We investigate the degradation of the magnetic moment of a 300 nm thick FePt film induced by Focused Ion Beam (FIB) milling. A 1 μm × 8 μm rod is milled out of a film by a FIB process and is attached to a cantilever by electron beam induced deposition. Its magnetic moment is determined by frequency-shift cantilever magnetometry. We find that the magnetic moment of the rod is \( \mu = 1.1 \pm 0.1 \times 10^{-12} \) Am\(^2\), which implies that 70\% of the magnetic moment is preserved during the FIB milling process. This result has important implications for atom trapping and magnetic resonance force microscopy, which are addressed in this paper. © 2015 AIP Publishing LLC.

The fabrication and characterization of micron sized permanent magnets are necessary for a broad range of applications such as magnetic tweezers, imaging, and atom trapping with chips. These chips are planar structures that generate magnetic fields, which are widely used to control ultra-cold atoms. The incorporation of permanent magnets in atom chips offers several advantages over the use of current carrying wires, they dissipate no heat and allow more complex trap shapes. Moreover, permanent magnets can create larger field gradients, which facilitate tighter confinement of atoms, resulting in shorter time scales in trapping experiments. This does require the magnets to be patterned on small length scales. One of the materials currently under investigation is FePt in its L1\(_0\) phase, a corrosion resistant material with high magnetocrystalline anisotropy. FePt atom traps that are currently in use are made by optical lithography and plasma etching. The currently used patterns have length scales on the order of 10 μm.

Micron sized magnets can also be used as a field gradient source for a magnetic resonance force microscopy (MRFM). This is a technique that uses a small magnet mounted on an ultrasonic cantilever to measure the magnetic interaction with spins in a sample underneath the cantilever. It thereby combines the advantage of elemental specificity of conventional Magnetic Resonance Imaging (MRI) techniques with the local and very sensitive probing techniques of Atomic Force Microscopy (AFM). Required properties for MRFM magnets are high magnetocrystalline anisotropy and a large remanent field. Small dimensions of the magnet are beneficial too, as they result in large magnetic field gradients, which increase the sensitivity of measurements. These requirements are similar to the requirements for atom traps and are all fulfilled by the aforementioned FePt.

One of the techniques to pattern FePt films is to use a Focused Ion Beam (FIB). However, FIB milling can damage the film, possibly degrading the magnetic properties. Examples of such damage include implantation of ions and other ion beam induced alterations to the crystal structure. Determining the magnetic moment after FIB exposure is crucial for applications in both atom trapping and MRFM experiments.

In this letter, the damage caused by FIB milling on a FePt film is quantified by measuring the magnetic moment of a micron sized rod, which has been milled out of the film, and comparing it to the expected magnetic moment calculated from its volume and its remanent field. The rod is attached to a cantilever, and its magnetic moment is determined by cantilever magnetometry, a sensitive technique to determine small magnetic moments. We demonstrate that FIB milling is a suitable way to shape magnetic films for atom trapping experiments and to prepare probes for MRFM.

The 300 ± 10 nm thick FePt film has been made at the Almada Research Center of Hitachi. Films of FePt have been sputtered on a Si substrate with a thin RuAl underlayer and a Pt interlayer at a temperature of 400 °C. This growth process leads to FePt in its L1\(_0\) phase, which has a particularly high out-of-plane magnetization.

As a first step to create rods, an indentation in the edge of the film is made with a FIB (Ga\(^+\)-ions, 30 keV, 7 nA ion current, Strata 235 Dual Beam from FEI). The edge is then crenelated (Fig. 1(a)) (ion current 500 pA), and rods are created in the sides of the crenels (Fig. 1(b)). The dimension of the rods is 8.1 μm in length, 1 μm in width, and 1 μm in height (consisting of 300 nm FePt and 700 nm substrate). The sample is rotated by 90° to remove the material underneath the rods. The geometry facilitates the access necessary to mount a rod onto a cantilever.

The FePt film and a cantilever (a single-crystalline silicon beam) are then placed on two stages of an in-house developed nanomanipulator inside a Scanning Electron Microscope.

FIG. 1. Fabrication of rods at the edge of a FePt film sputtered on a Si wafer: (a) crenelation of the edge, (b) five rods at the end of the FIB process. The material has been milled from two perpendicular directions, see arrows.

Microscope (NanoSEM 200 from FEI, USA). Using the nanomanipulator, we bring the cantilever in contact with a FePt rod (Fig. 2(a)). Subsequently, fixation is achieved by an electron beam induced deposition process with Pt(PF3)4 as a precursor gas. The last connection between the rod and the film is broken by suddenly retracting the cantilever. The finished assembly of the cantilever and the rod is shown in Figs. 2(b) and 2(c).

Prior to the fabrication of the rods, the magnetization loop has been measured for a film of size 3 mm × 3 mm × 300 nm in a SQUID magnetometer (Quantum Design MPMS-5 S). The measurement has been performed at room temperature in two different geometries (Fig. 3): with an in-plane and an out-of-plane external field \( \mathbf{H} \). The remanent magnetization is \( \mu_0 M = 0.76 \pm 0.03 \) T for the out-of-plane geometry, while it is \( \mu_0 M = 0.50 \pm 0.03 \) T for the in-plane geometry. In Fig. 3, the remanent magnetic moment shows negligible dependence on the external magnetic field. This is expected for FePt, as the coercivity increases when the lateral size decreases.\(^{20}\) Therefore, the external field used in the cantilever magnetometry experiment should not affect the magnetic moment of the rod.

The rods are magnetized in a 3 T field at room temperature along the out-of-plane direction (i.e., along the direction of motion of the cantilever), to achieve a higher remanent field.

Subsequently, dynamic-mode cantilever magnetometry is performed at room temperature at a pressure of \( 10^{-5} \) mbar. The external magnetic field is provided by a Helmholtz coil of approximately 300 turns, generating magnetic fields up to 2 mT. The external magnetic field points along the direction of motion of the cantilever. To determine the magnetic moment \( \mu \) of the rod, the resonance frequency is measured as a function of magnetic field strength. A fiber optic interferometer working at a wavelength of 1550 nm is used to detect the cantilever motion. The resonance frequency is determined by fitting the thermal motion of the cantilever’s fundamental mode to a Lorentzian curve. A ring-down measurement, shown in Fig. 4(b), provides a more accurate measure of the quality factor \( Q \).

The resonance frequency as a function of magnetic field is shown in Fig. 4(a). For the low magnetic field regime, the frequency shift \( \Delta f \) as a function of magnetic field \( \mathbf{H} \) is given by\(^{21}\)

\[
\Delta f = \frac{f_0}{2\pi} \left( \frac{2\pi}{\gamma} \right)^2 \mu \mu_0 H, \quad (1)
\]

where \( f_0 \) is the resonance frequency in the absence of a magnetic field, \( l = 200 \) \( \mu \)m is the length of the cantilever, \( \gamma = 1.377 \) is a constant factor derived for beam cantilevers, and \( k = 3.3 \pm 0.2 \times 10^{-5} \) N/m is the stiffness of the cantilever, determined by the “added-mass method.”\(^{22}\)

Making use of Eq. (1), the magnetic moment of the cantilever is deduced to be \( \mu = 1.1 \pm 0.1 \times 10^{-12} \) Am\(^2\). Given the remanent magnetization of the FePt film and the volume of the magnet of \((1.00 \pm 0.02) \mu \text{m} \times (8.10 \pm 0.02) \mu \text{m} \times (0.30 \pm 0.01) \mu \text{m}\), we would have expected a magnetic moment of \( \mu = 1.5 \pm 0.1 \times 10^{-12} \) Am\(^2\), if the magnet
Concerning atom trapping, the factor limiting the resolution of FePt traps created by optical lithography and plasma etching is the redeposition of the etched material, the magnetic properties of which are unknown.\textsuperscript{28} SEM images show that this redeposition can be of the order of several hundreds of nanometers. From SEM images made after FIB milling, we conclude that for the FePt rods described in this paper redeposition of FePt is negligible compared to the loss of magnetic volume caused by the FIB milling process. Furthermore, the damage induced can possibly be reduced by using a helium FIB. Hence, FIB milled patterns could have an advantage over the patterns created by optical lithography and plasma etching, when aiming for trap sizes on the order of a micrometer.\textsuperscript{29,30} For the formation of such traps, a better understanding of the shape of the damaged region of magnetic films would be needed. FIB milling of FePt will probably not suffice to go to an atom trap scale of the order of 100 nm. Electron beam lithography is the most suitable technique when aiming for submicrometer sizes.\textsuperscript{29} This method is currently used in various groups.

We have shown a fabrication process for micrometer size FePt magnets by FIB milling and a way to attach these magnets to ultrasmall cantilevers by electron beam induced deposition. This technique could, in principle, be used for any magnetic film. From cantilever magnetometry measurements, we conclude that 60\%-80\% of the magnetic moment is preserved during the FIB milling process. FIB milled magnets could, therefore, be used in atomic trapping experiments when aiming for a trap size on the order of a micrometer. The magnet attached to the cantilever can be used as a probe in MRFM experiments. The small dimensions of the magnet are expected to improve the sensitivity of MRFM.
