on the visible cross section from new physics. Due to the discrete nature of the number-of-observed-events likelihood distribution in background-only pseudo-experiments, when both the expected number of background events and its uncertainty are close to zero the expected limit is dominated by the case of zero observed events. This leads to a very narrow one-standard-deviation range for the expected limit for $SR^{\gamma\gamma}_{W-L}$ and $SR^{\gamma\gamma}_{W-H}$.

Based on the numbers of observed events in the ten SRs and the background expectation shown in Table IX, 95% confidence-level (CL) upper limits are set for each SR on the number of events from any scenario of physics beyond the SM, using the profile likelihood and CL$_s$ prescriptions [82]. Uncertainties on the background expectations are treated as Gaussian-distributed nuisance parameters in the maximum-likelihood fit. Assuming that no events due to physical processes beyond those of the SM populate the various CRs used to estimate SR backgrounds, observed 95% CL limits on the number of such events vary between 3.0 (for the $SR^{\gamma\gamma}_{W-L}$ and $SR^{\gamma\gamma}_{W-H}$ SRs) and 14.2 (for the $SR^{\gamma\gamma}$ SR). Taking into account the integrated luminosity of $20.3 \pm 0.6$ fb$^{-1}$ these number-of-event limits translate into 95% CL upper limits on the visible cross section for new physics, defined by the product of cross section, branching fraction, acceptance and efficiency for the different SR definitions. Correspondingly, the observed visible cross-section limits vary between 0.15 and 0.70 fb.

By considering, in addition, the value and uncertainty of the acceptance times efficiency of the selection requirements associated with the various SRs, as well as the NLO (+NLL) GGM cross sections [33–37], which vary steeply with gluino and gaugino mass, 95% CL lower limits may be set on the masses of these states in the context of the various GGM scenarios explored in this study. For the diphoton, photon + $b$ and photon + $\ell$ analysis, the SR with...
the best expected sensitivity at each simulated point in the parameter space of the corresponding GGM model(s) is used to determine the degree of exclusion of that model point. For the photon + $\ell'$ analysis, the 95% CL exclusion limits are derived from the combined likelihood of the electron and muon channels, taking into account the correlation between the systematic uncertainty estimates in the two channels.

For the diphoton analysis, SR$^{\gamma\gamma}_{S-H}$ is expected to provide the greatest sensitivity to the gluino-bino model for bino...
FIG. 7 (color online). (Left) $E_T^{\text{miss}}$ distribution for the sample surviving all SR$^\ell_\gamma$ requirements except the $E_T^{\text{miss}}$ requirement itself. Overlaid are the expected SM backgrounds as a function of $E_T^{\text{miss}}$, separated into the various contributing sources. Also shown are the signal expectations for the two points in the $M_3 - \mu$ parameter space of the GGM model relevant to the photon + $j$ analysis. (Right) $E_T^{\text{miss}}$ distribution for the combined sample of events surviving all SR$^\mu_\gamma$ and SR$^\ell_\gamma$ requirements except the $E_T^{\text{miss}}$ requirement itself. Overlaid are the expected SM backgrounds as a function of $E_T^{\text{miss}}$, separated into the various contributing sources. Also shown is the signal expectation for the $m_{\tilde{g}}$ = 300 GeV GGM model relevant to the photon + $\ell$ analysis. For both figures, the lower plot shows the ratio of observed data to the combined SM expectation, with the inner band representing the range of statistical uncertainty and the outer band the combined statistical and systematic uncertainty. Events outside the range of the displayed region are included in the highest-valued bin.

FIG. 8 (color online). Exclusion limits in the gluino-bino mass plane, using the SR$^\gamma\gamma_{5-6}$ analysis for $m_{\tilde{g}} \geq 800$ GeV and the SR$^\gamma\gamma_{4-6}$ analysis for $m_{\tilde{g}} < 800$ GeV. Combinations of gluino and bino mass are excluded at 95% CL in the area below the unbroken curve. The observed limits are exhibited for the nominal SUSY model cross-section, as well as for a SUSY cross section increased and decreased by 1 standard deviation of the cross-section systematic uncertainty. Also shown is the expected limit, as well as the ±1 and ±2 standard-deviation ranges of the expected limit.

masses above 800 GeV and SR$^\gamma\gamma_{4-6}$ for bino masses below this. For the wino-bino model, the similar transition point between the use of SR$^\gamma\gamma_{4-6}$ and SR$^\gamma\gamma_{5-6}$ is found to be at 350 GeV. The resulting observed limits on the gluino and wino masses are exhibited, as a function of bino mass, for the diphoton analysis gluino and wino production models in Figs. 8 and 9, respectively. For the purpose of establishing these model-dependent limits, for all four diphoton SRs both the normalization of the $W(\rightarrow \ell\nu) + \gamma\gamma$-background estimate and the limit on the possible number of events from new physics are extracted from a simultaneous fit to the SR and $W(\rightarrow \ell\nu) + \gamma\gamma$ control region, although the signal contamination in the $W(\rightarrow \ell\nu) + \gamma\gamma$ control sample is appreciable only for the low-bino-mass region of the wino-bino parameter space. Also shown for these two figures, as well as for the following two figures (Figs. 10 and 11), are the expected limits, including their statistical and background uncertainty ranges, as well as observed limits for SUSY model cross sections ±1 standard deviation of theoretical uncertainty from their central value. Conservatively choosing the −1 standard-deviation observed contour, 95% CL lower limits of 1290 and 590 GeV are set by the diphoton analysis on the value of the gluino or wino mass, respectively, for
any value of the NLSP bino mass less than that of the gluino (wino) mass.

Due to the discrete nature of the number-of-observed-events likelihood distribution in background-only pseudoexperiments, when both the expected number of observed events and its uncertainty are close to zero, the expected limit is dominated by the case of zero observed events. This leads to a very narrow one-standard-deviation range for the expected limit, as observed for the expected-limit contour displayed in Fig. 8. In addition, because the observed number of events is very close to the expected number of events for $S_{\gamma\gamma}^{\mu}$ and $S_{\gamma\gamma}^{\mu}$, the expected and observed limits are nearly identical in Fig. 8.

For the photon $+j$ analysis, limits are set in the two-dimensional plane of the GGM parameters $\mu$ and $M_3$ for the higgsino-bino GGM model with a positive value of the $\mu$ parameter. For values of $\mu$ near the 95% CL exclusion contour, $S_{\gamma\gamma}^{\mu}$ is expected to provide a greater sensitivity for NLSP masses below approximately 900 GeV, and so is made use of in this region; above that, $S_{\gamma\gamma}^{\mu}$ is used to establish the degree of exclusion of GGM model-space points. The resulting observed exclusion contour is shown in Fig. 11. Again choosing the $-1$ standard-deviation observed contour, in the context of this GGM model a conservative lower limit of 1140 GeV is established for the gluino mass parameter $M_3$ over much of the range of the $\mu$ parameter. For values of $M_3$ close to the value of $\mu$ for which the gluino mass approaches that of the higgsino-bino NLSP, the sensitivity of the analysis lessens due to the restriction of phase space for producing multiple high-$p_T$ jets.

For the photon $+\ell$ analysis, a limit is set on the wino mass, the single free parameter of the wino-NLSP model. Figure 12 shows the observed limit on the cross section for wino production in this model, as well as the corresponding expected limit with $\pm 1$ and $\pm 2$ standard-deviation uncertainty bands. Also shown is the cross section as a function of wino mass, with its $\pm 1$ standard-deviation range. In the context of this wino-NLSP model, conservatively choosing the $-1$ standard-deviation cross-section exclusion contour leads to an
the wino mass parameter $M_{\tilde{W}}$ < 361 GeV; for $M_{\tilde{W}}$ < 124 GeV the signal contamination in the $W\gamma$ CR becomes too large to permit a reliable estimate of the $W\gamma$ background. These limits are based on the direct production of the wino NLSP in the limit where squark masses are infinite, and are independent of gluino mass.

**X. CONCLUSION**

Making use of 20.3 fb$^{-1}$ of $pp$ collision data at $\sqrt{s} = 8$ TeV recorded by the ATLAS detector at the LHC, a search is performed for photonic signatures of new physics associated with significant $E_T^{\text{miss}}$. Four experimental signatures are explored, each involving at least one energetic isolated final-state photon in association with significant $E_T^{\text{miss}}$, and used to search for evidence for several GGM SUSY scenarios. No significant excess of events over the SM expectation is observed in any of the searches and so limits are set on possible contributions of new physics. Model-independent limits are set on the numbers of events from new physics and the associated visible cross section. Model-dependent limits are set on the masses of SUSY particles or on mass parameters associated with the various GGM scenario models.

A diphoton signature is used to explore both strongly and weakly produced SUSY states with a decay chain proceeding through a binolike NLSP. In the context of these models, lower limits of 1290 and 590 GeV are set on the masses of a degenerate octet of gluinos and a degenerate set of winos, respectively, for any value of the bino mass less than the mass of these produced states. A photon-plus-$b$-jet signature is used to search for a scenario in which the GGM NLSP is a higgsino-bino admixture with a roughly equal branching fraction to photons and to the SM Higgs boson. In the context of this model, a lower limit of 1260 GeV is established for the gluino mass over much of the range of the higgsino-bino NLSP mass; for NLSP masses below approximately 450 GeV, the onset of the direct production of gaugino states makes the analysis insensitive to the value of the gluino mass. A photon-plus-jet signature is used to search for an alternative scenario for which the GGM NLSP is a higgsino-bino admixture with a roughly equal branching fraction to photons and to the SM Z boson. In the context of this model, a lower limit of 1140 GeV is established for the gluino mass parameter $M_{\tilde{G}}$ over much of the range of the higgsino mass parameter $\mu$. Finally, a photon-plus-lepton signature is used to search for a scenario for which the GGM NLSP is a degenerate set of three wino states. Based on the possible direct production of these states, in the limit of infinite squark mass GGM winos are excluded in the range $124 < M_{\tilde{W}} < 361$ GeV, independent of the gluino mass.

**ACKNOWLEDGMENTS**

We thank CERN for the very successful operation of the LHC, as well as the support staff from our institutions without whom ATLAS could not be operated efficiently.
We acknowledge the support of ANPCyT, Argentina; YerPhI, Armenia; ARC, Australia; BMWF and FWF, Austria; ANAS, Azerbaijan; STSC, Belarus; CNPq and FAPESP, Brazil; NSERC, NRC and CFI, Canada; CERN; CONICYT, Chile; CAS, MOST and NSFC, China; COLCIENCIAS, Colombia; MSMT CR, MPO CR and VSC CR, Czech Republic; DNkRF, DNSRC and BNR, Denmark; EPLANET, ERC and NSRF, European Union; IN2P3-CNRS, CEA-DSM/IRFU, France; GNSF, Georgia; BMBF, DFG, Helmholtz Association, MPG and AvH Foundation, Germany; INFN, Italy; MEXT and JSPS, Japan; GUSTO, Korea; CNRST and NSRF, Greece; RGC, Hong Kong SAR, Research Grants Council, Hong Kong, China; ISF, MINERVA, GIF, I-CORE and Benoziyo Center, Israel; INFN, Italy; MEXT and JSPS, Japan; CNRST, Morocco; FOM and NWO, Netherlands; BRF and RCN, Norway; MNiSW and NCN, Poland; GRICES and FCT, Portugal; MNE/IFA, Romania; MES of Russia and NRC KI, Russian Federation; JINR; MSTD, Serbia; MSSR, Slovakia; ARRS and MIZŠ, Slovenia; DST/NRF, South Africa; MINECO, Spain; SRC and Wallenberg Foundation, Sweden; SER, SNSF and Cantons of Bern and Geneva, Switzerland; NSC, Taiwan; TAEK, Turkey; STFC, the Royal Society and Leverhulme Trust, U.K.; DOE and NSF, U.S. The crucial computing support from all WLCG partners is acknowledged gratefully, in particular from CERN and the ATLAS Tier-1 facilities at TRIUMF (Canada), NDGF (Denmark, Norway, Sweden), CC-IN2P3 (France), KIT/GridKA (Germany), INFN-CNAF (Italy), NL-T1 (Netherlands), PIC (Spain), ASGC (Taiwan), RAL (U.K.) and BNL (U.S.) and in the Tier-2 facilities worldwide.
