Combined in situ x-ray photoemission spectroscopy, scanning tunneling microscopy, and angle resolved photoemission spectroscopy of molecular beam epitaxy grown Bi$_2$Te$_3$ on lattice mismatched substrates reveal high quality stoichiometric thin films with topological surface states without a contribution from the bulk bands at the Fermi energy. The absence of bulk states at the Fermi energy is achieved without counterdoping. We observe that the surface morphology and electronic band structure of Bi$_2$Te$_3$ are not affected by in vacuo storage and exposure to oxygen, whereas major changes are observed when exposed to ambient conditions. These films help define a pathway towards intrinsic topological devices.

I. INTRODUCTION

Topological insulators (TIs) are materials with an insulating bulk interior and spin-momentum-locked metallic surface states as a result of a band inversion from large spin-orbit interaction [1,2]. Bismuth telluride (Bi$_2$Te$_3$) is one of the 3D TI materials that has received a considerable amount of attention as a potential candidate for room temperature spintronics and quantum computational devices [3]. However, despite significant progress in bulk preparation techniques of TI materials, growing high-quality bulk Bi$_2$Te$_3$ crystals with a low number of defects and without shunt conduction through the bulk of the material is still a major challenge. The bulk carrier conduction complicates the direct exploitation of the remarkable properties of TI surfaces.

Molecular beam epitaxy (MBE) is an established method for growing high-quality crystalline thin films of TIs with surface-dominated conduction [4–6]. Using this technique, it has been possible to prepare thin films that are insulating in the bulk. By varying the growth parameters and using substrates with negligible lattice mismatch, bulk insulating thin films of Bi$_2$Te$_3$ have been synthesized [7–9]. It would be good, on the other hand, to investigate the growth mode of high quality intrinsic Bi$_2$Te$_3$ films on lattice mismatched substrates and especially on insulating substrates (with high relative dielectric constant), as these offer the prospect of strong, gate-induced modulation of the sample’s carrier density [10].

One of the current challenges, though, for realizing TI devices is that grown films are often exposed to air during mounting of contacts or subsequent device fabrication steps. This leads to possible shifts of the Fermi level which result in enhanced bulk conductance [11,12]. To date, it is not well understood how ex situ contamination processes affect surface and bulk states of Bi$_2$Te$_3$ films so that precautions can be taken before taking them ex situ for further investigations. Recently, it was shown for bulk-insulating Bi$_2$Te$_3$ films that pure oxygen exposure, at low pressure (10$^{-6}$ mbar) has no significant influence on their charge transport properties [9]. Nevertheless, since most magnetotransport studies and fabrication processes are carried out in ambient conditions, it is good to understand the impact of oxygen at atmospheric pressure, exposure to air and other ex situ contaminations. For these investigations, it is necessary to have high quality films since their inertness to oxidation, for example, depends on the amount of surface defects and grain boundaries.

In this work, we first focus on optimizing our growth procedure in order to realize bulk insulating films grown on lattice mismatched [13] insulating substrates (Al$_2$O$_3$[0001] and SrTiO$_3$[111]). Secondly, we perform a systematic in situ characterization to investigate the effect of aging/degradation due to any vacancies or antisite defects for films stored in vacuo. Thirdly, our in situ angle resolved photoemission spectroscopy (ARPES) experiments clearly reveal topological Dirac surface states, consistent with a linear increase in the density of states (DOS) measured by in situ scanning tunneling microscopy. Lastly, we study the effect of pure oxygen exposure at atmospheric pressure; and then the effect of ex situ contamination in air. We use x-ray photoemission spectroscopy (XPS) for the characterization and detection of any Te/Bi excess in our films, and we employ low temperature scanning tunneling spectroscopy (STS) to acquire differential conductivity spectra for samples kept in situ, then exposed to pure oxygen at atmospheric pressure and later to air. Our STS analysis is further confirmed by in situ ARPES investigations at low temperature and room temperature for samples kept in situ and later exposed to ambient conditions.

Our spectroscopy data (STS and ARPES) reveal that the as-grown Bi$_2$Te$_3$ films on lattice mismatched insulating substrates possess an intrinsically topological electronic structure, meaning that the Fermi level only crosses the topologically nontrivial metallic surface states. This is achieved without any counterdoping. Combining in situ and ex situ spectroscopy and topography data, we find that in situ storage in ultrahigh vacuum and (short) exposure to pure oxygen at atmospheric pressures leave the band structure at the surface unaffected, whereas breaking vacuum and exposing the sample surface to air results in notable changes in the surface band structure spectra and topography of the films.

II. FILM GROWTH AND CHARACTERIZATION

Thin films of Bi$_2$Te$_3$ were grown on c-plane sapphire Al$_2$O$_3$[0001] and SrTiO$_3$[111] (STO) substrates using MBE by coevaporating high purity Te (99.999%) and Bi (99.999%)...
in a Te rich environment. The base pressure in the deposition chamber was lower than $5 \times 10^{-10}$ mbar. During deposition, the flux ratio Te/Bi was kept at about 10, the growth rate at $\sim 4 \, \text{Å/min}$, and the highest pressure recorded was $2.8 \times 10^{-8}$ mbar. Before introducing the sapphire substrates in the MBE chamber, they were cleaned with acetone and ethanol in an ultrasonic bath, then annealed at 1050 °C for 1 h at atmospheric conditions. This cleaning procedure resulted in straight step edges and atomically flat terraces at the substrate surface, with a width of $\sim 150$ nm. For the STO [111] substrates, to achieve atomically flat surfaces before loading them into the MBE chamber, we used a method similar to that reported in Refs. [14,15]. In order to avoid disordered interfacial layers at the interfaces between our films and the substrate, we used a two-step temperature growth scheme [16,17], which results in atomically sharp interfaces between the TI film and the substrate. The first nucleation layer was deposited at a temperature of 190 °C, then slowly annealed to higher growth temperature of 230 °C in order to improve the crystalline quality. The annealed layer was then used as a template for subsequent epitaxial growth of the second layer. Compared to films grown in a one-step temperature scheme, we observe a much better quality for the two-step growth procedure in terms of a flat morphology, and considerably reduced number of 3D growth defects. Similar significant reduction of 3D structure density has also been reported recently on two-step grown Bi$_2$Te$_3$ films [17]. To further improve the surface smoothness and quality of the films, we continued to anneal at 230 °C for an additional 30 min; then cooled down to room temperature at a rate of 3 °C/min. This growth procedure yields high quality Bi$_2$Te$_3$ films. Using this growth procedure, we present in this study spectroscopy data of two samples of 30 and 20 nm grown on Al$_2$O$_3$[0001] and one 15 nm film grown on SrTiO$_3$ [111].

After growth, samples were characterized in situ using XPS to investigate the surface elemental composition and stoichiometry. Samples were transferred to XPS without breaking ultrahigh vacuum (UHV) conditions since the XPS system is connected to the growth chamber via a distribution chamber. The UHV conditions of this system ensure that films are free from ex situ contamination. Figure 1(a) shows an in situ XPS scan, where only Bi and Te peaks are resolved with no appearance of extra peaks such as carbon and oxygen as often seen in films exposed to atmosphere [18–21] [see Fig. S2(a) in the Supplemental Material [22]]. This lack of other core level signatures is an indication of a clean surface, free from contaminations. The surface chemical stoichiometry was studied by fitting the area under the Te 3d$_{5/2}$, Te 3d$_{3/2}$ and Bi 4f$_{7/2}$, Bi 4f$_{5/2}$ peaks. The ratio is determined to be $1.49 \pm 0.05$. Figures 1(b) and 1(c) show these Te and Bi peaks, respectively, together with the Voigt function fits (after subtraction of Shirley background).

To further confirm the high crystalline quality of our Bi$_2$Te$_3$ films after in situ measurements (STM/STS and ARPES), we performed ex situ x-ray diffraction (XRD) measurements, which confirmed that the films were grown with in-plane and out-of-plane lattice constants $a = 4.34$ Å and $c = 30.41$ Å, respectively. These lattice parameters are consistent with values reported previously for Bi$_2$Te$_3$ films [17,25]. From XRD measurements of films grown on Al$_2$O$_3$[0001] and STO [111] substrates (see Fig. S3 in the Supplemental Material [26]), in the $2\theta$–$0\theta$ scan only substrate peaks and the (0 0 3) of diffraction peaks from the films are resolved, implying the films are aligned along the $c$ axis. From the rocking curves, the measured full width half maximum of the (0 0 6) peak are 0.0414° (for films grown on sapphire) and 0.0417° (for films grown on STO), confirming the excellent quality of our films. Despite the lattice mismatch between Bi$_2$Te$_3$ [001] and these substrates, smooth films had formed. This is because of the van der Waals epitaxy [6,27,28], which relaxes the lattice-matching condition required for most common epitaxial growth of covalent semiconductors and their heterostructures.

III. IN SITU SPECTROSCOPY

After in situ XPS measurements, samples were subsequently transferred to the low temperature STM chamber,
which is not connected to the growth chamber. The transfer was done using a UHV suitcase equipped with a nonevaporable getter (NEG) pump [29] together with an ion pump. During the transfer process, the pressure remained lower than $2 \times 10^{-9}$ mbar. Once samples were transferred to the STM, its UHV conditions (in the $10^{-12}$ mbar range) ensured that the film surface remained free from collecting further adsorbates for months. The in situ STM/STS data were acquired at 77 K. Many topography and spectroscopy maps were taken at random positions on the surface of the film at a bias voltage and set-point current of $+350$ mV and 1 nA. The results were consistent with previously published STM studies on Bi$_2$Te$_3$ [30–32]. Figure 2(a) shows a typical STM image of the atomically smooth Bi$_2$Te$_3$ surface. The corresponding height profile across the surface is plotted in Fig. 2(b). The step height of adjacent terraces is 10.3 Å. This value is consistent with one quintuple layer (QL) of Bi$_2$Te$_3$ since its stacking sequence of adjacent terraces is 10.3 Å, corresponding to the tellurium-terminated surface of Bi$_2$Te$_3$. The interatomic spacing of these tellurium atoms was determined to be 4.3 Å, corresponding to the tellurium-terminated surface in Bi$_2$Te$_3$. No surface adatoms were observed, which is an indication of a clean surface of our high quality thin films.

Now, we present spectroscopy data of Bi$_2$Te$_3$ films. Figure 3(a) shows low temperature differential conductivity curves of a 30 nm film grown on sapphire measured after one day in the STM chamber (blue line), after 6 weeks in situ storage (green), and later after being oxidized for 10 min in 1 atm., pure O$_2$ (red). The spectra were obtained by numerical differentiation of many $I-V$ curves [33] with set point parameters of $V_0 = +350$ mV at $I = 1$ nA. In this figure, $E_{B-BCB}$ marks the bottom of the bulk conduction band, whereas $E_{T-BVB}$ the top of the bulk valence band. $E_F$ and $E_D$ correspond to the Fermi level and Dirac point, respectively. $E_{B-BCB}$ and $E_{T-BVB}$ are determined by the point where additional states appear with respect to the surface states, and by taking a literature value of $\sim 210$ meV for the band gap of Bi$_2$Te$_3$ [24,34,35]. From these spectra, we find linearly increasing DOS, indicative of Dirac surface states residing in the bulk energy gap between the bulk conduction band (BCB) and bulk valence band (BVB). Since the Dirac point is located in the BVB, by extrapolating this linearly increasing DOS, the Dirac point is approximately at 0.23 eV below $E_F$. The linear part of the spectra exhibits a plateau appearing at around $\sim 50$ mV. This latter feature is often attributed to the hexagonal warping of the surface band in Bi$_2$Te$_3$ samples and has been seen before in STS spectra of Bi$_2$Te$_3$ thin films and single crystals [31,32,36]. A complete description of a cubic warping term in the Hamiltonian for the Dirac cone is given in Ref. [37], the main parameter being $\lambda$, which describes the strength of the hexagonal warping. When fitting the DOS of the warped Dirac cone to the kink feature in the data, we find that the warping alone is not strong enough (for reasonable parameter values) to explain the kink. Including a $k$-dependent tunneling probability, implying that the states with larger parallel momenta contribute less to the tunneling current [38], does not significantly improve the fit. However, from ARPES measurements along the $\Gamma$-$\bar{M}$ direction, it is known that the Dirac cone bends outwards, as visible also in ab initio calculations [41]. Tight binding models exist that incorporate this effect [2], and it can also be included in the Dirac Hamiltonian by including a small negative mass term. For reasonable parameter values (see details in the Supplemental Material [42]) that fit the ARPES dispersion curves well, a DOS was calculated as function of energy, shown in the inset of Fig. 3(a). These are the DOS from the Dirac cone alone. It is clear that the plateau feature can indeed be qualitatively understood on the basis of the outward bending of the Dirac cone along the $\Gamma$-$\bar{M}$ direction, and that it is not related to the bulk conduction band. These STS data are in agreement with previously published STS data on Bi$_2$Te$_3$ [31], and indicate that there are no bulk states present at the Fermi level.

To further confirm the presence of topological surface states without a contribution from the bulk bands at $E_F$ and also verify larger scale homogeneity of the surface states, we also performed ARPES measurements on Bi$_2$Te$_3$ films. After growth and XPS characterization (Fig. S1 in the Supplemental Material [43]), samples were stored in the UHV suitcase for three days and transferred to an ARPES setup. The pressure in the UHV suitcase remained lower than $2 \times 10^{-10}$ mbar throughout this procedure. Figure 3(b) shows a representative ARPES spectrum in the vicinity of the Fermi level of a 20 nm Bi$_2$Te$_3$ film grown on sapphire around the $\Gamma$ point. The spectra were taken at a temperature of $\sim 17$ K using a helium photon source of energy 21.2 eV. The characteristic V-shaped surface state is clearly observed, confirming the
presence of the topological Dirac cone surface state in our Bi$_2$Te$_3$ films. The white dashed line shows the position of the Fermi level, which lies well within the bulk band gap with no observable contribution of the bulk conduction band at the Fermi energy. The Fermi velocity is $\hbar v_F = 2.31 \pm 0.20$ eVÅ, which is consistent with previous ARPES studies [9,17] and theoretical calculations [2]. The Dirac point was measured to be at 0.24 eV below $E_F$, which is in good agreement with the STS measurements for the 30 nm thick Bi$_2$Te$_3$ film shown in Fig. 3(a) and previously published ARPES data [44]. The fact that there are no bulk bands at $E_F$ implies that electrical conduction in these films is only due to the surface states [45], which is desirable for electronic transport experiments.

Here, we emphasize that to stabilize the Fermi level in the band gap with no bulk bands at $E_F$, no counterdoping was necessary in our MBE-grown thin film samples. Counterdoping reduces the surface mobility and adds disorder in samples [15,45]. To show that we have a stable and reproducible procedure for obtaining bulk insulating Bi$_2$Te$_3$ samples, we have also grown our films on STO [111] substrates. Figure 4 depicts an illustrative ARPES $I(k,E)$ image from a 15 nm Bi$_2$Te$_3$ film grown on STO. The data from the film grown on STO substrate agree with those from films grown on sapphire in that the Fermi level is clearly situated in the bulk band gap. This finding also confirms that, despite large lattice mismatch between the film and the substrate [13], intrinsic Bi$_2$Te$_3$ films are grown. In particular, one can exploit these bulk insulating Bi$_2$Te$_3$ films grown on STO for fabrication of hybrid devices consisting of bottom gate-tunable topological insulator interfaced to either a superconductor or ferromagnet, by using STO [111] substrate as a back gate because it has a very high relative dielectric constant at low temperature [10].

To investigate the effect of UHV storage (at room temperature) and oxidation on the band structure of our Bi$_2$Te$_3$ films, we compare STS spectra of a film measured after one day in the STM chamber, with spectra taken after 6 weeks and after being oxidized for 10 min at 1 atm. The oxidation was performed in the load lock of the STM system, at atmospheric pressure. From all three traces in Fig. 3(a) it is remarkable to observe that even after keeping films in situ for weeks and

FIG. 3. (Color online) (a) STM spectroscopy measurements at 77 K on a 30 nm Bi$_2$Te$_3$ film (blue curve). Effect of storing films in situ at $P \sim 10^{-12}$ mbar for weeks (red curve) and exposing them to pure oxygen (green curve). The inset shows calculated density of states as function of energy from the Dirac cone alone. (b) ARPES $I(k,E)$ image around the $\Gamma$ point of a 20 nm Bi$_2$Te$_3$ film recorded at 17 K. The white dashed line indicates the position of the Fermi level, which is in the bulk band gap without bulk band contribution. Both samples were grown on sapphire.

FIG. 4. (Color online) ARPES spectra around the $\Gamma$ point of a 15 nm Bi$_2$Te$_3$ film grown on SrTiO$_3$ [111]. As was the case for the film grown on sapphire, for this sample only the topological surface states cross the Fermi level.
allowing them to interact with pure oxygen, no noticeable
degradation and no corresponding shifts in the STS spectra
take place. The overall key features: the linear surface band, the
plateau due to “warping,” and the position of the Fermi energy
relative to the bulk bands, remain unchanged. This observation
is further confirmed by the ARPES data shown in Fig. 3(b)
and Fig. 4 since these samples were measured after storage for
three days in the UHV suitcase ($P \sim 2 \times 10^{-10}$ mbar), and no
bulk conduction bands were observed. Aging effects have been
reported in ARPES data from bulk single crystals of $\text{Bi}_2\text{Te}_3$
within hours after cleavage under UHV conditions [34,46]. As
for our films, the surface is stable as long as they are kept in situ
in UHV conditions (see Fig. S6 in the Supplemental Material
[47]) or when exposed to pure oxygen. This conclusion is
consistent with recent in situ four-point probe conductivity,
angle resolved photoemission spectroscopy, and conductive
probe atomic force microscopy studies [9,48].

IV. EXTRINSIC DEFECTS

Next, we study the effect of exposure to ambient conditions.
This is relevant for the understanding of how ex situ contamination
processes affect surface and bulk states of $\text{Bi}_2\text{Te}_3$ films for future ex situ fabricated hybrid topological insulators devices.
For this investigation, we employ both STM/STS and ARPES
since they are complementary tools for probing reliably the
band structure of materials. Figure 5(a) depicts an ARPES
$I(k,E)$ image of the 20 nm $\text{Bi}_2\text{Te}_3$ film grown on sapphire.
This time, the sample was measured at room temperature before exposure to ambient conditions. This $I(k,E)$ image was
recorded after the sample had been in the ARPES chamber for 5 days, after measurement of the low-$T$ data shown in
Fig. 3(b) (which themselves were after three days in UHV
suitcase and transfer to ARPES setup). The Fermi level is
still lying below the bottom of the bulk conduction band
($B$-$BCB$). From this room temperature ARPES spectra, states
up to $\sim 50$ meV above the Fermi level are resolved due to
thermal population. We took this 20 nm film measured in situ,
both at room and low temperature, out of the ARPES
system and exposed it to air for 10 min. After this exposure,
we loaded the sample again (no further treatments such as
annealing of the sample) and reacquired ARPES data in order
to assess the influence of air exposure on the band structure
of our $\text{Bi}_2\text{Te}_3$ films. We can clearly see from Fig. 5(b)
that bulk valence bands have moved downward after exposure
and compared to the pristine sample, evident changes in the
linearly dispersing Dirac surface states are observed. There
are no surface states resolved after exposure to air, implying
that the film degradation is deeper than the probing depth of
the ARPES experiment ($\sim 1$ nm). Thus the conductance of the
films will be influenced by this downward shift of bulk bands,
and the corresponding upward shift of $E_F$. Recently, upward
shift of $E_F$ in $\text{Bi}_2\text{Te}_3$ films exposed to air has also been reported
in ARPES study [9].

We now discuss the effect of exposure to air in STM/STS
data. We took the previously in situ measured 30 nm $\text{Bi}_2\text{Te}_3$
film grown on sapphire out of the STM system and exposed
it to air for 10 min. After this procedure, we acquired several
topography and spectroscopy maps at different position on
the exposed surface. We used the same setpoint parameters
as for the spectra shown in Fig. 3(a). We observe once more
clear changes in the general shape of the spectra (Fig. S5
in the Supplemental Material [49]): most notably, the region
previously associated with linearly dispersing surface bands is
absent in the exposed sample. This observation is consistent
with our ARPES data of the exposed 20 nm film [see Fig. 5(b)]
since, there also, a clear degradation of the Dirac surface states
was observed.

Based on a comparison of measured STM topographies
before and after exposure, we find indications that extrinsic
defects due to contamination are responsible for the ob-
served degradation of the surface states in the spectroscopic
measurements. Figure 5(c) shows atomically resolved STM
topography image of a 30 nm $\text{Bi}_2\text{Te}_3$ film after exposure to
ambient conditions, in which additional defects can be readily
identified. On top of the observed defects and the observed
disappearance of surface states, also shifts in the position
of the bulk bands due to band bending are observed in the
STS spectra (see Fig. S5 in the Supplemental Material [49]).
Whether bands shift upward or downward might sensitively depend on the exact exposure conditions as well as the position
where spectra are taken (e.g., close to a defect). Nonetheless,
from the combined ARPES and STS spectroscopic data it is
clear that exposure to ambient pressures changes notably the
surface states of our Bi$_2$Se$_3$ thin films. These results underline the need of protecting films before taking them \textit{ex situ} for further studies, since extrinsic defects may be responsible for the change of sign of the carriers in the surface conductivity of TIs [50], for the deterioration of the topological surface state properties [19], and the reduction of the spin polarization [51]. The XPS surface analysis of the exposed sample reveals a splitting of the Te $3d_{5/2}$ and Te $3d_{3/2}$ peaks consistent with the formation of tellurium oxide [52] (TeO$_2$); see Figs. S2(b) and S2(c) in the Supplemental Material [22]. Since it was already shown that only pure oxygen doesn’t affect topological surface states (see above and Ref. [9]) we believe that other molecules from atmosphere, most likely water vapor, are the origin of the observed contamination. This conclusion emphasizes that for further \textit{ex situ} electronic transport investigations and quantum device fabrication, films should first be capped \textit{in situ} to avoid any possible contamination as has already been indicated for Bi$_2$Se$_3$ thin films [54]. For Bi$_2$Te$_3$ films, though, a systematic study is needed in order to determine a suitable capping layer that can preserve the surface states and avoid unintentional doping induced by ambient conditions. An insulating layer would be appropriate since it will allow the fabrication of nearly damage-free top gate structures, so that the carriers in the top surface can be efficiently tuned [55].

V. CONCLUSION

In summary, we have systematically investigated the effect of \textit{in situ} exposure to pure oxygen at atmospheric pressure and of \textit{ex situ} contamination on high quality intrinsic Bi$_2$Te$_3$ films grown sapphire and STO. The XPS studies show narrow and symmetric Te and Bi peaks highlighting the absence of Te or Bi excess in our films. STM confirms that the surface has atomically flat terraces and is free from intrinsic defects. The analysis of STS spectra underlines that the surface states of Bi$_2$Te$_3$ films are stable against oxidation and do not degrade as long as they are stored \textit{in situ} in ultrahigh vacuum or in pure oxygen. ARPES data recorded from films grown in the same manner further confirms the presence of topological surface states with no bulk bands at the Fermi level. This study also provides a platform to investigate bottom gate tunable hybrid transport [56,57] at the surface of intrinsic Bi$_2$Te$_3$ films grown on STO [111] substrates. The combined \textit{in} and \textit{ex situ} spectroscopy study reported here emphasizes the importance of capping these films before exposure to subsequent device fabrication steps. A possible route is to \textit{in situ} cap the Bi$_2$Te$_3$ and other TI films with an insulating AlO$_x$ layer.

This work is financially supported by the Dutch Foundation for Fundamental Research on Matter (FOM), the Netherlands Organization for Scientific Research (NWO), and by the European Research Council (ERC).

To get differential conductivity spectra shown in this work, the measured kink feature in conductance spectra.

This improved fitting yielded an insufficient result since the form (see Refs. [39,40] for details):

\[ \frac{dI}{dV} \propto k^2 \sqrt{C + k^2} \]

is the tip-sample separation in the tunneling experiment, and \( C \) the height of the tunneling barrier in units of \( k^2 \). Nonetheless, this improved fitting yielded an insufficient result since the modeled kink due to warping was not strong enough to capture the measured kink feature in conductance spectra.

For to perform this analysis, we added a probability factor of the form (see Refs. [39,40] for details): \( P \propto e^{z \sqrt{C + k^2}} \), where \( z \) is the tip-sample separation in the tunneling experiment, and \( C \) the height of the tunneling barrier in units of \( k^2 \). Nonetheless, this improved fitting yielded an insufficient result since the modeled kink due to warping was not strong enough to capture the measured kink feature in conductance spectra.

[42] See Supplemental Material at http://link.aps.org/supplemental/10.1103/PhysRevB.92.035405 for details on the procedure followed to model Bi2Te3 dispersion relations along the \( \Gamma - M \) and \( \Gamma - K \) directions, together with the resulting spectral functions.

[50] To find the stoichiometry of the TeOx layer, we fitted the oxidized XPS spectra in Fig. 1. The TeOx peak was found at 576 ± 0. 10 eV, which is in agreement with the peak position of TeO2 given in [53].
