I. INTRODUCTION

In 2012, the Fermi Large Area Telescope (LAT) Collaboration measured for the first time the autocorrelation angular power spectrum (auto-APS) of the diffuse gamma-ray emission detected far from the Galactic plane [1]. In that analysis, point sources in the first Fermi LAT source catalog (1FGL) [2] and a band along the Galactic plane with Galactic latitude |b| < 30° were masked in order to isolate the contribution to the auto-APS from the so-called isotropic gamma-ray background (IGRBR).

DOI: 10.1103/PhysRevD.94.123005
The IGRB is what remains of the gamma-ray sky after the subtraction of the emission from resolved sources and from the Galactic diffuse foreground induced by cosmic rays [3,4]. It dominates the gamma-ray sky at large Galactic latitudes and its intensity energy spectrum is found to be compatible with a power law with a slope of 2.32 ± 0.02 between 100 MeV and ∼300 GeV, and with an exponential cutoff at higher energies [4]. These values for the spectral slope and for the energy cutoff are those found when “model A” from Ref. [4] is used to describe the Galactic diffuse foreground emission. A different foreground model for the Galaxy would lead to a slightly different energy spectrum for the IGRB. Deviations can be as large as 20%–30% depending on energy.

The IGRB is interpreted as the cumulative emission of sources (e.g., blazars, star-forming and radio galaxies) that are too faint to be detected individually (see Ref. [5] for a recent review and the references therein). Yet, its exact composition remains unknown. It is expected to be isotropic on large angular scales but it can still contain anisotropies on small angular scales. Indeed, the contribution to the IGRB from unresolved sources imprints anisotropies in the diffuse emission which can be used to infer the properties of the contributing sources (see Refs. [6–15] among others). For example, the detection of a significant angular power in Ref. [1] determined an upper limit to the contribution of unresolved blazars [10,11,16] to the IGRB. Additional tools to reconstruct the nature of the IGRB are the study of its cross-correlation with catalogs of resolved galaxies [17–22], with gravitational lensing cosmic shear [23] and with lensing of the cosmic microwave background radiation [24]. Complementary information can also be inferred by modeling its 1-point photon count distribution [25–27].

The detection of the auto-APS presented in Ref. [1] was based on ∼22 months of data. Since then, Fermi LAT has increased its statistics by approximately a factor of 4. Therefore, we expect that an updated measurement of the auto-APS will significantly improve our understanding of the IGRB. In the first part of this work, we perform this measurement by analyzing 81 months of Fermi LAT data from 0.5 to 500 GeV, extending the 1–50 GeV energy range considered in Ref. [1]. This enables a more precise characterization of the energy dependence of the auto-APS. Indeed, looking for features in the so-called “anisotropy energy spectrum” is a powerful way to single out different components of the IGRB [28]. We also compute, for the first time, the cross-correlation angular power spectrum (cross-APS) of the diffuse gamma-ray emission between different energy bins. The cross-APS additionally enhances our ability to break down the IGRB into its different components since it provides information about the degree of correlation of the emission at different energies, which is stronger if the emission originates from one single source population (see, e.g., Refs. [29,30]).

In the second part of this paper, we focus our analysis on one possible contributor to the IGRB, namely the emission induced by dark matter (DM). If DM is a weakly interacting massive particle (WIMP), its annihilation or decay could generate gamma rays. The radiation produced in extra-Galactic and Galactic DM structures could contribute to the IGRB (see Ref. [5] and references therein) and, therefore, the IGRB could be used to indirectly search for nongravitational DM interactions. Indeed, both the measurement of the IGRB energy spectrum [4] and of its auto-APS [1] have been already used to set constraints on the possible DM-induced gamma-ray emission [14,31–33].

In this work, we also update the predictions for the auto- and cross-APS expected from DM annihilation or decay with respect to Ref. [34]. The distribution and properties of DM structures are modeled according to the results of state-of-the-art N-body cosmological simulations. We also employ well-motivated semianalytical recipes to account for the emission of DM structures below the mass resolution of the simulations. The latter is a significant part of the expected signal, at least in the case of annihilating DM. We take special care to estimate the uncertainties introduced when modeling the clustering of DM, especially at the smallest scales. Our predicted DM signal is then compared to the updated Fermi LAT measurement of the auto- and cross-APS. In the most conservative scenario, this comparison provides an upper limit to the gamma-ray production rate by DM particles, i.e., an upper limit to its annihilation cross section or a lower limit to its decay lifetime, as a function of DM mass.

The paper is organized as follows. In Sec. II we provide details on the data set that will be used in Sec. III, where we describe our data analysis pipeline. We validate the latter in Sec. IVA on Monte Carlo (MC) simulations of the unresolved gamma-ray sky. In Sec. V, we present our results for the auto- and cross-APS, and we describe the validation tests performed. Section VI provides a phenomenological interpretation of our results in terms of one or multiple populations of gamma-ray sources. In Sec. VII we focus on DM-induced gamma-ray emission: we provide details on how this signal is simulated, distinguishing among different components and discussing the main uncertainties affecting its calculation. In Sec. VIII the auto- and cross-APS expected from DM are compared to the measurements and exclusion limits are derived. Finally, Sec. IX summarizes our conclusions.

II. DATA SELECTION AND PROCESSING

The data analysis pipeline proceeds similarly to what was described in Ref. [1]. We use Pass 7 Reprocessed Fermi LAT data taken between August 4, 2008, and
May 25, 2015, (MET Range: 239557417–454279160), and restrict ourselves to photons passing the ULTRACLEAN event selection. Thus, we use P7REP_ULTRACLEAN_V15 as the instrument response functions (IRFs). We place standard selection cuts on the Fermi LAT data, removing events entering the detector with a zenith angle exceeding 100°, events recorded when the Fermi LAT instrument was oriented at a rocking angle exceeding 52° and events recorded while the Fermi LAT was passing through the South Atlantic anomaly, or when it was not in science survey mode. Since photons which pair-convert in the front of the Fermi LAT detector have a better angular resolution, we split our data set into front- and back-converting events, running each data set through the same calibration and the photon noise within each larger energy bin. We bin the resulting Fermi LAT event counts and exposure maps into HEALPix-format maps\(^2\) with angular bins of size \(\sim 0.06°\) (HEALPix order 10, \(N_{side} = 1024\)), as well as into 100 logarithmically spaced energy bins spanning the energy range between 104.46 MeV and 1044.65 GeV. The conversion of the exposure maps into HEALPix-format maps is performed with the GaRDiAn package [36]. Flux maps are, then, built by dividing the count map by the corresponding exposure map, in each energy bin. The flux maps obtained with the fine energy binning are later coadded into 13 larger bins spanning the energy range between 500 MeV and 500 GeV. This is done to ensure sufficient statistics within each energy bin. We use the smaller energy bins to calculate the beam window function and the photon noise within each larger energy bin, as described in Sec. III.

### III. ANISOTROPY ANALYSIS

#### A. Auto- and cross-correlation angular power spectra

An intensity sky map can be decomposed into spherical harmonics as follows:

\[
I(\psi) = \sum_{\ell m} a_{\ell m} Y_{\ell m}(\psi),
\]

where \(I(\psi)\) is the intensity from the line-of-sight direction \(\psi\) and \(Y_{\ell m}(\psi)\) are the spherical harmonic functions. The auto-APS \(C_\ell\) of the intensity map is given by the \(a_{\ell m}\) coefficients as

\[
C_\ell = \frac{1}{2\ell + 1} \sum_{m=-\ell}^{\ell} |a_{\ell m}|^2.
\]

Similarly, the cross-APS between two intensity maps \(I_i\) and \(I_j\) is constructed from the individual \(a_{\ell m}^j\) and \(a_{\ell m}^i\) coefficients, obtained from the decomposition in the two energy bins, independently:

\[
C_{ij} = \frac{1}{2\ell + 1} \sum_{m=-\ell}^{\ell} a_{\ell m}^i a_{\ell m}^*.
\]

The auto- and cross-APS are computed with specific numerical tools as, e.g., HEALPix and POLSPICE [37]. However, before applying Eqs. (2) and (3), the data set must be prepared, accounting for possible masking, foreground subtraction and pixelization. Additionally the calculations are complicated by the finite angular resolution of the instrument. In the following subsections, we summarize how these aspects are taken into consideration.

#### B. Masking

We apply a mask to the all-sky data to reduce contamination from Galactic diffuse foregrounds and from sources already detected in the third Fermi LAT source catalog (3FGL) [38]. The mask applied in our default analysis excludes low Galactic latitudes (\(|b| < 30°\)). We also mask each pointlike source in 3FGL with a disk whose radius depends on the flux detected from the source between 0.1 and 100 GeV: for the 500 brightest sources we consider a disk with a radius of 3.5°, for the following 500 sources a disk with a radius of 2.5°, a disk with a radius of 1.5° for the following 1000 sources, and, finally, a radius of 1.0° for the remaining objects. Validation of the choice for the mask will be performed in Sec. V C. The 3FGL catalog contains three extended sources at moderate and high latitudes: Centaurus A and the Large and Small Magellanic Clouds. Centaurus A and the Large Magellanic Cloud are each masked excluding a 10° region from their center in the catalog. We employ a 5° mask for the Small Magellanic Cloud. The fraction \(f_{\text{sky}}\) of the sky outside the mask is 0.275.

We also consider an alternative mask that covers the same strip around the Galactic plane but only the sources in the second Fermi LAT source catalog (2FGL) [39]. In this case, we mask all the sources with a 2°-radius disk. The validation for this choice is performed in Sec. V C and, in this case, \(f_{\text{sky}} = 0.309\).

As an illustrative example, the intensity sky maps of the data between 1.0 and 2.0 GeV are shown in Fig. 1, both unmasked (top panel) and with the default mask excluding sources in the 3FGL (bottom panel).

#### C. Foreground cleaning

Despite applying a generous cut in Galactic latitude, some Galactic diffuse emission remains visible in the unmasked area of the sky map, particularly at low energies (see Fig. 1). To reduce this contamination further, we perform foreground cleaning by subtracting a model of the Galactic diffuse emission. We use the

\(^2\)http://healpix.jpl.nasa.gov.
recommended model for Pass 7 Reprocessed data analysis, i.e. gll_iem_v05_rev1.fit. Details of the derivation of the model are described in Ref. [40]. This foreground model, together with an isotropic component, is fitted to the data in the unmasked region of the sky and in each one of the 13 coarser energy bins, using GARDIAN. The default mask is adopted when fitting the diffuse components. The resulting best-fit model is then subtracted from the intensity maps in each energy bin to obtain residual intensity maps, on which the anisotropy measurements are performed.

Figure 2 shows an example of the residual intensity map for the Galactic foreground subtracted (see Sec. III C). The residuals have been smoothed with a Gaussian beam with \( \sigma = 0.5^\circ \) and their projection scheme is Mollweide.

We investigate the impact of foreground cleaning on the auto- and cross-APS measurements in Sec. V C.

D. Noise and beam window functions

We calculate the auto- and cross-APS of the intensity maps using the POLSPICE package [37] to deconvolve the effect of the mask on the spectra and to provide the covariance matrix for the estimated \( C_\ell \).

Both the finite angular resolution of the instrument [given by its point-spread function (PSF)] and the finite angular resolution of the map (i.e., the pixelization scheme) suppress the measured auto- and cross-APS at large multipoles (i.e. small angular scales). This effect is described using the beam window function \( W_{\text{beam}}^\ell \) and pixel window function \( W_{\text{pix}}^\ell \), respectively. We note that they affect the signal but not the noise term \( C_N \) (see Ref. [1]). We use the beam and pixel window functions to correct the suppression at large multipoles so that our estimation for the auto- and cross-APS is as follows:

$$ C_{\ell}^{\text{signal},ij} = \frac{C_{\ell}^{\text{Pol},ij} - \delta^{ij} C_N}{(W_{\text{beam}}^\ell)^2(W_{\text{pix}}^\ell)^2}, $$

where the \( i \) and \( j \) indexes run from 1 to 13 and label emission in different energy bins. The case \( i = j \) corresponds to the auto-APS and the one with \( i \neq j \) to the cross-APS between energy bins. Also, \( C_{\ell}^{\text{Pol},ij} \) is the APS delivered by POLSPICE, which is already corrected for the effect of masking. The noise term \( \delta^{ij} C_N^k \) is equal to zero for the cross-APS since it is due to shot noise from the finite statistics of the gamma-ray events, which is uncorrelated between different energy bins. We compute \( C_N^k \) from the shot noise \( C_N^k \) of the 100 finely gridded intensity maps, where

$$ C_N^k = \frac{\langle n_{\gamma,\text{pix}}^k \rangle}{\Omega_{\text{pix}}} \left( \frac{A_{\text{pix}}^k}{\langle A_{\text{pix}}^k \rangle^2} \right), $$

where \( n_{\gamma,\text{pix}}^k \) and \( A_{\text{pix}}^k \) are the number of observed events and the exposure, respectively, in each pixel and for the \( k \)th

---

---

4In the remainder of the paper, we commonly refer to this estimator simply by \( C_\ell \) instead of \( C_{\ell}^{\text{signal}} \).
finely gridded energy bin. The averaging is done over the unmasked pixels. Ω_{pix} is the pixel solid angle, which is the same for each pixel. See Appendix A for a derivation of Eq. (5). The noise term C_N for the auto-APS in the i-th large energy bin is given by the sum of the noise terms in Eq. (5) of all the finely gridded energy bins covered by the i-th bin. We note that Eq. (5) is more accurate than the shot noise used in Ref. [1], i.e. C_N = ⟨n_{pix}/(Ω_{pix}A_{pix}^2)⟩.

The beam window function is computed as follows:

\[ W_{\text{beam}}(E) = 2\pi \int_{-1}^{1} d\cos\theta P_r(\cos(\theta))\text{PSF}(\theta; E), \quad (6) \]

where \( P_r(\cos(\theta)) \) are the Legendre polynomials and PSF(\( \theta; E \)) is the energy-dependent PSF for a given set of IRFs, with \( \theta \) denoting the angular distance in the PSF. We use the gtipsf tool in the SCIENCE TOOLS package to calculate the effective PSF, as a function of energy, averaged over the actual pointing and live-time history of the LAT. The beam window functions are calculated separately for the P7REP_ULTRACLEAN_V15 front- and back-converting events. Finally, the pixel window function \( W_{\varphi}^{\text{pix}} \) is computed using the tools provided in the HEALPix package for Nside = 1024. Since we use the same map resolution for all maps, the pixel window function does not depend on the energy.

The pixel window function and the beam window function for front and back events are shown separately in Fig. 3, for the P7REP_ULTRACLEAN_V15 IRF at four representative energies. They are also available at https://www-glast.stanford.edu/pub_data/552. Note that the pixel window function (short-dashed gray line) has a negligible effect up to multipoles of, at least, \( \sim 500 \) and it is subdominant with respect to the beam window functions at all multipoles and energies. At energies below \( \sim 0.5 \text{ GeV} \), the beam window function leads to a strong suppression of power for \( \ell \gtrsim 100 \), even with the front event selection.

Given that the PSF of the Fermi LAT varies significantly over the energy range considered in this analysis, and in some cases within the individual energy bins used when computing the auto- and cross-APS, it is necessary to calculate an effective beam window function for each energy bin. Therefore, for the i-th energy bin, we define the average window function \( \langle W_{\varphi}^{\text{beam},i} \rangle \) by weighting Eq. (6) with the intensity spectrum of the events in that bin outside the mask:

\[ \langle W_{\varphi}^{\text{beam},i} \rangle = \frac{1}{I_{\text{bin}}} \int E_{\text{min},i} \rightarrow E_{\text{max},i} dE W_{\varphi}^{\text{beam}}(E) \frac{dI(E)}{dE}, \quad (7) \]

where \( I_{\text{bin}} \equiv \int E_{\text{min},i} \rightarrow E_{\text{max},i} dE(dI/dE) \) and \( E_{\text{min},i} \) and \( E_{\text{max},i} \) are the lower and upper bounds of the i-th energy bin. We approximate the energy spectrum of the data by using the measured differential intensity \( dI/dE \) outside the mask in each intensity map for the finely binned energy bins.

IV. MONTE CARLO VALIDATION OF THE BINNING OF THE APS AND OF ITS POISSONIAN FIT

A. Autocorrelation angular power spectrum

In this section we describe in detail the procedure used to bin the auto-APS estimated in Eq. (4) into large multipole bins. Binning is required in order to reduce the correlation among nearby \( C_{\ell} \) due to the presence of the mask.

In contrast with the analysis of Ref. [1], in the present work the binned spectra \( C_{\ell} \) are taken to be the unweighted average of the individual \( C_{\ell} \)'s in the bin. Also, the error \( \sigma_{C_{\ell}} \) on \( C_{\ell} \) is computed by averaging all the entries of the covariance matrix provided by PolSpice in the block corresponding to the bin under consideration. A dedicated set of MC simulations of all-sky data are produced to validate these choices and to additionally test alternative binning schemes. The MC validation procedure is described below.

1. Monte Carlo simulations

The simulations are performed for a single energy bin from 1 to 10 GeV. We assume an underlying population of sources with a power-law source-count distribution, i.e., \( dN/dS = A(S/S_0)^{-\alpha} \). The parameters \( A \), \( S_0 \) and \( \alpha \) are fixed to the values 3.8 \( \times 10^8 \) cm\(^2\) s\(^{-1}\), 10\(^{-8}\) cm\(^2\) s\(^{-1}\) and 2.0, respectively, in agreement with the best-fit results of Ref. [26]. We consider sources with fluxes in the energy...
range between 1 and 10 GeV) from $10^{-11}$ cm$^{-2}$ s$^{-1}$ to $10^{-10}$ cm$^{-2}$ s$^{-1}$. The upper value is roughly equal to the 3FGL sensitivity threshold. In this way, the level of anisotropy expected from these sources is roughly equal to that observed in the data when masking the 3FGL sources. The lower value is not crucial since the auto-APS is dominated by the sources just below the detection threshold. From the source count distribution $dN/dS$, we create a realization of the source population, producing about 40,000 objects and assigning them random positions in the sky. This creates a map with a Poissonian (i.e., constant in multipole) auto-APS, $C_p$, whose value can be computed by summing together the squared flux, $\Phi_l^2$, of all the simulated sources divided by $4\pi$: $C_p = \sum \Phi_l^2 / 4\pi$. This is equivalent to the usual way of calculating $C_p$ by integrating $S^2dN/dS$ over the range in flux mentioned above. The resulting Poissonian auto-APS $C_p$ is $3.42 \times 10^{-18}$ cm$^{-4}$ s$^{-2}$ sr$^{-1}$. This is the nominal auto-APS that we want to recover by applying our analysis pipeline to the simulations.

We use the exposure (averaged in the energy range between 1 and 10 GeV) for 5 years of data taking to convert the intensity map into a counts map. The map is also convolved with the average PSF for the P7REP_ULTRACLEAN_V15 IRFs for front-converting events (averaged in the 1–10 GeV range, assuming an energy spectrum $\propto E^{-2.3}$). The result is a HEALPix-formatted map with resolution $Nside = 1024$ containing the expected emission, in counts, from the simulated sources. Purely isotropic emission is also included by adding an isotropic template to the map, which was also convolved with the IRFs and normalized to give the number of counts expected from the IGRB measured in the 1–10 GeV energy range, including the contamination from residual cosmic rays. For simplicity we did not model the Galactic foregrounds. This final map is then Poisson-sampled pixel by pixel 200 times to yield 200 different realizations of the expected counts. The auto-APS of each map is calculated with POLSPICE, after applying the default mask used in the analysis of the real data, i.e., excluding the region with $|b| < 30^\circ$ and the sources in 3FGL, even though the simulation does not include those sources. Finally, noise subtraction and beam correction are also applied as described in Sec. III D.

2. Binning validation

We first validate our recipe to determine the binned auto-APS. In this case, the standard analytic error $\sigma_{\ell}$ on each $C_{\ell}$ (assuming that $C_{\ell}$ follows a $\chi^2_{2\ell+1}$ distribution [41]) is

$$
\sigma_{\ell} = \sqrt{\frac{2}{(2\ell+1)f_{sky}} \left( C_{\ell} + \frac{C_N}{W_{\ell}^2} \right)},
$$

with $W_{\ell} = W_{\ell}^{beam}W_{\ell}^{PSF}$. We test three approaches to obtain $\overline{C_{\ell}}$: (i) computing the weighted average of the $C_{\ell}$ in each multipole bin, using $w_{\ell} = \sigma_{\ell}^2$ as weight; (ii) computing the weighted average of the $C_{\ell}$ in the bin, with a weight $w_{\ell} = \sigma_{\ell}^2$, defining $\sigma_{\ell}$ as in Eq. (8) but only with the noise term $C_N/W_{\ell}^2$; and (iii) computing the unweighted average of the $C_{\ell}$ in the bin. Note that in the first approach, the weight $w_{\ell}$ depends on the data via the $C_{\ell}$ term in Eq. (8), while in the second and third methods there is no dependence on the estimated auto-APS. The first method is the one employed in Ref. [1].

In Fig. 4, we show a histogram of the binned $\overline{C_{\ell}}$ in the bin between $\ell = 243$ and 317 for the 200 MC realizations. The nominal $C_{\ell}$ is denoted by the gray vertical solid line. The solid black histogram refers to the case in which no weights are used [method (iii)], while the dashed blue histogram is for the weighted average with weights given in Eq. (8). The solid red curve is a Gaussian distribution centered on the nominal $C_{\ell}$ and with a standard deviation of $9.3 \times 10^{-19}$ cm$^{-4}$ s$^{-2}$ sr$^{-1}$, as estimated with POLSPICE.
weight the data at each multipole, a downward fluctuation of $C_\ell$ is assigned a smaller error bar and, thus, a larger weight. This will lead to a downward biased $\bar{C}_\ell$. Finally, the histograms also show that the distribution of the $\bar{C}_\ell$ obtained from the MC realizations is, to a good approximation, Gaussian. Indeed, it agrees well with the solid red curve representing a Gaussian distribution centered on the nominal $C_\ell$ and with a standard deviation of $9.3 \times 10^{-19}$ cm$^{-4}$ s$^{-2}$ sr$^{-1}$ (see below).

To assign an error $\sigma_\ell$ to the binned auto-APS $\bar{C}_\ell$ we also test three methods: (i) the unweighted average of $\sigma_\ell^2$ from Eq. (8) in the bin, (ii) the weighted average of $\sigma_\ell^2$ from Eq. (8) with weight $w_\ell = \sigma_\ell^2$ and (iii) the average of the covariance matrix computed by POLSPICE in the bin.\footnote{POLSPICE returns the covariance matrix of the beam-uncorrected $C_\ell$, denoted here by $V_\ell$. In method (iii) the error $\sigma_\ell^2$ is defined as $\sum_{\ell\ell'} V_{\ell\ell'}/(W_\ell^2 W_{\ell'}^2 \Delta\ell)$, where the sum runs over $\ell, \ell'$ inside each multipole bin and $\Delta\ell$ is the width of the bin.}

Differently from the estimation of $\bar{C}_\ell$, the three methods for the estimation of $\sigma_\ell$ produce similar results. Thus, we decide to choose method (iii) as our standard prescription. This has also the advantage that, by averaging different blocks of the covariance matrix provided by POLSPICE, one can build a covariance matrix for the binned auto-APS. The average of $\sigma_\ell$ from method (iii) in the multipole bin between $\ell = 243$ and 317 over the 200 MC realizations is $9.3 \times 10^{-19}$ cm$^{-4}$ s$^{-2}$ sr$^{-1}$, i.e. the value considered in Fig. 4 for the standard deviation of the red curve. Our validation with MC simulations shows that our estimate of the errors is reliable and that higher-order effects, e.g. those related to the bispectrum and trispectrum discussed in Ref. [42], can be neglected. It remains interesting, nonetheless, to understand if a small bispectrum and trispectrum can be used to independently constrain the sources contributing to the IGRB.

3. Poissonian fit validation

Having validated the binning procedure for the measured auto-APS, we are now interested in fitting the binned auto-APS $\bar{C}_\ell$ with a constant value. Indeed, a Poissonian APS $C_\ell$ (i.e. an APS that is constant in multipole) is a natural expectation for the anisotropies induced by unclustered unresolved point sources. One possibility is to infer $C_\ell$ by minimizing the following $\chi^2$ function:

$$\chi^2(C_\ell) = \sum_\ell \frac{(\bar{C}_\ell - C_\ell)^2}{\sigma_\ell^2},$$

where $\bar{C}_\ell$ and $\sigma_\ell$ are the the binned data and their errors, as described in the previous section.

A second possibility is to consider a likelihood function $\mathcal{L}$ that, up to a normalization constant, can be written as follows:

$$\log \mathcal{L}(C_\ell) = -\sum_\ell \log(\sigma_\ell^2) - \frac{1}{2} \sum_\ell \frac{(\bar{C}_\ell - C_\ell)^2}{\sigma_\ell^2}. \quad (10)$$

This expression for the likelihood takes into account the fact that $\sigma_\ell^2$ also depends on $C_\ell$, since $\sigma_\ell^2$ in Eq. (10) is defined as the average of

$$\sigma_\ell^2 = \frac{2}{(2\ell + 1) f_{\text{sky}}} \left( C_\ell + N_\ell \right)^2,$$

over the specific multipole bin. In fact, for large multipoles, the expected $\chi^2_{\ell+1}$ distribution of a given $C_\ell$ can be approximated by a Gaussian for which the mean and the standard deviation are not independent but related as in Eq. (11). Thus, the main difference between the $\chi^2$ minimization [as in Eq. (9)] and the likelihood method is that, in the latter, $\sigma_\ell$ depends on $C_\ell$. Ignoring such a dependence may bias the result of the fit.

The two methods described above are used to determine the best-fit $C_\ell$ for the 200 MC realizations described above, by considering 10 $\bar{C}_\ell$ in 10 bins in multipole uniformly spaced in $\log \ell$ between $\ell = 49$ and 706. As we discuss in Sec. V, this multipole range excludes the large angular scales where the reconstructed $C_\ell$ are most uncertain due to possible contamination of the Galactic foreground, and the high-multipole range where the effect of the window functions becomes too severe. The results are summarized in Fig. 5: the vertical gray line is the nominal $C_\ell$, while the solid black histogram shows the distribution of the $C_\ell$ determined by maximizing the log $\mathcal{L}$ of Eq. (10) if the binned $\bar{C}_\ell$’s are computed with no weights. This approach produces a distribution that is approximately Gaussian and centered on the nominal $C_\ell$. On the other hand, if the binned $\bar{C}_\ell$ are computed with the weights from Eq. (8), then the maximization of log $\mathcal{L}$ underestimates the Poissonian auto-APS (long-dashed blue histogram in Fig. 5). Making use of the $\chi^2$ function in Eq. (9) instead of the log $\mathcal{L}$ in Eq. (10) gives similar results, i.e. an unbiased distribution for $C_\ell$ if the binned $\bar{C}_\ell$ are computed without weights (short-dashed pink line) and an underestimation of the nominal $C_\ell$ when weights are included (not shown in Fig. 5).\footnote{Note that applying the log $\mathcal{L}$ or the $\chi^2$ approach to the unbinned $C_\ell$ provided by POLSPICE also leads to an underestimation of $C_\ell$.}

The error associated to the best-fit $C_\ell$ for the 200 MC realizations described above, is assigned a smaller error bar and, thus, a larger

123005-7
errors. Therefore, in the following, we will quote Poissonian cross-APS derived with this method.

We end this section by noting that the proper way to estimate $C_P$ for the cross-APS would be to use the likelihood method but replacing the auto-APS $C_{1,\ell}$ and $C_{2,\ell}$ in Eq. (12) with their Poissonian estimates $C_{1,P}$ and $C_{2,P}$, and to perform a joint likelihood fit to all three quantities, i.e. $C_P$, $C_{1,P}$ and $C_{2,P}$. However, this approach would not provide results that are significantly different than the ones obtained as described above. In fact, at present, the noise terms in Eq. (12) dominate over the signal terms, reducing the effect of covariance between energy bins.\(^7\)

V. MEASURED AUTO- AND CROSS-CORRELATION ANGULAR
POWER SPECTRA OF THE ISOTROPIC
GAMMA-RAY BACKGROUND

Following the analysis described in the previous section, we measure the auto- and cross-APS in 13 energy bins spanning the energy range between 500 MeV and 500 GeV.

A. Autocorrelation angular power spectra

The auto-APS of the IGRB is shown in Fig. 6 for two representative energy bins. The auto-APS for all 13 energy bins considered is shown in Appendix B and it is available at https://www-glast.stanford.edu/pub_data/552. The $\gamma$-axis range of Fig. 6 and in Appendix B has been chosen to better illustrate the auto-APS in the multipole range of interest, i.e. between $\ell = 49$ and 706, divided into 10 bins equally spaced in log $\ell$. The red circles indicate the auto-APS for our reference data set (i.e., P7REP_ULTRACLEAN_V15 front events) and the default mask covering only 3FGL sources, as described in Sec. III B. Instead, the blue triangles refer to the same data set but using the default mask covering only 2FGL sources (see Sec. III B). Note that the blue triangles are systematically higher than the red circles, due to the anisotropy power associated with the sources that are present in 3FGL but still unresolved in 2FGL.

Figure 7 shows the auto-APS for the two same energy bins but over a broader multipole range, i.e. from $\ell = 10$ to 2000. This illustrates the behavior of the auto-APS above and below the signal region used in our analysis, i.e. between $\ell = 49$ and 706. At large scales (i.e., low multipoles), there might be some residual contamination from the Galactic foregrounds. This motivates our choice of neglecting the APS below $\ell = 49$. In Sec. V C the effect of foreground contamination is discussed in more detail. On the other hand, at high multipoles and at low energies

\(^7\)The noise terms in Eq. (12) are a factor of 4–5 larger than $C_P$, $C_{1,P}$ and $C_{2,P}$. Therefore, not performing the joint likelihood fit as described in the text generates an error of, at most, 10%–20% on $\sigma_{\ell}$. The effect on the estimated best-fit Poissonian auto- and cross-APS will be even smaller.
the size of the error bars increases dramatically due to the strong signal suppression caused by the beam window functions. Our signal region neglects any $C_l$ above 706. At high energies, the effect of the beam window function is more modest, even up to $\ell = 2000$ (see Fig. 3). In principle, for high energies, we could consider a signal region in multipole that extends to smaller scales. However, we prefer to work with a window in multipole that is independent of the energy bin and, therefore, we choose the value of $\ell = 706$ as a reasonable compromise.

Note that each individual data point in Figs. 6 and 7 can be negative, since our auto-APS estimator quantifies the excess of power with respect to the photon noise $C_N$. We fit the auto-APS (between $\ell = 49$ and 706) in each energy bin to a constant value, in order to determine the Poissonian $C_P$ (the possibility of a nonconstant $C_l$ is considered later). The fit is performed as discussed in the previous section.

FIG. 6. Auto-APS of the IGRB for two representative energy bins (between 1.38 and 1.99 GeV in the left panel and between 50.0 and 95.27 GeV in the right panel) and for the reference data set (P7REP_ULTRACLEAN_V15 front events) using the reference mask which excludes $|b| < 30^\circ$ and 3FGL sources (red circles). The blue triangles show the same but masking the sources in 2FGL. Data have been binned as described in Sec. IV.A. The solid red line shows the best-fit $C_P$ for the red data points, with the pink band indicating its 68% C.L. error. The dashed blue line corresponds to the best-fit $C_P$ for the blue data points. Note that only the results in our signal region (i.e. between $\ell = 49$ and 706) are plotted and that the scale of the $y$-axis varies in the two panels. Also, the blue triangles have been slightly shifted horizontally with respect to the red circles to increase the readability of the plots. This will happen also in many of the following plots.

FIG. 7. Same as Fig. 6, but showing a wider range in multipole, going from $\ell = 10$ to 2000. The two dashed gray vertical lines indicate the lower and upper bounds of the multipole range used for the present analysis. Note the different scale of the $y$-axis in each panel.
The best-fit $C_P$'s are reported in Tables I and II for the different energy bins and for the masks around 3FGL and 2FGL sources, respectively. They are also available at https://www-glast.stanford.edu/pub_data/552 and they are reported as the solid red and dashed blue lines in Figs. 6, 7, 29 and 30, when masking sources in 3FGL and 2FGL, respectively. In the former case, we also show the estimated 68% C.L. error on $C_P$ as a pink band. The significance of the measured Poissonian auto-APS can be quantified by computing the test statistics (TS) of the best-fit $C_P$, defined as the difference between the $-2 \ln \mathcal{L}$ of the best fit and the $-2 \ln \mathcal{L}$ of the null hypothesis. The latter is obtained from Eq. (10) by setting $C_P$ to zero. Assuming Wilks’s theorem, TS is distributed as a $\chi^2$ distribution with 1 degree of freedom and, thus, it can be used to estimate the significance associated to $C_P$. For the default data set masking 3FGL sources, the significance of the measured auto-APS $C_P$ is larger than 3$\sigma$ for all energy bins up to 21.8 GeV, except between 5.00 and 10.45 GeV. The significance of the detection is reported in italics in Tables I and II. In the case of the mask around 3FGL sources, the highest significance in the auto-APS is 6.3$\sigma$ and it is reached in the second energy bin, i.e. between 0.72 and 1.04 GeV.

The way the auto- and cross-APS depend on the energy (i.e. the so-called “anisotropy energy spectrum”) is an informative observable that can provide insight into the emission causing the anisotropical signal. In fact, in the case that the auto-APS is produced by a single population of sources, the anisotropy energy spectrum allows their energy spectrum to be reconstructed [28,43,44]. If more than one class of objects is responsible for the signal, then, by detecting features in the anisotropy energy spectrum, it may be possible to identify energy regimes where the different classes dominate the signal.

The measured anisotropy energy spectrum for the auto-APS is shown in Fig. 8. In the figure, the data points are weighted by $E^4 i / \Delta E_i$, where $E_i$ is the log center of the energy bin and $\Delta E_i$ is the width of the bin. This weighting is introduced in order to compare the anisotropy energy spectrum directly with the squared intensity energy spectrum of the sources responsible for the anisotropy signal. Figure 8 compares the auto-APS $C_P$, for the case of the mask excluding 3FGL sources (red circles) to that of the mask excluding 2FGL sources (blue triangles). As already mentioned, the amplitude of the auto-APS is lower when we exclude the sources in 3FGL. In both data sets, the low-energy part of the spectrum appears generally consistent with a power law, while a feature is apparent around 7 GeV. We comment further on the structure of the anisotropy energy spectrum in Sec. VI.

---

8 The anisotropy energy spectrum traces the intensity energy spectrum of the sources responsible for the anisotropy signal only if the clustering of the source population is independent of energy.

---

9 Note that in some cases the best-fit $C_P$ is negative. However, whenever that happens the estimated error is large and the measurement is compatible with zero.

B. Cross-correlation angular power spectra

Two examples of the cross-APS between energy bins are shown in Fig. 9. The left panel is for the cross-APS between bins at low energies. A clear correlation is detected in the multipole range of interest (bounded by the vertical gray lines in the figure). Note the effect of the beam window function on the error bars at high multipoles, as in Fig. 7. The right panel shows the cross-APS between two high-energy bins. This combination does not correspond to a significant detection, as the best-fit $C_P$ is compatible with zero at a 2$\sigma$ level.

The best-fit $C_P$’s for the cross-APS between the $i$th and the $j$th energy bins are shown in Appendix C, multiplied by $E_i^4 E_j^4 / \Delta E_i \Delta E_j$ and for all the possible combinations of energy bins. Cross-APS $C_P$ is detected in most combinations of energy bins, with the ones failing to yield a detection mainly involving the two highest energy bins. Tables I and II report the detected cross-APS with their significance. The largest detection significance is 7.8$\sigma$ for the case of the cross-APS between the energy bin between 1.99 and 3.15 GeV and the energy bin between 3.15 and 5.0 GeV.

The tables also report in bold the $\chi^2$ associated with the best-fit $C_P$ according to the definition in Eq. (9). Figure 10 shows the distribution of the 91 $\chi^2$ of best-fit $C_P$’s in the 91 independent combinations of the 13 energy bins. The solid black line refers to the case when all sources in the 3FGL are masked and the dashed blue line when only sources in the 2FGL are masked. Both distributions are compatible with that of a $\chi^2$ distribution with 9 degrees of freedom (i.e. the 10 data points inside the signal region in multipole minus 1 fitted parameter). The latter is represented by a solid red line in Fig. 10. Only 3 (4) combinations of energy bins have a $\chi^2$ larger than 16.9 (that would correspond to a $p$-value of 0.05) when masking 3FGL (2FGL) sources.

Together with the auto-APS in Fig. 8, the cross-APS provides an important handle to characterize the emission responsible for the anisotropy signal. In particular, if the latter is due to only one class of unresolved sources, the auto-APS $C_P$ allows us to reconstruct their energy spectrum and the cross-APS can be predicted as $C_P = \sqrt{C_P'C_P'}$. Alternatively, if we define the so-called cross-correlation coefficients $r_{ij}$ as $C_P'C_P' / \sqrt{C_P'C_P'}$, any deviation from 1 when $i \neq j$ can be interpreted as an indication of multiple source classes contributing to the signal. In Fig. 11, we show the cross-correlation coefficients corresponding to the best-fit $C_P$'s for the data set obtained by masking 2FGL sources (left panel) and masking 3FGL sources (right panel). In the former case,
TABLE I. Best-fit Poisson auto- and cross-APS $C_p$ for the default data set and for the mask covering all sources in 3FGL, in units of $\text{cm}^{-4} \text{s}^{-2} \text{sr}^{-1}$. The numbers in italics indicate the significance of the detection in units of standard deviation (see text), while the numbers in bold give the $\chi^2$ associated with the corresponding $C_p$. The entries marked in gray correspond to the auto-APS.

*TABLE II*. Same as Table I but with the mask covering the sources in 2FGL. Data are available at [https://www-glast.stanford.edu/pub_data/552](https://www-glast.stanford.edu/pub_data/552).
it is clear that the cross-correlation coefficients of low-energy bins are systematically smaller than 1, when correlated with high-energy bins. This is in qualitative agreement with the findings of Ref. [16], in which the auto-APS measured in Ref. [1] was explained by the sum of two different populations of unresolved blazars at low energies, while, above $\sim 10$ GeV, the signal was compatible with only one source class. Figures 33 and 34 in Appendix D show, for each energy bin $i$, how the cross-correlation coefficients $r_{i,j}$ depend on energy $E_j$.

When 3FGL sources are masked (right panel) the situation is less clear as errors are larger (especially at high energies) and the estimated $C_P$ more uncertain. We further discuss the nature of our auto- and cross-APS in Sec. VI. Note that in some cases the coefficients $r_{i,j}$ shown in Fig. 11 are larger than 1, since only the best-fit values are plotted. They are, however, compatible with 1, within their uncertainty. Also, some coefficients are negative (and they are associated with a black pixel). Although within the error bars these negative $r_{i,j}$ are actually compatible with 0, we note that negative values are allowed, in the case of anticorrelations between two energy bins.

We finish this section by studying whether the binned auto- and cross-APS $C_P$ are better described by an APS that

FIG. 8. Anisotropy energy spectra for the auto-APS using the reference data set with the default 3FGL mask (red circles) in comparison with the case in which we use the default mask around 2FGL sources (blue triangles).

FIG. 9. Cross-APS for two representative combinations of energy bins as indicated above the two panels. The default data set and 3FGL mask are used to compute the red circles, while the blue triangles are for the mask excluding 2FGL sources. The vertical dashed gray lines denote the bounds of the multipole range used in the analysis. The best-fit $C_P$ is shown as a solid red line in the case of the mask around 3FGL sources, with a pink band indicating its 68% C.L. error. The dashed blue line corresponds to the best-fit $C_P$ for the blue data points (i.e. masking 2FGL sources).

FIG. 10. Normalized distribution of the $\chi^2$ [defined as in Eq. (9)] for the best-fit Poissonian $C_P$ for all 91 independent combinations of energy bins. The solid black line is for the case when 3FGL sources are masked and the dashed blue line is for the mask covering 2FGL sources. The solid red curve is a $\chi^2$ distribution with 9 degrees of freedom.
changes with the multipole, instead of a constant value. We fit the binned $C_{\ell}$ with a power law,\textsuperscript{10} i.e., $C_{\ell} = A(\ell/\ell_0)^{-\alpha}$, with $\ell_0 = 100$. We leave the normalization $A$ free to vary independently in all 91 combinations of energy bins but we consider one common slope,\textsuperscript{11} i.e. $\alpha$. The best-fit value of $\alpha$ is $-0.06 \pm 0.08$ and it corresponds to a $\chi^2$ per degree of freedom of 0.91. This should be compared to the global (i.e. for all 91 combinations of energy bins) Poissonian fit, which also has a $\chi^2$ per degree of freedom of 0.91. Therefore, we cannot deduce any preference for the power-law scenario.

C. Validation studies

We note that the uncertainties reported in the last section only include statistical errors. It is therefore important to estimate any systematic errors as, e.g., those related to the analysis (such as the foreground cleaning and the use of the mask) or to the characterization of the instrument, which may affect the effective area and beam window functions. We discuss possible sources of systematic errors in the following sections.

\textsuperscript{10}The fit is performed with MINUIT2 v5.34.14, http://lcgapp.cern.ch/project/cls/work-packages/minuit/index.html.

\textsuperscript{11}If the auto- and cross-APS are interpreted as produced by a population of unresolved sources, they can be expressed in terms of the three-dimensional power spectrum of the density field associated with the sources of the gamma-ray emission [5,45,46]. The latter determines the dependence on the multipole, and hence the shape of the auto- and cross-APS. Normally, the three-dimensional power spectrum is only mildly dependent on the gamma-ray energy, which is encoded in the “window function.” Therefore, the APS associated with different combinations of energy bins is expected to have approximately an energy-independent shape. It is therefore reasonable to assume a constant $\alpha$.

FIG. 11. Cross-correlation coefficients between energy bins. Each pixel in the panels corresponds to a pair $(i, j)$ of energy bins and it is colored according to the cross-correlation coefficient $r_{i,j}$. By construction the panels are symmetric with respect to the diagonal. The panel on the left refers to the default data set with a mask that covers the sources in 2FGL, while the one on the right is for the mask covering 3FGL sources. Cross-correlation coefficients below 1 indicate that the signal is due to multiple populations of sources.

1. Foreground cleaning

The Galactic diffuse emission is bright, especially at low energies, and generally displays an approximate symmetry around the disk of the Galaxy, leading to excess power at low multipoles, corresponding to large angular scales. The measured auto-APS calculated both with and without performing foreground cleaning is shown in the left panel of Fig. 12 (red dots and blue triangles, respectively) for a selected energy bin at low energy. The default mask and data set are used. The effect of foreground cleaning is dramatic at low multipoles, significantly reducing the measured $C_{\ell}$ below $\ell \sim 50$. On the other hand, our analysis only considers multipoles larger than $\ell = 49$, where the effect of foreground cleaning is smaller, although still important enough to be non-negligible. Above $\ell \sim 150$, however, it is clear that its impact becomes subdominant, and the APS could be measured even without performed any cleaning. This is confirmed by the right panel of Fig. 12, where the best-fit Poissonian auto-APS for the case with foreground cleaning and our signal region, i.e. $\ell$ between 49 and 706 (red circles, the same as in Fig. 8), is compared to the best-fit $C_{P}$ for the case without foreground cleaning but performing the fit only between $\ell = 143$ and 706 (blue triangles), i.e. neglecting the first four bins in the multipole inside our signal region. Errors at low energies are larger for the uncleaned case than for the cleaned one. This is due to the fact that, at low energies, only the few $C_{\ell}$ with $\ell \lesssim 300$ play a role in the determination of the best-fit $C_{P}$, since at larger $\ell$ the beam suppression is too strong. Therefore, cutting the signal region at $\ell = 143$ means that the best-fit $C_{P}$ is determined only by very few data. Nonetheless, the two cases are found to be in good agreement within their uncertainties at all energies. From this we can conclude that the foreground cleaning is
effective even down to \( \ell \sim 50 \), therefore validating our choice for the signal region in multipole.

Also, from the left panel of Fig. 12, it is clear that the binned APS \( \overline{C}_\ell \) without foreground cleaning is characterized by much larger error bars than with cleaning, at least for \( \ell \lesssim 150 \). The reason for this can be understood by looking at the covariance matrix of the binned auto-APS: in Fig. 12 the errors on \( \overline{C}_\ell \) are simply the square root of the diagonal elements of the covariance matrix, while the full covariance matrix is plotted in Fig. 13, for the data between 1.04 and 1.38 GeV, with (left panel) and without (right panel) foreground cleaning. Each pixel in the panels corresponds to a pair of bins in multipole and its color provides the covariance between those two bins. We do not directly plot the covariance matrix but, instead, each element \( \sigma_{ij} \) is divided by the square root of the product of the corresponding diagonal elements \( \sqrt{\sigma_{ii}\sigma_{jj}} \). The main difference between the two panels is at low multipoles, where the case without foreground cleaning is characterized by a large covariance among different bins. This large covariance causes the diagonal terms at \( \ell \lesssim 30 \) to correlate with diagonal terms at higher multipoles. But multipoles \( \ell \lesssim 30 \) are characterized by larger \( \overline{C}_\ell \) (and, thus, also larger errors) for the uncleaned data set than for the cleaned one. This translates into large error bars also around \( \ell \sim 50–100 \), for the case without foreground cleaning.

FIG. 12. Left: Auto-APS in the energy bin between 1.04 and 1.38 GeV, comparing the data with (red circles) and without (blue triangles) foreground cleaning. The solid red line indicates the best-fit \( C_p \) for the case with foreground cleaning, and the pink band its 68% C.L. error. The two dashed vertical lines mark our signal region in multipole. Right: Poissonian auto-APS as a function of the energy for the case with foreground cleaning and a signal region between \( \ell = 49 \) and \( 706 \) (red circles) and for the case without foreground cleaning and a signal region between \( \ell = 143 \) and \( 706 \) (blue triangles). Default data selection and a 3FGL mask are used.

FIG. 13. Normalized covariance matrix \( \overline{C}_{ij} = \overline{C}_i \overline{C}_j \) of the binned \( \overline{C}_\ell \) shown in the left panel of Fig. 12, i.e., for the energy bin between 1.04 and 1.38 GeV, default data selection and default mask covering 3FGL sources. The left panel shows the case with foreground cleaning, while the right panel is for the uncleaned case. The comparison between the two panels indicates that large covariances are present in the case without foreground cleaning up to multipoles \( \ell \sim 100 \).
Therefore, the introduction of the foreground cleaning reduces the intensity of the signal at \( l \approx 50 \) and it considerably removes the coupling between multipoles, leading to smaller and weakly correlated estimated errors. It also justifies the use of Eqs. (9) and (10) for the determination of the Poissonian APS, since they are valid only under the hypothesis that covariances are negligible.\(^{12}\)

### 2. Data selection

Next we consider the impact of our choice of data set. As described in Sec. II, our analysis is based on P7REP_ULTRACLEAN_V15 front events. For comparison, we now show the results for two different event selections using Pass 8 data, i.e., the most recent revision of the event-level Fermi LAT reconstruction analysis [47]. In particular, we will use the PS8R2_ULTRACLEANVETO_V6 class, designed to reduce the cosmic-ray contamination significantly. We consider separately two event selections, i.e. only Pass 8 front-converting events and the so-called PSF3 events. PSF3 is a new selection available with Pass 8 data and it is characterized by an improved angular resolution. The effective area for the PSF3 events is roughly a factor of 2 smaller than that for the front events, since PSF3 represents the quartile of events with the best angular resolution, while the front events constitute approximately half the total events gathered by the LAT. The same analysis pipeline applied to the Pass 7 data is employed to the Pass 8 data, including foreground cleaning with the same Galactic diffuse model (refitted to the Pass 8 events outside the mask).

\(^{12}\)Note that in Ref. [1] the covariance between multipole bins was not discussed.

In Fig. 14 we compare the measured auto-APS in one energy bin between the default data set (i.e., Pass 7, denoted by red circles) and the two Pass 8 selections: Pass 8 front-converting events in the left panel (orange squares) and Pass 8 PSF3 in the right panel (blue triangles). The solid red line marks the best-fit \( C_P \) for the default Pass 7 data set, with the pink band indicating its 68% C.L. error. The dashed orange (blue) line gives the best-fit \( C_P \) for Pass 8 front (PSF3) in the left (right) panel. The vertical gray dashed lines mark the signal region between \( \ell = 49 \) and 706. The default mask covering 3FGL sources is applied.

FIG. 14. Left: Comparison of the auto-APS measurement in the energy bin between 1.04 and 1.38 GeV between the default Pass 7 data set (red circles) and the Pass 8 front event selection (orange squares). Right: Same as the left panel but the comparison is between the Pass 7 data (red circles) and the Pass 8 PSF3 event selection (blue triangles). The solid red line marks the best-fit \( C_P \) for the default Pass 7 data set, with the pink band indicating its 68% C.L. error. The dashed orange (blue) line gives the best-fit \( C_P \) for Pass 8 front (PSF3) in the left (right) panel. The vertical gray dashed lines mark the signal region between \( \ell = 49 \) and 706. The default mask covering 3FGL sources is applied.

In Fig. 15 we show the anisotropy energy spectra for the three data sets discussed above. Their Poissonian auto-APS agree well within the measurement uncertainties in
the various energy bins. The sharp drop in $C_p$ around $\sim 7$ GeV apparent in the Pass 7 data is less significant in the Pass 8 PSF3 data and absent in the Pass 8 front data, suggesting that the feature in the Pass 7 data may be the result of a statistical fluctuation. Also, with Pass 8, the auto-APS around 70 GeV has a larger value than with Pass 7, although the difference is only at the 2σ level and, thus, not very significant. We stress that this is only a qualitative comparison and a more thorough analysis of the Pass 8 data should be performed. With Pass 8, the measurement of the auto-APS and cross-APS is expected to improve in several ways, e.g. taking advantage of the new PSF classes (from PSF0 to PSF3), especially at low energies where the measurement uncertainties in the Pass 7 data are dominated by the suppression induced by the beam window functions and (potentially) by the leaking from bright sources outside the mask (see Sec. V C 3). Also, new data selections are available with Pass 8, characterized by different balances between effective area and cosmic-ray contamination. In fact, the improvement expected from using Pass 8 PSF3 or Pass 8 front data can already been seen in the reduction of the error bars for the blue triangles and orange squares in Fig. 15, with respect to the red circles, especially at around 100 GeV. A detailed study with Pass 8 is beyond the scope of the present analysis and is left for future work.

We further investigate the impact of event selection by comparing the results obtained from the Pass 7 data using front data only (i.e., our default choice) to the results obtained using both the front and back data. Including back-converting events in the analysis has the advantage of increasing the statistics by enlarging the effective area by a factor of $\sim 2$. However, the average PSF for the front + back data set is poorer than for the front events alone, leading to a larger suppression due to the beam window function and to a stronger leakage outside the mask from bright pointlike sources. In this comparison it should be kept in mind that the data sets are not independent since, by definition, the front + back data set contains all the front-converting events. Also, it is important to note that due to the poorer PSF of the front + back data set, our source-masking scheme may not be sufficiently effective for that data set, particularly at low energies where the PSF is broadest (see also the discussion in Sec. V C 3).

The left panel of Fig. 16 shows the auto-APS $C_p$ in a specific energy bin. Red circles refer to the Pass 7 front data set and the blue triangles to the Pass 7 front + back one. The right panel indicates the Poissonian auto-APS as a function of energy, with the same color code. The measured $C_p$ is in good agreement between the two data sets at all multipoles in our signal region. The same is true for the Poissonian $C_p$, except in the lowest energy bin, where the front + back data yield a significantly higher $C_p$. This discrepancy is consistent with the possibility that, for the front + back data set, the mask employed here (covering all sources in the 3FGL) is not big enough to get rid of the emission of the sources at low energies. Note that, also in this case, the significance of the dip at $\sim 7$ GeV is strongly reduced.

3. Mask around resolved sources

We now investigate the effect of any possible leakage of emission outside the mask around the resolved sources. We recall that our default mask excludes (in addition to a latitude cut of $|b| < 30^\circ$) a disk with a radius of 3.5° around...
FIG. 17. Left: Comparison of the auto-APS in the energy bin from 1.04 to 1.38 GeV among the case with the default mask covering the sources in 3FGL (red circles), the case with the 2° mask (blue triangles) and the one with the 1° mask (orange squares). The solid red line marks the best-fit $C_\ell$ for the default mask, with the pink band indicating its 68% C.L. error. The long-dashed blue line gives the best-fit $C_\ell$ when the 2° mask is employed and the short-dashed orange one for the case with the 1° mask. The vertical gray dashed lines mark the signal region between $\ell = 49$ and 706. Right: Poissonian auto-APS as a function of energy for the case with the default mask (red circles), the 2° mask (blue triangles) and the 3.5° mask (green squares).

Above a few GeV, where the PSF is narrower, we expect the 1° mask to be sufficient to exclude the emission of the sources detected in 3FGL. However, at low energies some leakage may appear. Results are summarized in Fig. 17. The left panel shows the measured auto-APS in the energy bin between 1.04 and 1.38 GeV, for the 1.0° mask (orange squares), for the 2.0° mask (blue triangles) and for the default one (red circles). It is clear that there is a significant contamination due to power leakage outside the 1.0° mask, especially at $\ell < 50$, but up to $\ell \sim 80$. The other two more aggressive masks give consistent results in this energy bin. In the right panel, we plot the anisotropy energy spectrum for the 2° masks (blue triangle), for the default one (red circle) and for the 3.5° mask (green squares). While, at high energies, the three cases yield consistent results, the 2° mask shows still an excess of power in the first energy bin. On the other hand, results for the 3.5° mask are consistent with our default mask. The anisotropy energy spectrum for the 4° mask (not shown in Fig. 17 for clarity) is also consistent with the default case. This validates our choice of the latter as our fiducial mask when dealing with 3FGL sources.\(^\text{13}\)

A similar validation is performed on the mask covering the sources in 2FGL. We find that cutting a 1° disk around all 2FGL sources leads to some power excess at low energies. However, extending the mask by covering a disk with a radius of 2° for all sources is enough to get rid of the

---

\(^{13}\)We also test an additional mask that covers exactly the same region of sky as our default mask for 3FGL sources but it also masks the region around loop I and the Galactic lobes. The best-fit $C_\ell$’s with this more aggressive cut are compatible with the default Poissonian $C_\ell$’s in Fig. 8, within their statistical errors.
leakage and there is no need of more aggressive masks as for the case of 3FGL sources. This is probably due to the fact that, when masking 2FGL sources, the measured power spectra are intrinsically larger than when masking sources in 3FGL (see Sec. V). Thus, the contamination from leakage has a relatively minor impact.

D. Effect of the gamma-ray emission from the Sun

Steady gamma-ray emission from the Sun was detected in the Fermi LAT data in Ref. [48] from 0.1 to 10 GeV. Later, Ref. [49] extended the detection up to 100 GeV, also establishing that the flux varies with time and anticorrelates with Solar activity. Gamma rays are produced from the interaction of cosmic rays with the Solar atmosphere [50], as well as from inverse-Compton (IC) scattering of cosmic-ray electrons and positrons with Solar photons [51–53].

The emission is quite difficult to see with the eye because, even if quite significant, it is spread over the path followed by the Sun in the sky, i.e. the ecliptic. However, it may still induce some features in the auto- and cross-APS. We test this possibility by masking the region of 1.5° above and below the ecliptic. The auto- and cross-APS obtained after having introduced this additional mask are compatible with our default case within their uncertainty. Thus, we conclude that the effect of the Sun on the measured anisotropies is negligible.\textsuperscript{14}

E. Comparison with previous measurement

We conclude this section by comparing our new measurement to the previous (indeed, the first) anisotropy measurement from Ref. [1]. Our current analysis includes many improvements with respect to the original one, both from the perspective of the data set (as we now use Pass 7 Reprocessed events and IRFs, compared to the Pass 6 events used in Ref. [1]) and in terms of the analysis method, including an improved calculation of the noise term $C_N$, the deconvolution of the mask (performed now with POLSPICE) and a MC-validated procedure to bin the auto-APS in multipole and to estimate its error. The improved data set also allows us to measure the auto-APS with better precision over a larger multipole range covering the window between $\ell = 49$ and 706, while the analysis in Ref. [1] was restricted to $\ell = 155 – 504$. We also extend the energy range, spanning the interval between 500 MeV and 500 GeV, compared to the original 1–50 GeV range. Moreover, we use an improved diffuse model for foreground cleaning, compared to what was available at the time of Ref. [1].

\textsuperscript{14}The high-energy emission of the Moon peaked at about 200 MeV, with a similar intensity as the Sun [54]. However, at higher energies, it has an energy spectrum that is steeper than that of the Sun. Therefore, above 500 MeV, the effect of the Moon on the APS measurement is expected to be negligible.

FIG. 18. Poissonian auto-APS as a function of energy for the default data set in this analysis, with 13 energy bins (blue triangles) and with the 4 energy bins used in Ref. [1] (red circles). Note that data are obtained using the mask that covers a 2° circle around each source in 2FGL. The gray squares denote the measurement from Ref. [1] using the same mask.

In Fig. 18 we compare the anisotropy energy spectrum reported in Ref. [1] for the mask covering the sources in 2FGL (gray squares) to our new measurement calculated for the same mask but with our new default data set. We report our results for the 13 energy bins used in this work (blue triangles) and also compute the auto-APS in the same 4 energy bins used in Ref. [1] (red circles). While there is a slight trend toward a higher $C_P$ in our current measurement compared to the original one, we find good consistency with Ref. [1]. The only exception is the highest energy bin of the original analysis, which is lower than the current measurement and inconsistent at about 3$\sigma$. Many factors may lead to the small systematic increase of the new $C_P$ in the first 3 bins and to the larger difference in the last energy bin. However, we attribute this trend primarily to the way the data are binned in multipole and to the way the Poissonian fit $C_P$ is determined. As discussed in Sec. IV.A, in this analysis we follow a different procedure with respect to the original analysis in Ref. [1], after having verified that the latter can lead to a downward bias of both the $C_P$ and the best-fit $C_P$.

We end by noting that a concern about the auto-APS in Ref. [1] being somewhat underestimated was raised already in Ref. [55]. However, in that case it was claimed that the correct anisotropy should have been a factor of 5–6 larger than the measured one for each energy. In the light of the present analysis, this is true only for the highest energy bin, while for the others the difference is only of 20%–30%, and not significant within error bars.

VI. INTERPRETATION IN TERMS OF SOURCE POPULATIONS

In this section we provide a phenomenological interpretation of our measurement in terms of different
populations of unresolved sources. The main observables that we consider are the results of the Poissonian fits to the auto- and cross-APS, i.e., the anisotropy energy spectrum.

We assume the sources responsible for the signal to be pointlike and unclustered [7,10,16,19], and that they give rise only to a Poissonian auto- and cross-APS. We also assume each population to be characterized by a common intensity energy spectrum \( F_\alpha(E) \). The index \( \alpha \) runs over the number of source populations contributing to the signal. The contribution of the \( \alpha \)th source population to the auto-APS will be proportional to \( F_\alpha(E)^2 \), while it will be proportional to \( F_\alpha(E_i)F_\alpha(E_j) \) in the case of the cross-APS. Our choice of interpreting the auto- and cross-APS data in a phenomenological way is motivated by the desire to be model independent. Alternative interpretations in terms of physically motivated models of astrophysical gamma-ray emitters are ongoing. We start by considering one single source population with a power-law spectrum, i.e.

\[
F(E) = A \left( \frac{E}{E_0} \right)^{-\alpha},
\]

(13)

with \( E_0 = 1 \text{ GeV} \). We fit both the best-fit Poissonian auto- and cross-APS taken from Table I, i.e. for the mask around 3FGL sources. This scan and the following ones are performed with MULTINEST 3.9 [56–58] with 20,000 live points and a tolerance of \( 10^{-4} \) in order to provide a good sampling of the likelihood. The prior probability is chosen to be flat for all free parameters, between \(-15.0 \) and \(-5.0 \) for \( \log_{10}(A) \) (and all the normalizations, measured in \( \text{cm}^{-2}\text{s}^{-1}\text{sr}^{-1} \)), between \( 0.0 \) and \( 5.0 \) for the slopes and between \( 5.0 \text{ GeV} \) and \( 500.0 \text{ GeV} \) for the energy breaks (see Eq. 14). The best-fit solution is reported in Table III and is represented by a solid magenta line in the left panel of Fig. 19. The best fit has a \( \chi^2 \) per degree of freedom which is 1.52, corresponding to a \( p \)-value of 0.001.

Alternatively, we also consider a broken power law parametrized as follows:

\[
F(E) = \begin{cases} 
A(E/E_0)^{-\alpha} & \text{if } E \geq E_b \\
A(E_0/E_b)^{\alpha - \beta}(E/E_0)^{-\beta} & \text{otherwise}
\end{cases}
\]

(14)

In this case, the best fit is reported in Table III and shown as a solid blue line in the left panel of Fig. 19. Its \( \chi^2 \) per degree of freedom is 1.36 with a \( p \)-value of 0.01.

Then, we allow for the possibility of two independent populations, starting with the case of two power laws. The best-fit values are reported in Table III and the model is represented by the solid yellow line in the right panel of Fig. 19: one population explains the data points below a few GeV and another one reproduces the data at higher energies. The best fit has a \( \chi^2 \) per degree of freedom of 1.47, corresponding to a \( p \)-value of 0.003.

We also consider the possibility of two broken power laws. With a \( \chi^2 \) per degree of freedom of 1.10, it represents the best description to the data. The model is shown as a solid black line in both panels of Fig. 19: one broken power law reproduces the data at low energies (short-dashed black line) and the other one at higher energies (long-dashed black line). The best-fit solution for the cross-APS is shown in Figs. 31 and 32 in Appendix C.

Finally, we also test the hypothesis of one population emitting as a power law and one as a broken power law. This interpretation is characterized by a \( \chi^2 \) per degree of
The difference between the $\chi^2$ of the best-fit solution for a model with one population and the same quantity for the model with two populations can be used as a TS to determine whether we can exclude the one-source-population scenario. From the values of the $\chi^2$ in Table III, the exclusion is at 95% C.L. in all cases.\(^{15}\) We can test how the different interpretations perform also in a Bayesian framework. Indeed, we can define the Bayes factor $B$ as the ratio of the so-called “evidence” for two competing models (given the data) and it can be used to discriminate between them. In particular, with $\ln B = 0.5$, there is no preference between the interpretation with one or two power laws (according to the Jeffrey’s scale [59]), while, with $\ln B = 3.1$, there is a weak preference for the solution with two broken power laws over the solution with one.

\(^{15}\)In the comparison between one and two populations of sources, if the number of additional degrees of freedom is 2 (as for the case in which the sources in the second population emit as power laws), then the 95% C.L. exclusion corresponds to a $\Delta \chi^2$ of 5.99. On the other hand, if the second population emits as a broken power law, the number of additional degrees of freedom is 4 and the 95% C.L. limit is obtained for a $\Delta \chi^2$ of 9.49.

### VII. SIMULATING THE GAMMA-RAY EMISSION INDUCED BY DARK MATTER

From this section onwards we focus our attention on the DM-induced gamma-ray emission: we first summarize how we simulate this component, and then we analyze our mock gamma-ray sky maps by computing their auto- and cross-APS. This will constitute our prediction for the APS associated with DM that will be compared to the measured auto- and cross-APS presented in the previous sections.

The simulated DM signal needs to account for all DM structures (halos and subhalos) around us, including the emission generated in the halo of our own Milky Way (MW). We divide the DM auto- and cross-APS into different components that are discussed separately in the following subsections (from Sec. VII A to Sec. VII E). We follow closely the semi-analytical procedure developed in Ref. [34]; i.e., we directly employ catalogs of DM (sub) halos from N-body simulations and complement them with well-motivated recipes to account for the emission of DM halos and subhalos below the mass resolution of the simulations. As in Ref. [34], we make use of the Millennium-II and Aquarius simulations, from the Virgo Consortium [60–62] to simulate the Galactic and extra-Galactic components, respectively.

We take particular care in estimating the systematic uncertainties associated with the DM auto- and cross-APS. In particular, each time we introduce a quantity that is not
well determined, we consider a reasonable range of variability for it and determine its impact on the final DM signal.

We separately consider gamma-ray emission produced by annihilations or decays of DM particles, organizing our predictions in the form of HEALPix maps with Nside = 512. This corresponds to 3,145,728 pixels and an angular size of approximately 0.115°. The order is lower than the one used in the data analysis (see Sec. III). However, note that we will only compare our predictions for the DM signal to the measured spectra below $\ell' = 706$, i.e. for angular scales larger than 0.25°.

The gamma-ray flux (in units of cm$^{-2}$ s$^{-1}$) produced by DM annihilations in the ith energy bin and coming from the pixel centered towards direction $\mathbf{n}_j$ can be written as follows:

$$
\Phi(E_i, \mathbf{n}_j) = \frac{(\sigma_{\text{ann}} v)}{8\pi m^2 c^5} \int_{\Delta \Omega_i} d\Omega_n \int_{0.0}^{2.15} \frac{dz}{H(z)} \rho^2_T(z, \mathbf{n}_j) \times \int_{E_i}^{E_{i+1}} dE \frac{dN^\text{ann}_{E_i}(E_i(1 + z))}{dE} \times \exp[-\tau_{\text{EBL}}(E_i(1 + z))],
$$

(15)

where the integration $d\Omega_n$ extends over the pixel centered on $\mathbf{n}_j$. For redshifts higher than $\sim 2$, the evolution of the DM density field, combined with the larger comoving volume probed, attenuates the signal to a negligible level. Interaction with extra-Galactic background light (EBL) additionally reduces the emission from large redshifts.\footnote{References [29,34,63] show that more than 90% of the emission is produced below $z = 2$.}

The EBL attenuation is modeled in Eq. (15) by the factor $\exp(-\tau_{\text{EBL}}(E_i(1 + z)))$, which is taken from Ref. [64]. The thermal average of the cross section times the relative velocity and the mass of the DM particles are expressed by $\langle \sigma_{\text{ann}} v \rangle$ and $m_T$, while $c$ and $H(z)$ are the speed of light and the Hubble parameter. The function $\rho_T(z, \mathbf{n}_j)$ denotes the DM density at redshift $z$ towards the direction $\mathbf{n}_j$. The photon yield $dN^\text{ann}_{E_i}/dE$ determines the number of photons produced per annihilation. Different mechanisms of gamma-ray production contribute to $dN^\text{ann}_{E_i}/dE$. We specify which contribution is included when we discuss the different components of the total DM signal.

In the case of decaying DM, the expected gamma-ray emission is written as follows:

$$
\Phi(E_i, \mathbf{n}_j) = \frac{1}{4\pi m^2 c^5} \int_{\Delta \Omega_i} d\Omega_n \int_{0.0}^{2.15} \frac{dz}{H(z)} \rho^2_T(z, \mathbf{n}_j) \times \int_{E_i}^{E_{i+1}} dE \frac{dN^\text{dec}(E_i(1 + z))}{dE} \times \exp[-\tau_{\text{EBL}}(E_i(1 + z))].
$$

(16)

Contrary to Eq. (15), Eq. (16) depends linearly on the DM density and it features the DM decay lifetime $\tau$, instead of $(\sigma_{\text{ann}} v)$.

A. Extra-Galactic resolved main halos and subhalos (EG-MSII)

We label halos and subhalos as “resolved” if they are present in the Millennium-II catalog [60] with a mass larger than $6.89 \times 10^8 M_\odot/h$. We employ the same procedure used in Ref. [34] to fill the region below $z = 2.15$ with copies of the original Millennium-II simulation box (see Refs. [29] and [34] for further details). This provides a possible realization of the distribution of resolved extra-Galactic DM halos and subhalos along the past light cone. The sky map of their emission (i.e., what we call “EG-MSII” in the following) is obtained by determining, for each pixel in the map, which DM structures fall inside the angular area of the pixel (completely or partially, according to their size) and by summing together their gamma-ray flux. In the case of annihilating DM, the annihilation rate of a DM halo or subhalo is computed from $V_{\text{max}}$ and $r_{\text{max}}$ (i.e., the maximal circular velocity and the distance from the center of the halo where this occurs) and by assuming that all DM structures are characterized by a Navarro-Frenk-White (NFW) density profile [65]. A different choice of density profile would affect the overall intensity of the DM-induced emission (by a factor as large as 10, between extreme cases such as the Moore [66] and Burkert [67] profiles [29,63]) but it would not affect the shape of the auto- and cross-APS since only a relatively small number of the halos in EG-MSII appear as extended, i.e., covering more than one pixel in our sky map. In the case of decaying DM, the decay rate of a halo depends only on its mass, which is independent of the choice of the density profile.

The Millennium-II and Aquarius $N$-body simulations were performed assuming cosmological parameters favored by WMAP 1. Adopting the most recent values in agreement with the Planck mission [68] could modify the clustering and abundance of DM structures in the simulations. However, it was shown that the increased matter density $\Omega_m$ and the decreased linear fluctuation amplitude $\sigma_8$ (with respect to WMAP 1) have compensating effects [69] and, therefore, we neglect the dependence of our results on the cosmological parameters (see also Ref. [70]).

As in Refs. [29,34], the way the copies of the Millennium-II simulation box are positioned around the observer is a random process. Changing their orientation modifies the distribution of resolved DM halos and subhalos, affecting the shape of the auto- and cross-APS for EG-MSII. Reference [34] showed that this is just a 10% effect that can be neglected in comparison with other sources of uncertainty that will be mentioned later.

For EG-MSII, the photon yield $dN^\text{ann}_{E_i}/dE$ includes the primary gamma-ray emission (taken from Ref. [71]), i.e. hadronization of particles produced in the annihilation,
final state radiation and internal bremsstrahlung. We also consider secondary emission, namely the photons up-scattered by the IC of DM-induced electrons onto the cosmic microwave background (see Ref. [34] for details). In the case of decaying DM, the photon yield is determined as \( dN_i^{\text{decay}}(E)/dE = dN_i^{\text{ann}}(2E)/dE \), where \( i \) stands for either photons or electrons.

B. Extra-Galactic unresolved main halos (EG-UNRESMain)

The emission of unresolved main halos (i.e. with a mass smaller than \( 6.89 \times 10^8 M_\odot/h \)), all the way down to the mass of the smallest self-bound halos \( M_{\min} \), is referred to as “EG-UNRESMain.” \( M_{\min} \) depends on the nature of the DM particle and on its interactions with normal matter but, at least within the context of supersymmetric WIMPs, values between \( 10^{-12} M_\odot/h \) and \( 1 M_\odot/h \) are reasonable, while \( M_{\min} = 10^{-6} M_\odot/h \) has become a popular benchmark [72,73].

In order to estimate EG-UNRESMain, we assume that unresolved main halos share the same clustering properties of main halos with a mass between \( 1.39 \times 10^8 M_\odot/h \) and \( 6.89 \times 10^8 M_\odot/h \). These main halos are just below our threshold of resolved DM structures. They are barely resolved in the Millennium-II simulations (with a number of particles between 20 and 100) and they populate a mass range that the two populations of DM halos share the same spatial distribution. Following the formalism introduced in Ref. [45] this is also equivalent to assuming that they are characterized by the same two-halo term.

In the case of annihilating DM, the computation of \( L_h^{\text{ann}} \), which is the gamma-ray flux produced by a single main halo with mass \( M_{\min} \), is referred to as \( c(M,z) \) CONTRARY TO Ref. [34], we consider only the concentration model described in Ref. [74]: this model allows for \( c(M,z) \) to flatten as \( M \) decreases. Consequently, it agrees with the results of the recent \( N \)-body simulations in Refs. [75,76] and is a more accurate model than the ones from Refs. [77,78]. At \( z = 0 \) and for \( M_{\min} = 10^{-6} M_\odot/h \), Eq. (17) is 24 times larger than the emission of all main DM halos with a mass between \( 1.39 \times 10^8 M_\odot/h \) and \( 6.89 \times 10^8 M_\odot/h \). For \( M_{\min} = 10^{-12} M_\odot/h \), the number is 28 (15).

For decaying DM, \( L_k^{\text{decay}}(M,z) = M \) and the enhancement (with respect to the emission of DM halos with a mass between \( 1.39 \times 10^8 M_\odot/h \) and \( 6.89 \times 10^8 M_\odot/h \)) is 6.7, 6.5 and 5.8 for \( M_{\min} = 10^{-12}, 10^{-6} \) and \( 1 M_\odot/h \), respectively.

C. Extra-Galactic unresolved subhalos

In order to account for the emission of the subhalos of unresolved halos, we modify Eq. (17) as follows:

\[
\int_{M_{\min}}^{1.39 \times 10^8 M_\odot/h} dM \frac{dn_k(M)}{dM} L_k^j(M) B^j(M,z). \tag{18}
\]

The additional term \( B^j(M,z) \) is the so-called boost factor, describing how much the emission of main halos increases when the contribution of their subhalos is included. \( B^{\text{decay}} \) is equal to 1 for all DM halos and redshifts, while the value of \( B^{\text{ann}}(M,z) \) is quite uncertain. We consider two scenarios that we believe bracket the current uncertainty on \( B^{\text{ann}}(M,z) \):

(i) LOW scenario: This prescription is the same as in Ref. [34] and it is motivated by the parametrization (performed in Ref. [79] and extended in Ref. [80]) of the probability \( P(\rho, r) \) of finding a value of the DM density between \( \rho \) and \( \rho + d\rho \) in the data of the Via Lactea II \( N \)-body simulation. For this scenario and at \( z = 0 \), the overall enhancement in Eq. (18) (with respect to the emission of DM main halos with a mass between \( 1.39 \times 10^8 M_\odot/h \) and \( 6.89 \times 10^8 M_\odot/h \)) is 160, 88 and 23 for \( M_{\min} = 10^{-12}, 10^{-6} \) and \( 1 M_\odot/h \), respectively.

(ii) HIGH scenario: This is the same as the LOW recipe below \( 10^8 M_\odot/h \) and it predicts a boost factor 5 times larger above that mass. Indeed, recent results favor boost factors that are larger than the ones of the LOW framework. Reference [81] developed a semianalytic model that accounts for the mass accretion rate of subhalos in larger host halos. The model also describes the effect of tidal
stripping and dynamical friction experienced by subhalos. Including these effects increases the boost factor by a factor of 2–5, relative to the LOW scenario. A similar increase is expected when one accounts for the fact that the concentration of subhalos changes according to the distance of the subhalo from the center of the host halo [82]. Finally, Refs. [83,84] developed a new statistical method to describe the behavior of DM particles in collapsed structures, based on the modeling of the so-called particle phase-space average density (P²SAD). Reference [85] demonstrated that, when computed in the case of DM subhalos, the P²SAD is universal over subhalos of halos with a mass that goes from that of dwarf galaxies to that of galaxy clusters. Employing a reasonable parametrization of the P²SAD, Ref. [85] found boost factors that are as much as a factor of 5 larger than the LOW case, at least for massive DM halos.

The boost factor predicted in Ref. [85] for DM halos with a mass below $10^8 M_\odot/h$ is, however, moderate (see their Fig. 5). Thus, when we compute the emission of unresolved main halos from $10^{-6} M_\odot/h$ to $10^8 M_\odot/h$ as in Eq. (18), and we include the boost factor of Ref. [85], we find a very similar result to that of the LOW scenario. However, predictions are different for massive DM halos: for objects with a mass larger than $10^8 M_\odot/h$ a boost factor 5 times larger than for the LOW case is viable. We assume that such an increment is the same for all masses above $10^8 M_\odot/h$ and we do not concern ourselves with which mechanism (or combinations of mechanisms) is responsible for it among the ones mentioned above, since those studies agree on an increase of this magnitude. For the case with $M_{\text{min}} = 10^{-12} M_\odot/h$ ($M_{\text{min}} = 1 M_\odot/h$), the HIGH boost factor is defined to be a factor of 8.4 (2.1) larger than the LOW one (see Fig. 5 of Ref. [84]).

As in the case of resolved structures (EG-MSII), the emission of unresolved halos and subhalos is computed including the primary gamma-ray emission and that resulting from the IC scattering off the cosmic microwave background. The total extra-Galactic signal is defined as the sum of EG-MSII and EG-UNRESMain, boosted for the emission of unresolved subhalos. We refer to the total emission as “EG-LOW” and “EG-HIGH,” depending on the subhalo boost factor scheme employed.

---

17 Note that the boost factor in Ref. [85] is defined in a different way than in Ref. [34]. Whenever we take some information from Ref. [85], we translate it into the same definition used in Ref. [34].

18 Figure 5 of Ref. [84] refers to the boost factor of MW-like DM halo. Assuming that similar results apply for all DM halos with a mass larger than $10^8 M_\odot/h$ is therefore an approximation.

---

D. The smooth halo of the Milky Way (GAL-MWsmooth)

As in Ref. [34], the emission of the smooth halo of the MW (called “GAL-MWsmooth”) is modeled by assuming that the MW halo follows an Einasto profile [86]:

$$\log \left( \frac{\rho}{\rho_s} \right) = - \frac{2}{\alpha} \left[ \left( \frac{r}{r_s} \right)^\alpha - 1 \right].$$

The parameters in the above equation that provide the best fit to the data of the highest resolution halo, Aq-A-1, in the Aquarius simulation [61,62] are $\rho_s = 7.46 \times 10^{15} h^2 M_\odot$/Mpc$^3$, $r_s = 11.05$ kpc/h and $\alpha = 0.170$. This corresponds to a total MW halo mass of $1.34 \times 10^{12} M_\odot/h$, defined as the amount of DM contained in a sphere with an average density of 200 times the critical density of the Universe. Observationally, the mass of the MW DM halo remains uncertain: Fig. 1 of Ref. [87] shows how different methods (including, e.g., MW mass modeling, dynamics of different tracers and the study of the orbits of Andromeda and the MW) suggest values that go from $5.0 \times 10^{11} M_\odot$ to $2.0 \times 10^{12} M_\odot$. Halo Aq-A-1 described above is on the higher end of this range. In order to account for the uncertainty on the MW mass, we assume that $\rho_s$ can vary from its nominal value of $7.46 \times 10^{15} h^2 M_\odot$/Mpc$^3$ down to $1.87 \times 10^{10} h^2 M_\odot$/Mpc$^3$. The latter corresponds to a MW mass that is $1/4$ of the value of Aq-A-1.19 Note that the intensity of the DM-induced gamma-ray emission is proportional to $\rho_s^4$ and to $\rho_s$ for an annihilating and decaying DM candidate, respectively. On the other hand, the auto- and cross-APS of GAL-MWsmooth are proportional to $\rho_s^4$ for annihilation-induced gamma rays and to $\rho_s^2$ for decaying DM. Thus, the uncertainty on the MW halo mass is a major systematic for the predicted signal we are interested in.

Reference [61] also showed that a NFW profile provides a reasonable fit to the Aq-A-1 data. We do not consider this alternative here, since the difference compared to the Einasto profile described above would be evident only below $\sim 30^{\circ}$ from the center of the MW, i.e. in a region located inside the mask considered in the data analysis (see Sec. III B and Refs. [34] and [88]).

In the case of GAL-MWsmooth, the photon yield is computed while including primary emission and secondary emission from IC. The latter is computed using a full model for the interstellar radiation field of the MW, as described in Ref. [34], and not just the IC scattering off the cosmic microwave background. We also include the hadronic

---

19 Since the observer is located approximately at a distance of $R_0 = 8.5$ kpc from the center of the MW, the best-fit Einasto profile to Aq-A-1 corresponds to a local DM density of 0.45 GeV/cm$^3$. An uncertainty of a factor of 4 on $\rho_s$ would generate a variability of the same size on the local DM density.
FIG. 20. Dependence of the APS of the GAL-AQ component on the MW mass. Left: The lines show the auto-APS at a fixed multipole ($\ell = 49$ for the long-dashed red line, $\ell = 400$ for the solid black one and $\ell = 706$ for the short-dashed blue one) as a function of the mass of the DM halo of the MW, in our simulation of GAL-AQ described in the text. The auto-APS is computed between 0.5 and 0.72 GeV, for $m_\chi = 2.203$ TeV with a thermal annihilation cross section $\langle \sigma v \rangle = 3 \times 10^{-26}$ cm$^3$ s$^{-1}$ and for annihilations into $b\bar{b}$. For each value of the MW mass, 100 realizations of GAL-AQ are computed for different positions of the observer. The lines refer to the median of the distribution of the corresponding auto-APS, while the gray band denotes the variability between the 10% and the 90% quantiles of the distribution. The band is present only for the case with $\ell = 400$ for clarity. Right: The same as in the left panel but for decaying DM. The auto-APS is computed in the same energy bin, for the same $m_\chi$ and a decay lifetime of $2 \times 10^{27}$ s.

E. The subhalos of the Milky Way (GAL-AQ)

The last component to be considered is called GAL-AQ and it accounts for the emission of the subhalos of the DM halo of the MW. We derive this component from the subhalo catalog produced in the Aquarius N-body simulation. Structures with a mass larger than $1.71 \times 10^5 M_\odot$ are treated as "resolved." We place the observer at a distance of $R_0 = 8.5$ kpc from the center of the MW and we compute the sky map of the intensity of resolved Galactic subhalos by identifying which subhalos fall within each pixel of the map and summing up their gamma-ray flux. We neglect the contribution of unresolved subhalos (i.e., with a mass smaller than $1.71 \times 10^5 M_\odot$), as they do not contribute to the auto- and cross-APS as argued in Refs. [34] and [89].

As in Ref. [34], only the primary gamma-ray emission is considered when computing GAL-AQ.

Depending on the exact position of the observer on the sphere with radius $R_0$ and centered on the Galactic Center, the distribution of resolved subhalos changes, and so does the intensity of GAL-AQ and its auto- and cross-APS. We estimate this variability by producing 100 realizations of GAL-AQ, changing, each time, the position of the observer on the sphere. We compute the auto- and cross-APS for each realization and note that, for annihilating DM, the 10% quantile of the distribution of the auto-APS (at $\ell = 400$) among the 100 realizations is a factor of $\sim 1.5$ below the median, while the 90% quantile is a factor of $\sim 2.3$ above. See the gray band in the left panel of Fig. 20. These numbers are 2.1 and 5.6 (1.4 and 2.2) at $\ell = 49$ ($\ell = 706$). We suspect that the distribution gets more peaked (i.e. less variable) at large multipoles because it becomes more sensitive to the inner structure of DM subhalos (which is constant among the realizations), instead of their distribution in the sky. In the case of decaying DM, the 10% and 90% quantiles are always less than a factor of 1.5 away from the median (see the bands in the right panel of Fig. 20). The variability induced by changing the position of the observer is an important component in the total uncertainty of our DM predictions and it will be considered in the following sections.

When discussing GAL-MWsmooth (Sec. VII D), we considered the effect of allowing the MW mass to decrease by a factor of 4 with respect to the nominal

---

However, unresolved Galactic subhalos are expected to contribute to the intensity of the DM-induced emission. This should be kept in mind when, in Fig. 23, we compute our predictions for the DM-induced gamma-ray intensity.
value of Aq-A-1. This has an impact also on GAL-AQ as the number of subhalos in a DM structure is found to be proportional to the mass of the host halo [90,91]. If we define \( k \) as the fraction by which we decrease the MW mass, we consider 16 values of \( k \), from 0.0 to 0.25. For each \( k \), we randomly remove a fraction \( k \) of the subhalos in the Aquarius catalog, to simulate a lighter MW DM halo. For each value of \( k \), we produce 100 realizations of GAL-AQ for different positions of the observer. We compute the auto- and cross-APS for each of the realizations. In Fig. 20, the lines show the median of the distribution of the auto-APS of GAL-AQ (for a fixed multipole) as a function of \( k \) (and, thus, as a function of the MW mass). The left panel is for annihilating DM and the right one for decaying DM. The solid black line is for the auto-APS at \( \ell = 400 \), while the long-dashed red (short-dashed blue) one is for \( \ell = 49 \) (\( \ell = 706 \)). The colored band (when present) denotes the scatter between the 10\% and the 90\% quantiles in the distribution among the 100 realizations. For annihilating DM (left panel), the band becomes larger as the map is populated by fewer and fewer subhalos and, therefore, it depends more and more on their distribution. The variability induced by our partial knowledge of the MW mass is another important source of uncertainty that will be considered in the following sections.

For some values of the DM mass, annihilation cross section and decay lifetime, the gamma-ray flux of some DM subhalos in GAL-AQ may exceed the Fermi LAT source sensitivity threshold. These DM subhalos would appear as resolved sources in the sky and they would be included in the 3FGL catalog. Since the auto- and cross-APS are measured while masking the sources in 3FGL, DM subhalos that are bright enough to be detected should be neglected when simulating GAL-AQ. Being very bright, they may be responsible for a significant fraction of the auto- and cross-APS of GAL-AQ. Thus, neglecting them may affect significantly our predictions for GAL-AQ, as noticed in Ref. [33]. The solid lines show the median (over the 100 realizations) of the number of subhalos that have an energy flux above 0.1 GeV that is larger than the sensitivity flux in 3FGL at \(| b | > 10^\circ \), i.e., \( 3 \times 10^{-12} \text{erg cm}^{-2} \text{s}^{-1} \) [92]. We consider the energy flux and not the number flux, since the Fermi LAT sensitivity, expressed in terms of the energy flux, is more independent of the shape of the gamma-ray energy spectrum than when it is expressed by the number flux.

In a typical realization of GAL-AQ, almost all resolved DM subhalos have a \( r_s \) that corresponds to an angular size smaller than 1 degree. This is a reasonable value for the angular resolution of Fermi LAT at the energies of interest here. Thus, DM subhalos in GAL-AQ are rarely extended and the use of the point-source sensitivity is well motivated.

In Fig. 21, the solid lines show the median (over the 100 realizations) of the number of subhalos that have been excluded because they are too bright, as a function of the annihilation (red line, bottom axis) and decay (blue line, top axis) particle physics factor. At the upper end of the range considered for \( \Phi_{PP} \), this correction affects between 500 and 2000 DM subhalos for annihilating and decaying DM, respectively. These numbers correspond to approximately 1\%–2\% of the total number of subhalos considered in the Aquarius catalog. The colored bands indicate the variability associated with the 10\% and 90\% quantiles among the 100 realizations. The dashed vertical lines are included as a reference and they correspond to the particle physics factor for an annihilating DM candidate with a mass of 200 GeV and

\[
\Phi_{PP}^{\text{decay}} = \frac{1}{m_{\chi}^2} \int_{E_{\text{thr}}}^{m_{\chi}/2} \frac{dN_{\gamma}^{\text{decay}}}{dE} dE, \tag{21}
\]

where we choose a reference energy \( E_{\text{thr}} \) of 0.1 GeV. We consider reasonable ranges for the particle physics factors that go from \( 10^{-30} \) to \( 10^{-25} \text{cm}^3 \text{s}^{-1} \text{GeV}^{-1} \) for \( \Phi_{PP}^{\text{ann}} \) and from \( 10^{-30} \) to \( 10^{-24} \text{s}^{-1} \) for \( \Phi_{PP}^{\text{decay}} \). These are divided into 50 logarithmic bins and, for each bin, we build 100 realizations of GAL-AQ, varying the position of the observer. For each particle physics factor and for each realization, we identify the subhalos (if any) with an energy flux above 0.1 GeV that is larger than the sensitivity flux in 3FGL at \(| b | > 10^\circ \), i.e., \( 3 \times 10^{-12} \text{erg cm}^{-2} \text{s}^{-1} \) [92]. We consider the energy flux and not the number flux,

\[
\Phi_{PP}^{\text{ann}} = \langle \sigma_{\text{ann}} v \rangle \int_{E_{\text{thr}}}^{m_{\chi}/2} \frac{dN_{\gamma}^{\text{ann}}}{dE} dE, \tag{20}
\]

and

\[21\] one should also check that none of the DM halos or subhalos in EG-MSII is bright enough to be detected individually. We do not perform such a test because, even if some DM structures were to be removed, this would hardly affect the prediction for the auto- and cross-APS of EG-LOW and EG-HIGH.
In Fig. 21 we see the effect on the auto-APS of neglecting bright subhalos in Aquarius that are too bright. On the other hand, the impact of bright DM subhalos that should be masked and it will be accounted for by defining the following quantity:

$$k(\Phi_{PP}, \ell) = \frac{C_\ell(\Phi_{PP})}{C_\ell(\Phi_{PP}^{\min})},$$

where $\Phi_{PP}^{\min} = 10^{-30} \text{ cm}^3 \text{s}^{-1} \text{GeV}^{-1}$ for annihilating DM and $\Phi_{PP}^{\min} = 10^{-30} \text{ cm}^3 \text{s}^{-1}$ for decaying DM. $k$ is computed by using the median over the 100 realizations. We will employ it as a correction factor to account for the bright DM subhalos that should be masked and it will be multiplied by the APS of GAL-AQ with all the DM subhalos.

### F. Results

In this section we define some benchmark cases that we will use in the following to discuss our main results.

(i) REF: This is our reference case and it is constructed by summing EG-MSII and EG-LOW, with $M_{\min} = 10^{-6} M_\odot$. We also include GAL-MWsmooth (for the nominal value of the MW DM halo, taken from Aq-A-1, of $1.34 \times 10^{12} M_\odot/h$) and the median of GAL-AQ over the 100 realizations produced for the nominal MW DM halo mass.

(ii) MAX: We build this case by maximizing all the uncertainties considered (and discussed in the previous sections). Thus, we take it as a good estimate of the largest signal that can be associated with DM (for a given value of the particle physics factors and $M_{\min}$). The MAX benchmark scenario is defined by summing EG-MSII, EG-HIGH (for $M_{\min} = 10^{-6} M_\odot$), GAL-MWsmooth (for a nominal mass of the MW DM halo) and the 90% quantile among the 100 realizations of GAL-AQ relative to a $1.34 \times 10^{12} M_\odot/h$ MW.

(iii) MIN: Contrary to MAX, this benchmark is obtained by tuning all the uncertainties considered above to their minimal configuration. In particular, we sum
EG-MSII, EG-LOW (for \( M_{\text{min}} = 10^{-6} M_\odot \)), GAL-MWsmooth (for a MW mass that is \( 1/4 \) of the nominal value of Aq-A-1) and the 10% quantile of the 100 realizations of GAL-AQ for a MW mass that is \( 1/4 \) of the value of Aq-A-1.

In order to discuss the effect of changing \( M_{\text{min}} \), we also compute the MIN and MAX benchmarks for \( M_{\text{min}} = 10^{-12} M_\odot \) and \( M_{\text{min}} = 1 M_\odot \).

Figure 23 shows our predictions for the intensity of the DM-induced emission, averaged over the whole sky. The

![Image of Figure 22](https://example.com/figure22)

**FIG. 22.** Dependence of the APS of the GAL-AQ component on the particle physics factor defined in the text. Left: The solid lines show the DM-induced APS (computed above 0.1 GeV, for a fixed multipole and multiplied by \( \Phi_{\text{ann}}^{\text{pp}} \)) as a function of \( \Phi_{\text{ann}}^{\text{pp}} \), neglecting the DM subhalos that would be detected individually according to the Fermi LAT sensitivity threshold in the 3FGL catalog [92]. The black, red and blue lines are for \( \ell = 400 \), \( \ell = 49 \) and \( \ell = 706 \). They indicate the median over the 100 realizations with different positions for the observer, while the gray band (only for the case with \( \ell = 400 \)) shows the variability between the 10% and 90% quantiles. For reference, the value of \( \Phi_{\text{ann}}^{\text{pp}} \) for \( m_\chi = 200 \) GeV, \( h \sigma_{\text{ann}} v = 10^{-24} \text{ cm}^3 \text{ s}^{-1} \) and annihilation into \( b \bar{b} \) is marked by the gray vertical line. Right: The same as in the left panel, but for a decaying DM candidate. The vertical gray line is the particle physics factor of a DM candidate with \( m_\chi = 200 \) GeV, \( \tau = 2 \times 10^{26} \) s and decaying into \( b \bar{b} \). Note that the default mask covering 3FGL sources is employed when computing the auto-APS.

![Image of Figure 23](https://example.com/figure23)

**FIG. 23.** Left: The predicted energy spectrum of the gamma-ray emission induced by the annihilation of a DM particle with a mass of 212 GeV, \( (\sigma_{\text{ann}} v) = 3 \times 10^{-26} \text{ cm}^3 \text{ s}^{-1} \) and annihilation into \( b \bar{b} \). The black line stands for the REF scenario, while the red and blue ones are for the MAX and MIN cases. Thus, the gray band determines the variability between the MIN and MAX scenarios. In all cases \( M_{\text{min}} = 10^{-6} M_\odot \) (see text for details). The red and blue shaded areas indicate how the MAX and MIN benchmarks change if we let \( M_{\text{min}} \) vary between \( 10^{-6} \) and \( 1 M_\odot \). Right: The same as in the left panel but for a decaying DM particle with a mass of 212 GeV and a decaying lifetime of \( 2 \times 10^{27} \) s. The red and black lines overlap.
left panel is for annihilating DM with a mass of 212 GeV and \( \langle \sigma v \rangle = 3 \times 10^{-26} \text{ cm}^3 \text{s}^{-1} \), while the right panel is for a decaying candidate with the same mass and \( \tau = 2 \times 10^{27} \text{ s} \). Annihilations and decays produce gamma rays via \( bb \). The solid black line is for the REF scenario, while the red and blue ones are for the MIN and MAX benchmark (for \( M_{\text{min}} = 10^{-6} M_\odot \)). Thus, the gray band between the red and blue lines indicates how much our predictions change when accounting for the uncertainties mentioned above.

For annihilating DM, in the case of the REF benchmark, the emission is contributed, almost equally, by EG-LOW and GAL-MWsmooth. Thus, the difference between REF and MAX comes entirely from the different subhalo boosts employed to describe unresolved extra-Galactic DM structures (see Sec. VII C). The boost factor is larger at higher redshifts and, therefore, at energies close to \( m_{\chi} \), where the emission is dominated by nearby sources, the red line approaches the black one. On the other hand, in the LOW scenario the contribution of GAL-MWsmooth is suppressed and, therefore, the intensity of the LOW benchmark is almost halved compared to REF.

Subhalo boosts do not affect the predictions for decaying DM and, therefore, the REF and the MAX benchmarks in the right panel overlap. \(^{25}\) The lower intensity of the LOW case is, as before, due to the suppression of GAL-MWsmooth.

In the left panel, the blue and red shaded areas indicate how our predictions for MIN and MAX change when allowing \( M_{\text{min}} \) to vary in the range mentioned above. These uncertainty bands get larger for smaller energies, as the signal becomes sensitive to the emission at higher redshifts. Changing the minimal DM halo mass has a very minor effect on decaying DM and, thus, the shaded bands are not present.

The predictions of Fig. 23 can be compared with Fig. 12 of Ref. [34]: the main difference is the fact that our brightest configuration (i.e. the MAX scenario) predicts almost 1 order of magnitude less gamma-ray flux than in Ref. [34], given the new definition of the HIGH subhalo boost factor. On the other hand, our predictions are compatible with the results of Ref. [31].

In Fig. 24 we show the predicted auto-APS in the energy bin between 1.38 and 1.99 GeV, for a DM candidate with a mass of 212 GeV, \( \langle \sigma v \rangle = 3 \times 10^{-26} \text{ cm}^3 \text{s}^{-1} \) and annihilation into \( bb \). The auto-APS is divided by \( f_{\text{sky}} \) to correct for the presence of the mask described in Sec. III B. The black solid line and the gray band indicate the Poissonian auto-APS measured in this energy bin and for the mask around 3FGL sources (see Sec. V). The solid blue line is the median of the auto-APS for GAL-AQ over the 100 realizations with different positions for the observer and the blue band shows the variability between the 10% and 90% quantiles. The uncertainty band on GAL-AQ extends downwards (shaded blue area) if we account for an uncertainty of a factor 4 in the value of the mass of MW DM halo. The red and purple lines show the auto-APS for EG-LOW and EG-HIGH, for \( M_{\text{min}} = 10^{-6} M_\odot \). The green line stands for the GAL-MWsmooth component and the green band accounts for an uncertainty of a factor 4 in the mass of the MW DM halo. The wiggles in this component are due to the mask applied to cover the Galactic plane (see text for details). Right: The same as in the left panel but for a decaying DM particle with a mass of 212 GeV and a decaying lifetime of 2 \( \times 10^{27} \text{ s} \). The red and and purple lines overlap.

\(^{25}\) The contribution of GAL-AQ is subdominant.
to be corrected for the presence of the mask. In the analysis of the Fermi LAT data, this is done automatically by POLSPICE (see Sec. III B), while we correct our predictions by dividing the auto- and cross-APS obtained from the masked sky by $f_{sky}$, i.e., the fraction of the sky outside the default mask defined in Sec. III B. Such a recipe is based on the assumption that the masked region is characterized by the same clustering properties of the unmasked one. We test this hypothesis by computing the auto-APS of our simulated sky maps with and without the mask. For the extra-Galactic signal we find that, indeed, dividing the masked auto-APS by $f_{sky}$, we reproduce the unmasked one. On the other hand, for GAL-AQ, the masked auto-APS is 0.43 times smaller than the unmasked one (approximately at all multipoles). This factor is larger than $f_{sky}$, which suggests that the distribution of DM subhalos outside the mask is slightly more isotropic than the distribution inside the mask. This is to be expected since DM subhalos are more clustered towards the center of the host halo. Finally, the auto-APS of GAL-MWsmooth is significantly different if we include the mask: the intensity of the auto-APS decreases as we are covering the region which produces the majority of the emission. Also, the morphology of the mask induces some spurious fluctuations on the auto-APS.

A more sophisticated algorithm should be employed to correct for these features. Alternatively, the wiggles would be reduced by smoothing the edges of the mask. However, we note that, in the signal region defined in Sec. III, the GAL-MWsmooth component is not responsible for the majority of the signal and, therefore, using the reconstructed auto-APS of GAL-MWsmooth would not considerably change our results. Therefore, for both the GAL-AQ and the GAL-MWsmooth, we simply apply the $1/f_{sky}$ correction.

In the left panel of Fig. 24 we note that the dominant contribution is GAL-AQ: the solid blue line is the median over the 100 realizations with different observers (in the case of a MW DM halo with the same mass as Aq-A-1), while the filled blue band shows the variability between the 10% and 90% quantiles. If we also include the possibility that the MW DM halo may be up to four times lighter (see Sec. VII E and Fig. 20), the uncertainty band extends downwards to include the shaded blue band. Over the signal region, GAL-AQ is not constant and it decreases by approximately a factor of 10. The extra-Galactic signal is plotted in red and purple, for a LOW and HIGH subhalo boost, respectively. This uncertainty gives rise to the pink band that covers approximately 1 order of magnitude. The extra-Galactic component becomes nearly constant for $l \gtrsim 300$ but, over the whole signal region, it decreases by a factor of 10. Finally, the GAL-MWsmooth is plotted in green and the green band indicates how much the signal decreases when the mass of MW DM halo is allowed to decrease by up to a factor of 4 with respect to the value of Aq-A-1.

If we had considered $M_{\text{min}} = 10^{-12} M_\odot / h$ instead, the intensity of EG-LOW and EG-HIGH would have been approximately four times larger, while it would have decreased by a factor of 50 if we had considered $M_{\text{min}} = 1 M_\odot / h$. However, since the EG-LOW and EG-HIGH are not dominant components, the effect of changing $M_{\text{min}}$ on the total DM signal will not be as large.

In the right panel we follow the same color coding: the main difference with respect to the case of annihilating DM is the fact that the extra-Galactic contribution dominates the signal for most of the measured signal region. There is no uncertainty associated with the boost factor and, therefore, the red and purple lines coincide. As in the left panel, the auto-APS is nearly constant for $l \gtrsim 300$ and it decreases by a factor of \approx 50 overall. Another important difference, with respect to the case of DM annihilation, is the fact that the auto-APS of GAL-AQ is much steeper, decreasing by a factor of \approx 600 from $l = 49$ to $l = 716$.

Independently of how the different components are summed together,\textsuperscript{26} producing the different REF, MIN and MAX scenarios described above, the total signal associated with DM is not Poissonian but decreases at smaller angular scales. This will be crucial when comparing our predictions to the Fermi LAT data.

VIII. USING THE AUTO- AND CROSS-APS TO CONSTRAIN DARK MATTER ANNIHILATION AND DECAY

In this section we compare the predictions for the DM-induced auto- and cross-APS obtained in Sec. VII with the updated Fermi LAT measurement of the IGRB auto- and cross-APS presented in Sec. V. Such a comparison will allow us to determine whether the data are consistent with a DM interpretation or how we can use them to constrain the nature of DM. We follow two complementary approaches that will be described separately in the following subsections. Neither method finds a significant detection of DM in the auto- and cross-APS data and, therefore, the measurement is used to derive exclusion limits on the intensity of the DM-induced gamma-ray emission, as a function of $m_\chi$.

A. Conservative exclusion limits

This first strategy is motivated by the desire to be conservative. In particular, the DM-induced APS, for any energy bin or combination of bins, must not exceed the measured data. For a certain benchmark case (among REF, MIN and MAX) and for a certain value of $M_{\text{min}}$, imposing that constraint will translate into upper limits on $m_\chi$.

\textsuperscript{26}In principle, one should include the cross-correlation between the different components considered. We do not expect any correlation between extra-Galactic and Galactic emission. The cross-correlation between GAL-MWsmooth and GAL-AQ was computed in Ref. [93] and it is at least 1 order of magnitude below the autocorrelation of GAL-AQ. We neglect it here.
ANNULAR POWER SPECTRUM OF THE DIFFUSE GAMMA- …

FIG. 25. Conservative exclusion limits on annihilating and decaying DM from the new APS measurement. Left: The solid lines show the upper limits on $\langle \sigma_{\text{ann}} v \rangle$ derived from the auto- and cross-APS measured in Sec. III, as a function of $m_\chi$, for $M_{\text{min}} = 10^{-6} M_\odot$ and annihilations into $b\bar{b}$. The limits follow the conservative approach described in the text. The black line is for the REF scenario, while the red and blue ones are for MAX and MIN, respectively. The gray band represents our total systematic astro-physical uncertainty (for $M_{\text{min}} = 10^{-6} M_\odot$), accounting for all the sources of uncertainty mentioned in Sec. VII. The red and blue shaded bands describe the effect of changing $M_{\text{min}}$ between $10^{-12} M_\odot$ and $1 M_\odot$ for the MAX and MIN scenario. In the case of the the black, red and blue dashed lines, the upper limits are derived only by considering the measured auto-APS and neglecting the cross-APS. For comparison, the long-dashed gray line marks the annihilation cross section for thermal relics from Ref. [94] and the dashed-dotted gray line the upper limit obtained in Ref. [95] from the combined analysis of 15 dwarf spheroidal galaxies. Finally, the short-dashed gray line shows the conservative upper limit derived in Ref. [31] from the intensity of the IGRB. Right: The same as in the left panel but for the lower limits on $\tau$ for decaying DM. The short-dashed gray line represents the lower limit obtained in Fig. 6 of Ref. [96] from the IGRB intensity, while the dashed-dotted gray one is obtained from the combined analysis of 15 dwarf spheroidal galaxies in Ref. [97].

the intensity of the DM-induced signal or, by fixing $m_\chi$ and the annihilation/decay channel, into upper limits on $\langle \sigma_{\text{ann}} v \rangle$ for annihilating DM and into lower limits on $\tau$ for decaying DM. We refer to these exclusion limits as “conservative.”

We consider 60 values of $m_\chi$ between 5 GeV and 5 TeV. For each value of $m_\chi$, we compute the DM-induced auto- and cross-APS in the 13 energy bins defined in Sec. II, for the three benchmarks described in Sec. VII F, for three annihilation/decay channels (i.e., $b\bar{b}$, $e^+e^-$ and $\mu^+\mu^-$)27 and for three values of $M_{\text{min}}$ (i.e., $10^{-12}$, $10^{-6}$ and $1 M_\odot$). The APS associated with DM for energy bins $i$ and $j$ is averaged over the signal region in multipole and we require it to be smaller than the Poissonian APS measured for that pair of energy bins plus 1.64 times its error: $\langle C_{\ell,i}^{\chi}\rangle < C_{\ell,j}^{\chi} + 1.64 \sigma_{\ell,i}^{\chi}$. Assuming that the measured $C_\ell$ has a Gaussian probability distribution with a central value of $C_\ell$ and a standard deviation of $\sigma_{\ell,i}^{\chi}$, values further away than 1.64 times $\sigma_{\ell,i}^{\chi}$ from the central value correspond to a cumulative probability distribution larger than 0.95. Thus, excluding them provides a 95% C.L. exclusion bound. For each $m_\chi$, we take the most stringent limit among all the combinations of energy bins.

Figure 25 shows the upper limits on the $\langle \sigma_{\text{ann}} v \rangle$ (left panel) and the lower limits on $\tau$ (right panel), as a function of $m_\chi$, for annihilations/decays into $b\bar{b}$ and for the different benchmark scenarios considered above. The black line is for REF while the blue and red ones are for MIN and MAX. Thus, the gray band represents our total systematic astro-physical uncertainty (for $M_{\text{min}} = 10^{-6} M_\odot$), and it is as large as approximately a factor of 5 or 2, for annihilating and decaying DM, respectively. The limits have some wiggles because, depending on the DM mass, the emission peaks at different energies and different combinations of energy bins are responsible for the exclusion limit. Solid lines are obtained considering all the possible combinations of energy bins, while for the black, blue and red dashed ones only the auto-APS is employed. The figure shows that, at large DM mass and both for annihilating and decaying DM, the exclusion limits are driven by the cross-APS and not by the auto-APS, approximately for $m_\chi > 200$ GeV for annihilating DM and for $m_\chi > 700$ GeV for decaying DM.

In the left panel, the red and blue shaded areas account for the effect of changing $M_{\text{min}}$ between $10^{-12} M_\odot$ and $1 M_\odot$ and they are computed only for the MIN and MAX scenarios. The effect is more important for the MIN case since the emission from extra-Galactic DM structures

27See Ref. [34] on how to compute the emission for multiple annihilation/decay channels without having to recompute, for each case, the mock sky maps from the N-body simulations.
contributes more to the total signal in this case (see Fig. 24). If we include the variability on $M_{\text{min}}$ in our budget for the systematic uncertainty, the systematic error grows to a factor of 40. Compared to the conservative upper limits on $\langle \sigma_{\text{ann}} v \rangle$ derived by the intensity of the IGRB in Ref. [31], our uncertainty is approximately a factor of 2 larger. The long-dashed gray line is the thermal annihilation cross section computed in Ref. [94]. The line marks the beginning of the region where, for WIMP DM, one can find annihilation cross sections that correspond to a relic DM abundance in agreement with the Planck data [68].

Unfortunately, our conservative upper limits do not probe this region, as they are, at least, a factor of 3 away from it. Also, the REF upper limit is approximately 2 orders of magnitude higher than the upper limit derived from the observation of 15 dwarf spheroidal galaxies performed by Fermi LAT [95] and included here as a gray dashed-dotted line. Finally, it is a factor of 2 higher than the conservative upper limit derived from the intensity of the IGRB (short-dashed gray line) [31], at least below 100 GeV. Above this value, the IGRB intensity leads to an even more stringent exclusion.

In the right panel, it can be seen that the lower limits on $\sigma_{\text{ann}}$ derived here from the auto- and cross-APS are a factor of 5 less stringent than the upper limits obtained in Fig. 6 of Ref. [96] from the IGRB intensity, in their conservative scenario. The REF scenario is also at least a factor of 5 from the dashed-dotted gray line showing the lower limits obtained from the combined analysis of 15 dwarf spheroidal galaxies in Ref. [97].

Figures 35 and 36 in Appendix E show the exclusion limits on $\langle \sigma_{\text{ann}} v \rangle$ and $\tau$ in the case of the $\tau$ and $\mu$ channels.

### B. Fit to the data and realistic exclusion limits

In this section we describe our analysis of the auto- and cross-APS using a two-component model that includes a Poissonian term and a DM-induced one which, as we noticed in Fig. 24, deviates from a Poissonian behavior. The Poissonian component is interpreted as the APS of unresolved astrophysical sources, even if we do not try to predict its amplitude in terms of a specific model. This two-component model will be used to fit the Fermi LAT APS as a function of the multipole.

The fit minimizes the $\chi^2$ defined as

$$\chi^2 = \sum_{i,j,\ell} \frac{[C_{\ell,\text{DM}}^{i,j} - C_{\ell,\text{DM}}^{i,j} + C_{\text{P,astro}}^{i,j}]^2}{\sigma^{i,j}_v},$$

(23)

where the $i, j$ indexes in the sum extend over all 91 independent combinations of energy bins and the $\ell$ index runs over the 10 bins in multipole contained in the signal region. $C_{\ell,\text{DM}}^{i,j}$ indicates the APS measured in the $(i,j)$ combination of energy bins and in the $\ell$ multipole bin, while $C_{\ell,\text{DM}}^{i,j}$ and $C_{\text{P,astro}}^{i,j}$ are the DM and Poissonian components of our model in the same combination of energy bins and in the same multipole bin. Finally, $\sigma^{i,j}_v$ is the experimental error associated to $C_{\ell,\text{DM}}^{i,j}$ and provided by POLSPICE. The DM APS $C_{\ell,\text{DM}}^{i,j}$ are computed for the same 60 values of $m_\chi$ as in the previous section, the same three annihilation/decay channels, three benchmark scenarios and three values of $M_{\text{min}}$. The only remaining parameter needed to calculate $C_{\ell,\text{DM}}^{i,j}$ is either $\langle \sigma_{\text{ann}} v \rangle$ or $\tau$: they will be fixed to a specific value every time we compute $\chi^2$. On the other hand, the 91 independent values of $C_{\text{P,astro}}^{i,j}$ in Eq. (23) are left free in the fit. Putting the DM term to zero in Eq. (23) defines our null hypothesis. In that case, the fit to the Fermi LAT data leads us to the $C_\ell$ estimators discussed in Sec. III, whose auto-APS is plotted in Fig. 8. Including the DM component, for a fixed $m_\chi$, annihilation/decay channel, benchmark scenario and $M_{\text{min}}$, we repeat the minimization of $\chi^2$ in Eq. (23), for different values of $\langle \sigma_{\text{ann}} v \rangle$ and $\tau$.

We show an example in Fig. 26, for the case of the REF scenario for a DM candidate with a mass of 768.1 GeV, $\langle \sigma_{\text{ann}} v \rangle = 6.12 \times 10^{-24}$ cm$^3$ s$^{-1}$ annihilating into $bb$. The value of the annihilation cross section corresponds approximately to the exclusion upper limit for that value of DM mass, as will be computed later. The red circles show the measured auto-APS as a function of $\ell$ in the signal region for one reference energy bin, i.e., the one between 10.4 and 21.8 GeV.
21.8 GeV (when masking 3FGL sources). The solid red line with the pink band denotes the best-fit $C_p$ in that energy bin for the null hypothesis (i.e., without DM), while the dashed blue line is the best-fit Poissonian component $C_{p, astro}$ when the fit is done with the two-component model (i.e., including DM). The dashed line is lower than the solid one, since at these energies part of the signal is explained by DM and, therefore, there is less need of a Poissonian component. Energy bins not localized near the peak of the DM emission are only slightly affected by the inclusion of the DM term in the fit. The best-fit configuration for the two-component model is plotted with blue triangles: the inclusion of the DM term makes it multipole dependent so that it decreases by a factor of $\sim 3$ over the signal region.

We note that, including the DM component, it is possible to find a configuration that improves the $\chi^2$ of the best-fit point with respect to the null hypothesis, at least for DM masses above a few hundreds of GeV. This is probably due to the fact that the measured auto-APS is slightly multipole dependent. We can quantify the improvement in the fit provided by the DM component by building a two-dimensional grid in $(m_x, \langle \sigma v \rangle)$ for annihilating DM and in $(m_x, \tau)$ for decaying DM and plotting the TS $\Delta \chi^2$, i.e. the difference between the $\chi^2$ of the best fit for the null hypothesis and the $\chi^2$ of the best fit in the case of the two-component model. This is shown in Fig. 27, where the left panel refers to annihilating DM and the right one to decaying DM (for the $b$ channel and a REF scenario with $M_{\text{min}} = 10^{-6} M_\odot$). In both panels, the closed area indicates the region where the two-component model is preferred over the null hypothesis at a 68% C.L. The 90% and 95% C.L. regions are open and bounded by the corresponding white lines. This tells us that including the DM component in the model provides a better fit to the auto- and cross-APS measured in Sec. III, with a significance between 1 and 1.6$\sigma$. This is too small to consider as significant. Thus, we conclude that the data do not significantly prefer the addition of a DM component and we use the measured auto- and cross-APS to derive constraints on the DM signal.

The contour plots for the $\tau$ and $\mu$ channels can be seen in Appendix E. In both cases, the 68% C.L. region is the only closed one.

For each value of $m_x$, $M_{\text{min}}$, annihilation/decay channel and benchmark scenario, the exclusion limits on $\langle \sigma v \rangle$ and $\tau$ are derived by scanning on $\langle \sigma v \rangle$ and $\tau$ until we find the values that correspond to a best fit with a TS $\Delta \chi^2$ of 3.84 with respect to the null hypothesis. Such a value is derived by assuming that $\Delta \chi^2$ follows a $\chi^2$ probability distribution with one degree of freedom (i.e., $\langle \sigma v \rangle$ or $\tau$) and noting that values larger than 3.84 fall outside 5% of the cumulative distribution probability. This recipe provides the 95% C.L. exclusion limits on $\langle \sigma v \rangle$ and $\tau$ that are summarized in the left and right panels of Fig. 28, respectively.

In the left panel, as in Fig. 25, the black, blue and red solid lines correspond to the REF, MIN and MAX scenarios. The difference between MIN and MAX covers slightly more than a factor of 5. The blue and red shaded

---

$^2$The 68% C.L. area is obtained by identifying the region where the best-fit solution for the two-component model has a TS $\Delta \chi^2$ of 2.30 larger than the null hypothesis. The values are 4.61 and 5.99 for the 90% and 95% C.L. regions.
regions around the solid lines of the same color indicate how the upper limits change when we leave $M_{\text{min}}$ free to vary. This extends the range of the total systematic uncertainty to approximately a factor of 20. For comparison, the black dashed line is the REF upper limit in its conservative version (from Fig. 25). Fitting the data with the two-component model generates exclusion limits that are approximately a factor of 10 stronger, at least at low DM masses. As the mass increases, the method employed in this section starts to perform progressively worse and the solid black line gets closer to the dashed one. This is due to the fact that, for $m_\chi > 150$ GeV, the data slightly prefer the interpretation with DM as opposed to the null hypothesis. The figure also includes the thermal cross section from Ref. [94] as a long-dashed gray line: our upper limit for the REF case is slightly above it, below 10 GeV. It is also more than a factor of 10 weaker than the upper limit derived from the observation of 15 dwarf spheroidal galaxies in Ref. [95]. Finally, the short-dashed gray line indicates the exclusion limits obtained in Ref. [98] by studying the intensity of the IGRB with a two-component model that, similarly to what is done here, includes both a generic model-independent astrophysical contribution and a DM one. Our REF limit is slightly stronger than the short-dashed gray line for $m_\chi < 30$ GeV, suggesting that the study of the IGRB anisotropies could in principle be a more effective way of constraining DM than the IGRB intensity. However, for larger DM masses, our limit gets worse due, again, to the fact that the data slightly prefer an interpretation that includes DM.

The same color coding is used in the right panel for decaying DM. With no dependence on $M_{\text{min}}$, the band of the systematic uncertainty covers a factor of 2, and the REF upper limit is even 1 order of magnitude above the conservative one, at least at 60–70 GeV. For larger masses our limit worsens for the same reason as in the left panel. As in Fig. 25, the short-dashed gray line is the lower limit obtained from the analysis of the IGRB intensity from Ref. [96]. The line refers to the case in which the IGRB is modeled in terms of a component with a power-law energy spectrum and a DM contribution. Above 20 GeV, where both lines are available, the analysis of the IGRB intensity is always more powerful than the anisotropy study performed here. Finally, the dotted-dashed gray line is the lower limit obtained from the analysis of 15 dwarf spheroidal galaxies in Ref. [97]. Our REF scenario is always below this line, at least by a factor of 2.

In Appendix E we include the exclusion limits for the $\tau$ and $\mu$ channels.

When fitting with the two-component model, the 91 $C^j_{\text{DM}}$’s can vary independently and they react to the presence of the DM component by reproducing the...
measured APS in those combinations of energy bins where the DM component is subdominant. Therefore, it may be difficult to interpret a best-fit set of $C_{ijPLY}$ in terms of one or more populations of actual astrophysical sources, e.g. unresolved blazars or star-forming galaxies. A more physical approach can be obtained by considering the phenomenological description presented in Sec. VI. In this case, the astrophysical component in the two-component fit is described by means of the scenario with two broken power laws (see Table III). The latter depends on 8 free parameters instead of 91. We employ this revised version of the two-component model to fit the binned auto- and cross-APS $C_{ij}$ in all the combinations of energy bins. The exclusion limits on $\langle\sigma_{\text{ann}}v\rangle$ and $\tau$ are obtained by finding the configuration that yields a $\chi^2$ that is larger by 3.84 than the best-fit $\chi^2$ of the null hypothesis (i.e. no DM). The resulting upper limits are compatible with the ones shown in Fig. 28 and, therefore, we decided not to show them.

**IX. DISCUSSION AND CONCLUSION**

In this paper we measure the autocorrelation and cross-correlation angular power spectrum of the diffuse gamma-ray emission detected by Fermi LAT at high Galactic latitudes in 81 months of observation. The measurement builds on a similar analysis based on 22 months of data and published in Ref. [1]. With respect to the latter, this work takes advantage of the larger statistics, as well as of the improved event reconstruction achieved for Pass 7 Reprocessed events and instrument response functions. Other improvements, with respect to Ref. [1], consist of a revised method for binning the data in multipole and to compute the Poissonian auto- and cross-APS. We also correct the estimate of the photon noise and we employ a different method to account for the effect of the mask. Finally, we consider a more recent model of the diffuse Galactic foreground associated with the Milky Way (MW) disk.

The second part of the paper focuses on the auto- and cross-APS expected from annihilation or decay of DM. We employ a hybrid approach to model the distribution of DM, making use of catalogs of DM halos and subhalos from state-of-the-art $N$-body simulations and combining them with analytical recipes to account for DM structures below the mass resolution of the simulations. The methodology follows what was done in Ref. [34]. Compared to the latter, this work discards the possibility of very large subhalo boost factors induced by naive power-law extrapolations of the concentration parameter to low halo masses. We also account for the uncertainty associated with the mass of the MW, and we correct for the possibility of having very bright Galactic DM subhalos that would be individually resolved as gamma-ray sources.

The main results of this papers are summarized in the following list.

(i) **Detection of auto- and cross-APS**: Because of the instrumental improvements and of the refinements in the analysis mentioned before, the measurement presented here probes a larger energy range (compared to the original analysis in Ref. [1]), between 0.5 and 500 GeV, divided into 13 energy bins. We also compute, for the first time, the cross-APS between different energy bins. We detect significant auto-APS in almost all the energy bins below 21.83 GeV. Significant cross-APS is also measured in most combinations of energy bins (see Tables I and II).

(ii) **Independence on angular multipole**: Our results cover a larger range of multipoles than the original analysis, i.e., from $\ell = 49$ to 706. In this multipole range, the detected auto- and cross-APS are consistent with being Poissonian, i.e. constant in multipole. An alternative $\ell$-dependent model is also employed to fit the data but there is no significant preference for the $\ell$-dependent model over the Poissonian interpretation. If future data sets were able to detect a non-Poissonian behavior, it would represent the first detection of scale dependence in gamma-ray anisotropies. Such a result would provide valuable insight into the nature of the isotropic gamma-ray background, e.g. an upper limit on the contribution of sources like blazars or misaligned active Galactic nuclei, which are associated with a Poissonian APS. It would also probe other possible sources like star-forming galaxies or dark matter structures, from which we expect an $\ell$-dependent auto- and cross-APS [8].

(iii) **Detection of multiple source classes**: The anisotropy energy spectrum (i.e. the dependence of the auto- and cross-APS on the energy) is not featureless and it is best fitted by two populations of sources with broken-power-law energy spectra. The interpretation in terms of only one source population (whether emitting as a power law or broken power law) is excluded at 95% C.L. This suggests that the auto- and cross-APS result from a class of objects emitting mainly at low energies with a soft energy spectrum $\propto E^{-\alpha_1}$ with $\alpha_1 \sim 2.58$, and a second population of harder objects with $\alpha_2 \sim 2.10$. The crossover between the two source classes, according to our fit, happens at approximately 2 GeV. The harder spectral slope is compatible with that expected from BL Lacertae [38], which are thought to dominate the IGRB at high energies. At lower energies, the spectral slope is similar to that of flat-spectrum radio quasars [99] or of normal star-forming galaxies [8,100] (see also Ref. [101]).

(iv) **Presence of an high-energy cutoff**: Our best-fit interpretation shows a cutoff at around 85 GeV. This may be related to the absorption of the extra-Galactic background light, since a similar feature is
detected in the intensity energy spectrum of the IGRB in Ref. [4].\textsuperscript{29} If we were able to confirm that the cutoff is associated with the EBL, this would be the first time that the absorption by the EBL was detected via anisotropies. One way to achieve such a confirmation would be to detect a significant cross-correlation between the same data set employed here and a catalog of tracers of the large-scale structure of the Universe. The possibility of binning the catalog in redshift would allow us to perform a tomographic analysis and to select the emission coming from different comoving distances [21,22]. Alternatively, the cutoff may be an intrinsic feature of the energy spectrum of the sources responsible for the auto- and cross-APS at high energies.

(v) Systematic uncertainties in the anisotropies induced by annihilating DM: In the case of an annihilating DM candidate, an uncertainty of a factor of 4 in the mass of the MW induces a variation of a factor of \( \sim 30 \) in the auto- and cross-APS associated with Galactic subhalos. For a MW mass of the order of \( 10^{12} M_\odot \), Galactic subhalos dominate the expected anisotropic signal from DM. If the MW is less massive, i.e., a few times \( 10^{11} M_\odot \), the extra-Galactic component starts to be important, at least for large subhalo boost models. For DM annihilations occurring in extra-Galactic DM halos and subhalos, the uncertainties on the subhalo boost factor (for a fixed \( M_{\text{min}} \)) induce an uncertainty of a factor of \( \sim 20 \) on the expected auto- and cross-APS from this component. The gamma-ray emission produced by DM annihilations in the smooth halo of the MW generates a negligible anisotropic signal outside the adopted mask. The overall uncertainty on the predicted DM-induced APS (for a fixed \( M_{\text{min}} \)) is of a factor of 20, similar to the one estimated in Ref. [31] for the intensity of all-sky gamma-ray emission. Changing the value of \( M_{\text{min}} \) from \( 10^{-12} \) to \( 1 M_\odot \) approximately doubles the systematic uncertainty.

(vi) Systematic uncertainties in the anisotropies induced by decaying DM: In the case of decaying DM, the extra-Galactic signal dominates the expected auto- and cross-APS and the prediction is independent of the value of the subhalo boost factor. Decays in the smooth halo of the MW or in its subhalos are subdominant. The overall uncertainty (for a fixed value of \( M_{\text{min}} \)) is less than a factor of 2. Varying \( M_{\text{min}} \) over the range mentioned before has a negligible effect in the case of decaying DM.

(vii) Conservative exclusion limits on DM: Requiring that the DM-induced auto- and cross-APS does not exceed the measurement in any energy bin or combination of energy bins yields an upper limit on \( \langle \sigma v \rangle \) that is at least a factor of 2 less stringent that the one obtained in Ref. [31] from the analysis of the IGRB energy spectrum (for the REF scenario and the \( b \) channel). In the case of annihilations into \( b\bar{b} \), the constraint on the annihilation cross section reaches a value as low as \( 10^{-25} \text{ cm}^3 \text{s}^{-1} \) for a DM mass of 5 GeV and, therefore, it is approximately 2 orders of magnitude less constraining than the one inferred from the observation of dwarf spheroidal galaxies. For decaying DM, the lower limit on \( \tau \) is a factor of 5 weaker than the one from the IGRB intensity [96] and, at least, a factor of 5 weaker than the one from the analysis of dwarf spheroidal galaxies [97] (for the REF case and decays into \( b\bar{b} \)).

(viii) Exclusion limits from the two-component fit: Fitting the data with a two-component model that includes DM provides more constraining exclusion limits. The resulting upper limit for annihilating DM (in the REF scenario for a \( M_{\text{min}} \) of \( 10^{-6} M_\odot /h \) and annihilations into \( b\bar{b} \)) is still a factor of 10 less constraining than the combined analysis of dwarf spheroidals from Ref. [95]. However, below a DM mass of 30 GeV, it is slightly better than what was derived in Ref. [98] from the analysis of the IGRB intensity energy spectrum in terms of a two-component model. For decaying DM, the lower limits on \( \tau \) are, at least, a factor of 2 less stringent than those obtained from the IGRB intensity energy spectrum [96] or from the combined analysis of dwarf spheroidals [97].

The exclusion limits on DM, although they do not exclude new regions of the DM parameter space, are complementary to those computed from the intensity of the IGRB or from the observation of dwarf spheroidals and, therefore, they provide independent information. Also, they are expected to become more stringent as the measurement of the auto- and cross-APS will improve during the next few years. Beside making use of the data collected after May 2015, future analyses will rely on Pass 8 data, benefiting from the new event classes and data selections available (see Sec. V C). Also, future catalogs of sources, deeper than 3FGL, will explore faint sources that are now unresolved and will improve our modeling of those source classes. It will certainly be interesting to complement the measurement of gamma-ray anisotropies performed here with a similar observation at higher energies (which will be possible in the near future with the Cherenkov Telescope Array [102,103]) or in the sub-GeV regime (with future measurements of the IGRB).
satellites like ASTROGAM\textsuperscript{30} and ComPair [104]). Finally, in a multimessenger perspective, the study of gamma-ray anisotropies can be interfaced with similar analyses on the high-energy neutrinos recently discovered by IceCube [105–108]. Since the same sources that contribute to the IGRB (e.g., blazars, star-forming or radio galaxies) are also expected to emit neutrinos, the auto- and cross-APS measured in this work represents a useful indication for the minimal level of anisotropies that can be found in the distribution of neutrinos. A quantitative estimate of IceCube prospects to detect anisotropies can be found in Ref. [109].

\section*{ACKNOWLEDGMENTS}

The Fermi LAT Collaboration acknowledges generous ongoing support from a number of agencies and institutes that have supported both the development and the operation of the LAT as well as scientific data analysis. These include the National Aeronautics and Space Administration and the Department of Energy in the United States; the Commissariat à l’Energie Atomique and the Centre National de la Recherche Scientifique/Institut National de Physique Nucléaire et de Physique des Particules in France; the Agenzia Spaziale Italiana and the Istituto Nazionale di Fisica Nucleare in Italy; the Ministry of Education, Culture, Sports, Science and Technology (MEXT), High Energy Accelerator Research Organization (KEK) and Japan Aerospace Exploration Agency (JAXA) in Japan; and the K.A. Wallenberg Foundation, the Swedish Research Council and the Swedish National Space Board in Sweden. Additional support for science analysis during the operations phase is gratefully acknowledged from the Italian National Board for Space Research (ASI) and from the Danish National Research Foundation (DNRF). J. Z. is gratefully acknowledges support from the Netherlands Organization for Scientific Research (NWO) through a Vidi grant (P.I.: Dr. Shin’ichiro Ando), from the Leverhulme Trust and the project MultiDark CSD2009-00064. F. Z. acknowledges the support of the NWO through a Veni grant.

\section*{APPENDIX A: DERIVATION OF THE PHOTON NOISE $C_N$}

Let $n_i$ be the number of photons in a pixel $i$, $\bar{n}_i$ be its expectation value, and $\delta n_i = n_i - \bar{n}_i$ be a fluctuation around the mean. The photon flux is given by $n_i/A_i$, where $A_i$ is the exposure in pixel $i$. Then, the photon flux per unit solid angle is given by $n_i/(A_i \Omega_{\text{pix}})$, where $\Omega_{\text{pix}}$ is the solid angle of pixel $i$.

The spherical harmonics coefficients $a_{\ell,m}$ are

\begin{equation}
    a_{\ell,m} = \int d\Omega \frac{\delta n_i}{A_i \Omega_{\text{pix}}} Y_{\ell,m}(\Omega_i). \tag{A1}
\end{equation}

where $\Omega_i$ denotes the direction of pixel $i$. The expectation value of the product between two coefficients is

\begin{equation}
    \langle a_{\ell,m} a_{\ell',m'} \rangle = \int d\Omega_i \int d\Omega_j \frac{\langle \delta n_i \delta n_j \rangle}{A_i A_j \Omega_{\text{pix}}^2} Y_{\ell,m}(\Omega_i) Y_{\ell',m'}(\Omega_j). \tag{A2}
\end{equation}

If $\delta n_i$ is purely Poisson noise, $\langle \delta n_i \delta n_j \rangle / \Omega_{\text{pix}}^2 = \langle \bar{n}_i / \Omega_{\text{pix}} \rangle \delta(\Omega_i - \Omega_j)$ where $\delta$ is the Dirac delta function. Thus,

\begin{equation}
    \langle a_{\ell,m} a_{\ell',m'} \rangle = \int d\Omega_i \frac{\bar{n}_i}{A_i^2 \Omega_{\text{pix}}} Y_{\ell,m}(\Omega_i) Y_{\ell',m'}^{\ast}(\Omega_i). \tag{A3}
\end{equation}

Now, we calculate the diagonal element, i.e., $C_{\ell} = \sum_m \langle a_{\ell,m} a_{\ell,m}^{\ast} \rangle / (2\ell + 1)$, obtaining

\begin{equation}
    C_{\ell} = \int \frac{d\Omega_i}{4\pi} \frac{\bar{n}_i}{A_i^2 \Omega_{\text{pix}}}. \tag{A4}
\end{equation}

FIG. 29. Auto-APS of the IGRB for the first six energy bins and for the reference data set (P7REP_ULTRACLEAN_V15 front events) using the reference mask which excludes $|b| < 30^\circ$ and 3FGL sources (red circles). The blue triangles show the same but masking the sources in 2FGL, instead. Data have been binned as described in Sec. IV.A. The solid red line shows the best-fit $C_p$ for the red data points, with the pink band indicating its 68% C.L. error. The dashed blue line corresponds to the best-fit $C_p$ for the blue data points. The energy range is indicated on the top of each panel. Note that only the results in our signal region (i.e. between $\ell = 49$ and 706) are plotted and that the scale of the y-axis can vary from panel to panel.
FIG. 30. Same as Fig. 29 but for the last seven energy bins.
FIG. 31. Dependence of the cross-APS on the energy. Each panel shows the best-fit Poissonian $C_{i,j}$ for the cross-APS between the $i$th and the $j$th energy bins, as a function of $E_j$. Red circles are for the reference data set (P7REP_ULTRACLEAN_V15 front events) using the default mask masking 3FGL sources, while the blue triangles show the result for the same data set and for the default mask excluding 2FGL sources. The first six energy bins are shown in this figure and $E_i$ is indicated in the top of each panel. The solid black line is the best-fit solution when data are fitted assuming two independent populations of sources with broken-power-law energy spectra. The short-dashed and long-dashed black lines show the two populations independently.
FIG. 32. Same as Fig. 31, for the last seven energy bins.
FIG. 33. Dependence of the cross-correlation coefficients on the energy. Each panel shows the cross-correlation coefficients $r_{i,j}$ defined in Sec. VB between the $i$th and the $j$th energy bins, as a function of $E_j$. Red circles are for the reference data set (P7REP_ULTRACLEAN_V15 front events) using the default mask masking 3FGL sources, while the blue triangles show the result for the same data set and for the default mask excluding 2FGL sources. The first six energy bins are shown in this figure and $E_i$ is indicated in the top of each panel. The solid black line shows the $r_{i,j}$ corresponding to the best-fit solution when data are fitted by masking 3FGL sources and assuming two independent populations of sources with broken-power-law energy spectra (see Sec. VI).
FIG. 34. Same as Fig. 33, for the last seven energy bins.
The latter is independent on multipole $\ell$ and equivalent to the definition of $C_N$ in Eq. (5).

APPENDIX B: AUTOCORRELATION ANGULAR SPECTRA FOR ALL THE ENERGY BINS

Figures 29 and 30 show the binned auto-APS $C_\ell$ obtained as described in Sec. III, for all 13 energy bins considered. The auto-APS is shown only within the signal region, i.e. between a multipole of 49 and 706. Red circles refer to the data set obtained with our default mask covering the sources in 3FGL and the solid red line marks the corresponding best-fit $C_\ell$. The pink band denotes the 68% C.L. error on $C_\ell$. The blue data points are for the same data set but using the default mask covering sources in 2FGL. The dashed blue line

\[ \chi^2 \frac{1}{\tau} \sim \frac{1}{\mu} \]

Fig. 35. Conservative exclusion limits on annihilating and decaying DM from the new APS measurement, for the $\tau$ channel. Left: The solid lines show the upper limits on $\langle \sigma v \rangle$ derived from the auto- and cross-APS measured in Sec. III, as a function of $m_\chi$, for $M_{\text{min}} = 10^{-6} M_\odot$ and annihilations into $\tau^+ \tau^-$. The limits follow the conservative approach described in Sec. VIII A. The black line is for the REF scenario, while the red and blue ones are for MAX and MIN. The gray band between the MIN and MAX scenario represents our estimated total astrophysical uncertainty for $M_{\text{min}} = 10^{-6} M_\odot$, accounting for all the sources of uncertainty mentioned in Sec. VII. The red and blue shaded bands describe the effect of changing $M_{\text{min}}$ between $10^{-12} M_{\text{min}}$ and $1 M_{\text{min}}$ for the MAX and MIN scenario, respectively. In the case of the black, red and blue dashed lines, the upper limits are derived only considering the measured auto-APS and neglecting the cross-APS. For comparison, the long-dashed gray line marks the annihilation cross section for thermal relics from Ref. [94] and the dashed-dotted gray line the upper limit obtained in Ref. [95] from the combined analysis of 15 dwarf spheroidal galaxies. Finally, the short-dashed gray line shows the conservative upper limit derived in Ref. [31] from the intensity of the IGRB.

Right: The same as in the left panel but for the lower limits on $\tau$ for decaying DM. The short-dashed gray line represents the lower limit obtained in Fig. 6 of Ref. [96] from the IGRB intensity, while the dashed-dotted gray one is obtained from the combined analysis of 15 dwarf spheroidal galaxies in Ref. [97].

\[ \chi^2 \frac{1}{\tau} \sim \frac{1}{\mu} \]

FIG. 36. Same as Fig. 35 but for annihilations/decays into $\mu^+ \mu^-$. 

123005-44
stands for the Poissonian best fit to the blue triangles. Data are available at https://www-glast.stanford.edu/pub_data/552.

**APPENDIX C: ANISOTROPY ENERGY SPECTRUM FOR THE CROSS-CORRELATION ANGULAR POWER SPECTRUM**

Figures 31 and 32 show the best-fit $C_\Theta$ for the cross-APS as a function of energy. Red circles refer to the mask covering 3FGL sources and blue triangles to the mask of 2FGL sources. The solid black line denotes the best-fit solution discussed in Sec. VI, i.e., the one in terms of two populations of unresolved sources with broken-power-law energy spectra. The short-dashed and long-dashed black lines indicate the two source populations independently.

Data are available at https://www-glast.stanford.edu/pub_data/552.

**APPENDIX D: THE DEPENDENCE ON ENERGY OF THE CROSS-CORRELATION COEFFICIENTS**

Figures 33 and 34 show the cross-correlation coefficients $r_{i,j}$ defined in Sec. VB in terms of the best-fit auto- and cross-APS $C_{\Theta}$. Each panel shows $r_{i,j}$ at a specific energy $E_i$, as a function of $E_j$. Red circles refer to the mask covering 3FGL sources and blue triangles to the mask around 2FGL sources. The solid black line shows the cross-correlation coefficients corresponding to the best-fit solution discussed in Sec. VI in the case of two populations of unresolved sources with broken-power-law energy spectra with masked 3FGL sources. The fact that the blue triangles...
decrease with energy in the first panels, while they increase towards 1 in the last panels, indicates the lack of correlation between low and high energies. The same trend is noted for the red circles, but with a lower significance.

APPENDIX E: EXCLUSION LIMIT ON DARK MATTER FOR THE $\tau$ AND $\mu$ CHANNELS

Section VIII shows exclusion limits on the DM $\langle \sigma_{\text{ann}} v \rangle$ and $\tau$ in the case of annihilations/decay into $b\bar{b}$, $\mu^+\mu^-$. Here we calculate the same exclusion limits for two additional channels. Figure 35 shows the upper limits on $\langle \sigma_{\text{ann}} v \rangle$ (left panel) and on $\tau$ (right panel) as a function of the DM mass $m_\chi$, in the case of annihilations/decays into $\tau^+\tau^-$. The exclusion limits are obtained following the conservative approach described in Sec. VIII A. The solid black line refers to the REF scenario, while the solid red and solid blue lines stand for the MAX and MIN benchmarks. The solid red and solid black lines almost exactly overlap in the right panel. The dashed black, blue and red lines are obtained considering only the auto-APS measurement. The red and blue shaded bands indicate the variability of the exclusion limits in the MAX and MIN scenarios when $M_{\text{min}}$ is left free to vary between $1 M_\odot$ and $10^{-12} M_\odot$. The long-dashed gray line in the left panel shows the thermal annihilation cross section, as computed in Ref. [94], while the dotted-dashed gray line is the upper limit obtained in Ref. [95] from the analysis of 15 dwarf spheroidal galaxies. Finally, the short-dashed gray line is derived from the analysis of the IGRB intensity performed in Ref. [31]. On the other hand, the short-dashed gray line in the right panel of Fig. 35 is obtained from the study of the IGRB intensity in Ref. [96] and the dotted-dashed gray line comes from the observation of 15 dwarf spheroidal galaxies performed in Ref. [97].

Figure 36 shows the same exclusion limits as in Figure 35 but for annihilations/decays into the $\mu^+\mu^-$. Between approximately 20 and 200 GeV, the DM-induced signal is dominated by the IC emission associated with the smooth halo of the MW. That is the reason why the solid black and red lines overlap, since the REF and MAX scenarios only differ in the computation of the boost factor for the extra-Galactic component. For the same reason the blue and red shaded bands are reduced in width. Above 200 GeV, the IC emission for the extra-Galactic component starts to contribute more and the solid black and red lines deviate one from the other again.

The two-component model developed in Sec. VIII B is used to fit the measured auto-APS and cross-APS, for different values of DM mass, annihilation cross section or decay lifetime. Figure 37 shows the TS defined as the difference between the $\chi^2$ of the best fit for the null hypothesis (i.e. with no DM) and the $\chi^2$ of the best fit in the case with the DM component. The top panels are for

Annihilation, $\tau^+\tau^-$

Decay, $\tau^+\tau^-$

FIG. 38. Exclusion limits on annihilating and decaying DM (for the $\tau$ channel) from the fit to the binned $C_\ell$ in terms of the two-component model. Left: The solid lines show the upper limits that can be derived on $\langle \sigma_{\text{ann}} v \rangle$ as a function of $m_\chi$ (for annihilation into $\tau^+\tau^-$ quarks and $M_{\text{min}} = 10^{-12} M_\odot$) by fitting the Fermi LAT data with a two-component model that includes astrophysical sources and DM (see text for details). The black, blue and red lines correspond to the REF, MIN and MAX scenarios. The blue and red shaded areas indicate how the MIN and MAX upper limits change when leaving $M_{\text{min}}$ free to vary between $10^{-12} M_\odot$ and $1 M_\odot$. The black dashed line is the REF upper limit in the conservative case, from Fig. 35, while the long-dashed gray line is the thermal annihilation cross section from Ref. [94]. The dotted-dashed line is the upper limit derived in Ref. [95] from the combined analysis of 15 dwarf spheroidals, while the short-dashed gray line comes from the analysis of the IGRB intensity performed in Ref. [98]. Right: The same as in the left panel but for the lower limits on $\tau$, in the case of decaying DM. The short-dashed gray line represents the lower limit obtained in Ref. [96] from the IGRB intensity. The line is taken from Fig. 5 of Ref. [96], where the IGRB is interpreted in terms of a component with a power-law emission spectrum and a DM contribution. Finally, the dotted-dashed gray line is the upper limit from the analysis of 15 dwarf spheroidal galaxies performed in Ref. [97].
annihilation/decay into $\tau^+\tau^-$ and the bottom ones for the $\mu$ channel. The ones on the right are for an annihilating DM candidate and the ones on the left for decaying DM. They all refer to the REF scenario with $M_{\text{min}} = 10^{-6} M_\odot / h$. As indicated in the labels, the white lines determine the 68%, 90% and 95% C.L. regions.

Assuming that the measured auto- and cross-APS are well described simply by a Poissonian component, the two-component model is used to derive exclusion limits on DM as done in Sec. VIII B but in the case of annihilations/decays into $\tau^+\tau^-$ (Fig. 38) and into $\mu^+\mu^-$ (Fig. 39). In both figures the left panel is for annihilating DM and the right one for decaying DM. The solid black, red and blue lines show the REF, MAX and MIN scenarios for $M_{\text{min}} = 10^{-6} M_\odot / h$, respectively, and the blue and shaded areas around the corresponding solid lines indicate how the limits change when $M_{\text{min}}$ is left free to vary. The dashed black line is the exclusion limit in the conservative scenario, from Figs. 35 and 36. In the left panels, the long-dashed gray line is the thermal annihilation cross section from Ref. [94] and the dotted-dashed line is the upper limit derived in Ref. [95] from the combined analysis of 15 dwarf spheroidals. Also, the short-dashed gray line comes from the analysis of the IGRB intensity performed in Ref. [98]. On the other hand, in the right panels, the short-dashed gray line represents the lower limit from Fig. 5 of Ref. [96] from the IGRB intensity. The dotted-dashed gray line is the lower limit from the analysis of 15 dwarf spheroidal galaxies performed in Ref. [97].
