ABSTRACT
We use the Wide Field Camera 3 onboard the Hubble Space Telescope to obtain deep, high-resolution photometry of the young (age ∼ 300 Myr) star cluster NGC 1856 in the Large Magellanic Cloud. We compare the observed colour–magnitude diagram (CMD), after having applied a correction for differential reddening, with Monte Carlo simulations of simple stellar populations (SSPs) of various ages. We find that the main-sequence turn-off (MSTO) region is wider than that derived from the simulation of a single SSP. Using constraints based on the distribution of stars in the MSTO region and the Red Clump, we find that the CMD is best reproduced using a combination of two different SSPs with ages separated by 80 Myr (0.30 and 0.38 Gyr, respectively). However, we cannot formally exclude that the width of the MSTO could be due to a range of stellar rotation velocities if the efficiency of rotational mixing is higher than typically assumed. Using a King-model fit to the surface number density profile in conjunction with dynamical evolution models, we determine the evolution of cluster mass and escape velocity from an age of 10 Myr to the present age, taking into account the possible effects of primordial mass segregation. We find that the cluster has an escape velocity $V_{\text{esc}} \approx 17 \text{ km s}^{-1}$ at an age of 10 Myr, and it remains high enough during a period of $\approx 100$ Myr to retain material ejected by slow winds of first-generation stars. Our results are consistent with the presence of an age spread in NGC 1856, in contradiction to the results of Bastian & Silva-Villa.

Key words: globular clusters: general – Magellanic Clouds.

1 INTRODUCTION
Over the last ∼ half a dozen years, deep colour–magnitude diagrams (CMDs) from images taken with the Advanced Camera for Surveys (ACS) and the Wide Field Camera 3 (WFC3) aboard the Hubble Space Telescope (HST) revealed that several intermediate-age (∼1–2 Gyr old) star clusters in the Magellanic Clouds host extended main-sequence turn-off (MSTO) regions (Glatt et al. 2008; Mackey et al. 2008a; Goudfrooij et al. 2009, 2011b, 2014; Milone et al. 2009; Correnti et al. 2014), in some cases accompanied by composite red clumps (Girardi, Rubele & Kerber 2009; Rubele et al. 2011).

A popular interpretation of these extended MSTOs (hereafter eMSTOs) is that they are due to stars that formed at different times within the parent cluster, with age spreads of 150–500 Myr (Girardi, Rubele & Kerber 2009; Milone et al. 2009; Rubele, Kerber & Girardi 2010; Goudfrooij et al. 2011b, 2014; Rubele et al. 2011; Keller, Mackey & Da Costa 2012; Correnti et al. 2014). Alternative potential causes to explain the eMSTO phenomenon presented in the recent literature include spreads in rotation velocity among turn-off (TO) stars (Bastian & de Mink 2009; Yang et al. 2013, but see Girardi, Eggenberger & Miglio 2011), a photometric feature of interacting binary stars (Yang et al. 2011) or a combination of both (Li et al. 2012).

An important aspect of the nature of the eMSTO phenomenon among intermediate-age star clusters is that it is not shared by all such clusters (e.g. Milone et al. 2009; Goudfrooij et al. 2011a; Correnti et al. 2014). In this context, Goudfrooij et al. (2011a, hereafter G11a) suggested that the key factor in determining whether or not a cluster features an eMSTO is its ability to retain material ejected by first-generation stars that feature relatively slow stellar outflows (the so-called polluters). Following the arguments presented in G11a, eMSTOs can only be hosted by clusters for which the escape velocity was higher than the wind...
velocity of such polluter stars at the time such stars were present in the cluster.

Currently, the most popular candidates for first-generation ‘polluters’ are (i) intermediate-mass AGB stars (4 \lesssim M/M_\odot \lesssim 8, hereafter IM-AGB; e.g. D’Antona & Ventura 2007, and references therein), (ii) rapidly rotating massive stars (often referred to as ‘FRMS’; e.g. Decressin et al. 2007) and (iii) massive binary stars (de Mink et al. 2009).

For what concerns instead the formation scenario, the currently two favoured ones predict that the stars have been formed from or polluted by gas that is a mixture of pristine material and material shed by such ‘polluters’. In particular, in the ‘in situ star formation’ scenario (see e.g. D’Ercole et al. 2008, 2010; Conroy & Spergel 2011), subsequent generations of stars are formed out of gas clouds that were polluted by winds of first-generation stars to varying extents, during a period spanning up to a few hundreds of Myr, depending on the nature of the ‘polluters’. Conversely, in the alternative ‘early-disc accretion’ scenario (Bastian et al. 2013), the chemically enriched material, ejected from interacting high-mass binary systems or FRMS stars, is accreted on to the circumstellar discs of low-mass pre-main-sequence (PMS) stars that were formed in the same generation during the first \approx 20 Myr after the formation of the star cluster.

Two recent studies provided support to the predictions of the in situ scenario. Goudrooj et al. (2014, hereafter G14) studied in detail HST photometry of a sample of 18 massive intermediate-age star clusters in the Magellanic Clouds that covered a variety of masses, ages and radii. G14 found that all the star clusters in their sample host eMSTOs, featuring age spreads that correlate with the clusters’ escape velocity \( V_{\text{esc}} \), both currently and at an age of 10 Myr.

Furthermore, Coretti et al. (2014, hereafter C14) studied four low-mass (\approx 10^3 M_\odot) intermediate-age star clusters in the Large Magellanic Cloud (LMC) and found that the two clusters that host eMSTOs have \( V_{\text{esc}} \gtrsim 15 \text{ km s}^{-1} \) out to ages of \approx 100 Myr, whereas \( V_{\text{esc}} \lesssim 12 \text{ km s}^{-1} \) at all ages for the two clusters that do not exhibit eMSTOs. These results suggest that the ‘critical’ escape velocity for a star cluster to be able to retain the material ejected by the slow winds of the first-generation polluters seems to be in the approximate range of 12–15 km s\(^{-1}\). Interestingly, these escape velocities are consistent with wind velocities of IM-AGB stars which are in the range 12–18 km s\(^{-1}\) (Vassiliadis & Wood 1993; Zijlstra et al. 1996) and with the low end of observed velocities of ejecta of the massive binary star RY Scuti (15–50 km s\(^{-1}\); Smith et al. 2002; Smith, Bally & Walawender 2007).

However, in the context of the multiple population scenario, one piece of the puzzle that is still missing is the identification of an age spread (i.e. second-generation stars) in young massive star clusters. In fact, one of the prediction of the in situ scenario is that eMSTO should be observed also in young star clusters if they have the adequate properties in terms of mass and escape velocity. Young star clusters must be massive enough (i.e. \( M \gtrsim 10^5 M_\odot \)) in order to have deep enough potentials and high enough escape velocities to retain material lost due to stellar evolution of the first-generation stars and to be able to accrete new material from the pristine gas still present in the surroundings. Unfortunately, these strict constraints render young star clusters in which the presence of the eMSTO phenomenon is expected and verifiable very scarce. G11a identified the relatively young (\approx 300 Myr) massive star cluster NGC 1856 in the LMC as a promising candidate. Following this suggestion, Bastian & Silva-Villa (2013) analysed archival Wide Field & Planetary Camera 2 images of this cluster, finding no evidence for age spreads larger than \approx 35 Myr, which was interpreted by the authors as a suggestion that the eMSTO feature in intermediate-age clusters cannot be due to age spreads. However, the data analysed by Bastian & Silva-Villa (2013) seem to have reached only \approx 2 mag beyond the MSTO.

With this in mind, we present an analysis of new HST WFC3 photometry of NGC 1856. These data allowed us to sample the cluster population down to \approx 8 mag beyond the MSTO, obtaining deep CMDs that permit a thorough examination of the MSTO morphology and the nature of the cluster. We compare the observed CMD with Monte Carlo simulations in order to quantify whether it can be reproduced by one simple stellar population (SSP) or whether it is best reproduced by a range of ages. We also study the evolution of the cluster mass and escape velocity from an age of 10 Myr to its current age, to verify whether the cluster has the right properties to form and retain a second generation of stars. This analysis allows us to reveal new findings on the star formation history of the cluster NGC 1856 in the context of the multiple population scenario.

The remainder of the paper is organized as follows: Section 2 presents the observations and data reduction. In Section 3, we present the observed CMD, we describe the technique applied to correct the CMD due to the presence of differential reddening effects and we derive the best-fitting isochrones. In Section 4, we compare the observed CMD with Monte Carlo simulations, both using one SSP and a combination of two SSPs with different ages. We derive pseudo-age distributions for the observed and simulated CMDs and compare them. In Section 5, we investigate the presence of ongoing star formation in the cluster, looking for PMS stars of the second generation. In Section 6, we test the prediction of the stellar rotation scenario, while Section 7 presents the physical and dynamical properties of the cluster, deriving the evolution of the cluster escape velocity as a function of age. Finally, in Section 8, we present and discuss our main results.

2 OBSERVATIONS AND DATA REDUCTION

NGC 1856 was observed with HST on 2013 November 12 using the UVIS channel of the WFC3 as part of the HST programme 13011 (PI: T. H. Puzia). The cluster was centred on one of the two CCD chips of the WFC3 UVIS camera, so that the observations cover enough radial extent to study variations within cluster radius and to avoid the loss of the central region of the cluster due to the CCD chip gap. The cluster was observed in four filters, namely F438W, F555W, F658N and F814W. Two long exposures were taken in each of the four filters: their exposure times were 430 s (F438W), 350 s (F555W), 450 s (F814W) and 940 s (F658N). In addition, we took three short exposures in the F438W, F656N and F814W filters (185, 735 and 51 s, respectively), to avoid saturation of the brightest red giant branch (RGB) and asymptotic giant branch (AGB) stars. The two long exposures in each filter were spatially offset from each other by 2.401 arcsec in a direction +85\(^\circ\) from the positive \( X \) axis of the detector, in order to move across the gap between the two CCD chips, as well to simplify the identification and removal of hot pixels and cosmic rays. In addition to the WFC3/UVIS observations, we used the Wide Field Camera (WFC) of ACS in parallel to obtain images \approx 6 arcmin from the...
cluster centre. These ACS images have been taken with the F435W, F656N and F814W filters and provide valuable information of the stellar content and star formation history in the underlying LMC field, permitting us to establish in detail the field star contamination fraction in each region of the CMDs.

To reduce the images we followed the method described in Kalirai et al. (2012). Briefly, we started from the flt files provided by the HST pipeline, which constitute the bias-corrected, dark-subtracted and flat-fielded images. After correcting the flt files for charge transfer inefficiency using the dedicated cte correction software, we generated distortion-free images using MULTIDRIZLE (Fruchter & Hook 2002) and we calculated the transformation between the individually drizzled images in each filter, linking them to a reference frame (i.e. the first exposure). Through these transformations we obtain an alignment of the individual images to better than 0.02 pixels. After flagging and rejecting bad pixels and cosmic rays from the input images, we created a final image for each filter, combining the input undistorted and aligned frames. The final stacked images were generated at the native resolution of the WFC3/UVIS and ACS/WFC (i.e. 0.040 and 0.049 arcsec pixel$^{-1}$, respectively).

To perform the stellar photometry, we used the stand-alone versions of the DAOPHOT-II and ALLSTAR point spread function (PSF) fitting programs (Stetson 1987, 1994) on the stacked images. To obtain the final catalogue we first performed the aperture photometry on all the sources that are at least 3σ above the local sky, then we derived a PSF from ∼1000 bright isolated stars in the field, and finally we applied the retrieved PSF to all the sources detected through the aperture photometry. We retained in the final catalogues only the sources that were iteratively matched between the two images and we cleaned them eliminating background galaxies and spurious detections by means of $x^2$ and sharpness cuts from the PSF fitting.

Photometric calibration has been performed using a sample of bright isolated stars to transform the instrumental PSF-fitted magnitudes to a fixed aperture of 10 pixels (0.40 arcsec for WFC3/UVIS, 0.49 arcsec for ACS/WFC). We then transformed the magnitudes into the VEGAMAG system by adopting the relevant synthetic zero-points for the WFC3/UVIS and ACS/WFC filters. Positions and magnitudes, with the associated errors, for the first 10 objects in our final catalogue are reported in Table A1 in Appendix A.

We characterized the completeness as well as the photometric error distribution of the final photometry by performing artificial star tests, using the standard technique of adding artificial stars to the images and running them through the photometric routines that were applied to the drizzled images using identical criteria. We added to each image a total of nearly 700 000 artificial stars. To not induce incompleteness due to crowding in the tests themselves, the fraction of stars injected into a given individual image was set to be ∼5 per cent of the total number of stars in the final catalogues.

The overall distribution of the inserted artificial stars was chosen to follow that of the stars in the image. We distributed the artificial stars in magnitude in order to reproduce a luminosity function similar to the observed one and with a colour distribution that span the full colour ranges found in the CMDs. After inserting the artificial stars, we applied to each image the photometry procedures described above. The stars were recovered blindly and automatically cross-matched to the input star list containing actual positions and fluxes; they were considered recovered if the input and output magnitudes agreed within to 0.75 mag in both filters. Finally, we assigned a

3 CMD ANALYSIS

3.1 A wide MSTO region

Fig. 2 shows the F438W − F814W versus F438W CMD of NGC 1856, plotting only the stars within the core radius, based on the King (1962) model fit derived as described in Section 7.1. The observed CMD presents some interesting features. While the lower part of the MS (i.e. below the ‘kink’ at $F438W \approx 21.2$) is quite narrow and well defined, the MSTO region (with $F438W \lesssim 19.5$), appears relatively wide when compared with the photometric errors.

To determine whether the observed broadening of the MSTO region is a ‘real’ feature in the CMD, we first test whether it could be caused by the following effects: contamination by the underlying

---

3.2 The impacts of differential reddening and binary fractions

To check for the presence of differential reddening in the cluster field, we adopted the following approach. First of all, we selected a square region that circumscribes the area defined by the core radius (i.e., the length of the side of the square is equal to twice the core radius), we divided this region into nine equal-sized squares, and we compared the CMDs derived in each of them. The number of equal-sized region has been arbitrarily chosen in order to have a good sampling of the different region maintaining a statistically significant number of objects in each field. This approach has been adopted only to check if differential reddening effects are present in the cluster field and to have a rough estimate of the reddening variation. Fig. 3 shows the CMDs for the nine subregions; to yield a preliminary hint on the amount of differential reddening, we superimposed on each CMD an isochrone from Marigo et al. (2008) for which age, distance modulus and metallicity are fixed (see the top legend of Fig. 3), while the visual extinction $A_V$ is left free to vary. Fig. 3 clearly shows that the best fit is achieved in each CMD using a different value of the visual extinction $A_V$ (derived values of $A_V$ are reported in each field), confirming that a differential reddening is present in the cluster field, with variations of the order of $\Delta A_V = \pm 0.15$ mag with respect to the mean reddening value.

Once verified that the differential reddening is truly present in the cluster field, we corrected each star in the CMD using the following approach (for a more detailed description, see Milone et al. 2012). Briefly, we first defined a photometric reference frame in which the $X$-axis is parallel to the reddening line. In this reference system, it is much easier to determine reddening difference rather than in the original colour–magnitude plane, where the reddening vector is an oblique line. To do this, we arbitrarily defined an origin $O$, then translated the CMD such that the origin of the new reference frame corresponds to $O$ and then we rotated the CMD counterclockwise by an angle defined by the equation:

$$\theta = \arctan \left( \frac{A_{W438} - A_{W814}}{A_{W438}} \right),$$

(1)

where $A_{W438}$ and $A_{W814}$ are the appropriate extinction coefficients for the UVIS WFC3 filters. Using Cardelli, Clayton & Mathis (1989) and O’Donnell (1994) extinction curve and adopting $R_V = 3.1$, their values are $A_{W438} = 1.331A_V$ and $A_{W814} = 0.610A_V$, respectively. At this point, we generated a fiducial line using only MS stars. We divided the sample into bins of fixed ‘magnitude’ and we calculated the medians in the $X$- and $Y$-axis. The use of the median allows us to minimize the influence of outliers such as binary stars or stars with poor photometry left in the sample after the selection.
Among the MS stars, we selected a subsample located in the region where the reddening line defines a wide angle with the fiducial line, so that the shift in colour can be safely interpreted as an effect of the differential reddening. For this reason, we limited our sample to the central portion of the cluster MS, excluding the upper part near the MSTO and the lower portion, fainter than the magnitude at which the MS starts to bend in a direction parallel to the reddening line. For each selected star, we calculated the distance from the fiducial line along the reddening direction (i.e. $\Delta X$), and we used these stars as reference stars to estimate the reddening variations associated with each star in the CMD. Finally, to correct them, we selected the nearest 30 reference stars and we calculate the median $\Delta X$ that is assumed as the reddening correction for that particular star (to derive the differential reddening suffered by the reference stars, we excluded that star in the computation of the median $\Delta X$). We note that the median correlation length introduced with this approach is of the order of $\pm 20$ pixels (corresponding to 0.2 pc). After the median $\Delta X$ values have been subtracted from the $X$-axis value of each star in the rotated CMD, we obtained an improved diagram that we used to derive a more accurate selection of MS reference stars and a more precise fiducial line. We then applied again the described procedure, iterating the process until it converges (in this case, a couple of iterations were sufficient). At this point, the corrected $X$ and $Y$ ‘magnitude’ were converted back to the F438W and F814W magnitudes.

Fig. 4 shows the spatial distribution of the differential reddening inside the core radius of NGC 1856; each star is reported with a different colour, depending on the final $\Delta E(F438W - F814W)$ applied to correct it, derived with the method described above. In this context, we observe that the CMD in the central panel of Fig. 3, which represents the innermost region of the cluster, shows a quite wide MSTO, compared to the other panels.

Conversely, in the corresponding spatial region from which the CMD is drawn (i.e. the central part in the map of Fig. 4) the derived reddening is quite uniform, with $\Delta E(F438W - F814W) \simeq 0.04$ (corresponding to $\Delta A_V \simeq 0.055$). Moreover, it is worth to note that the reddening correction reaches its highest accuracy in this inner region, due to the high surface number density of stars (i.e. smaller distance of the star to be corrected from the reference stars used to derive $\Delta A_V$, see also Section 4.1).

We acknowledge that our differential reddening correction might be somewhat ineffective for a small fraction of stars, depending on their location in the field, e.g. in the outer regions, where the distance between stars is generally larger than in the inner regions. However, the number of stars in such regions is by nature relatively low (see e.g. the CMDs in the corner panels of Fig. 3). Thus, only a small fraction of MSTO stars can suffer from a less accurate correction, leaving the global morphology of the MSTO region unaltered.

The differential-reddening-corrected (DRC) CMD is shown in Fig. 5. The correction caused the lower part of the MS to be even more defined and narrow than it was in the observed CMD. Conversely, the MSTO region and upper MS is still fairly wide, although it has narrowed down slightly. This is illustrated in more detail in Fig. 6 which shows the distribution of $F438W - F814W$ colours in the magnitude range $18.7 \leq F438W \leq 19.2$ mag for the observed CMD and that obtained for the DRC CMD (red dashed and black solid lines, respectively). Note that the global shape and width of the two distributions is very similar, except for the fact that the observed one has more extended outer wings than the one derived from the DRC CMD. These extended wings are caused by stars that are located in the region where the differential reddening effects

\footnote{This magnitude range was selected in this context because it reflects the part of the upper MS for which the binary sequence is merged in with the single-star sequence (see Fig. 7). Hence, our result is robust against any given binary fraction.}
Section 4.1 and 4.2.  

4 MONTE CARLO SIMULATIONS

To further determine whether or not a single population can reproduce the observed CMD, we conducted Monte Carlo simulations of a synthetic cluster with the properties implied by the isochrone fitting (see G11a and G14 for a detailed description of the method adopted to produce these simulations). Briefly, to simulate an SSP with a given age and chemical composition, we populated an isochrone with stars randomly drawn using a Salpeter mass function and normalized to the observed (completeness-corrected) number of stars. To a fraction of these sample stars, we added a component of unresolved binary stars derived from the same mass function, using a flat distribution of primary-to-secondary mass ratios. The binary fraction was estimated by using as a template the part of the observed MS between the MSTO region and the TO of the background population in the magnitude range 22.5 ≤ F438W ≤ 19.5 (see Fig. 2). We derived that the value of the binary fraction that best fit the data is of ≃ 25 per cent. We estimated that the internal systematic uncertainty in the binary fraction is ≃ 5 per cent; for the purposes of this work, the results do not change significantly within 10 per cent of the binary fraction. Finally, we added photometric errors that were derived using our artificial star tests. We derived three different sets of synthetic CMDs: one with a single SSP of age 300 Myr, and two combining two SSPs of different ages (one with SSPs with ages of 300 and 300 Myr, and the other with ages of 300 and 410 Myr, respectively). In the last two cases, we derived a set of simulations in which we changed the ratio of the number of stars in the two populations, from 10 to 90 per cent of stars in the younger SSP, with a 5 per cent step increase in each run.

To compare in detail the observed MSTO region with the simulated ones, we created ‘pseudo-age’ distributions (see G11a for a detailed description). Briefly, pseudo-age distributions are derived by constructing a parallelogram across the MSTO, with one axis approximately parallel to the isochrones and the other approximately parallel to them (the adopted parallelogram is shown in Fig. 5). The (F438W − F814W, F438W) coordinates of the stars within the parallelogram are then transformed into the reference coordinate frame defined by the two axis of the parallelogram and the same procedure is applied to the isochrones tables to set the age scale along this vector. The pseudo-age distributions are calculated using the non-parametric Epanechnikov-kernel density function (Silverman 1986), in order to avoid possible biases that can arise if fixed bin widths are used. Finally, a polynomial least-squares fit between age and the coordinate in the direction perpendicular to the isochrones yields the final pseudo-age distributions. The described procedure is applied both to the observed and the simulated CMD. In the following sections, we describe the results obtained from the comparison of the observed and simulated pseudo-age distributions, for the synthetic CMDs obtained with a single SSP and for those obtained from the combination of two SSPs of different ages.

Figure 6. Comparison between the colour distributions obtained from the DRC CMD (black solid line) and the observed CMD (red dashed line).

3 i.e. the part of the MS with F438W ≤ 19.2 mag, where the binary sequence has joined the single-star sequence in F438W − F814W.

4.1 Comparison with the synthetic CMD of an SSP

The top panel of Fig. 7 shows the comparison between the observed and simulated CMD, the latter obtained from a single SSP with an age of 300 Myr. Overall, the SSP simulation reproduces the CMD features quite well in the fainter portion of the cluster MS (i.e. for F438W ≥ 20.5 mag). Conversely, we note that the MSTO region of the simulated SSP does not reproduce the observed MSTO region...
Figure 7. Top panel: comparison between DRC (grey dots) and simulated CMDs (red circles, single stars, magenta square, binary stars, respectively). The simulated CMD is obtained from Monte Carlo simulation of an SSP with an age of 300 Myr. The parallelogram box used to select MSTO stars and the fraction of the adopted binary stars are also reported. Bottom panel: pseudo-age distribution for the MSTO region of the DRC (black solid line) and simulated (red dashed line) CMDs.

very well, in that the latter is wider than the former. Furthermore, the faint end of the RC also does not seem to be reproduced well by the simulated SSP in that the simulated luminosity function of RC stars peaks more strongly at bright magnitudes than the observed one. Note that this is consistent with a fraction of stars in NGC 1856 having ‘older’ ages than that of the best-fitting SSP (see for reference the shape and location of the RC for the older isochrone in Fig. 5). This difference is even more evident in a comparison of the observed and simulated pseudo-age distributions (see the bottom panel of Fig. 7). Indeed, the observed pseudo-age distribution (shown as a black solid line in Fig. 7) reaches significantly older ages than the simulated one (red dashed line in Fig. 7), while the two distributions are very similar to each other in the left (‘young’) half of the respective profiles. To test the reliability of the SSP model and further verify that the simulated SSP cannot reproduce the observed spread in the MSTO, we compared the observed and simulated star density distributions obtained using a cross-cut through the cluster MS (shown as dashed parallelogram in the top panel of Fig. 7). Since the width of the cluster MS is not affected by age effects (i.e. isochrones of different ages have the same colour in this location of the CMD), the SSP simulation should provide a good representation of the observed one. This comparison is shown in Fig. 8. Note that the observed density distribution along the MS crosscut is indeed reproduced very well by the SSP simulation, especially in the single-star sequence. The small differences between the SSP crosscut and the observed one in the binary area can be understood in terms of small (and a priori unknown) differences in the distributions of the primary-to-secondary mass ratio. These results further confirm that an SSP cannot reproduce the observed spread in the MSTO.

To quantify the difference between the pseudo-age distribution of the cluster data and that of the SSP simulation in term of intrinsic MSTO width of the cluster, we measured the widths of the two sets of distributions at 50 per cent of their maximum values (hereafter called FWHM), using quadratic interpolation. The intrinsic pseudo-age range of the cluster is then estimated by subtracting the simulation width in quadrature:

\[
\text{FWHM}_{\text{MSTO}} = \left( \text{FWHM}_{\text{obs}}^2 - \text{FWHM}_{\text{SSP}}^2 \right)^{1/2},
\]

where the ‘obs’ subscript indicates a measurement on the DRC CMD and the ‘SSP’ subscript indicates a measurement on the simulated CMD for the SSP. With FWHM$_{\text{obs}} = 269$ Myr and FWHM$_{\text{SSP}} = 198$ Myr, we obtain FWHM$_{\text{MSTO}} \approx 182$ Myr, which is similar to the value of FWHM$_{\text{SSP}}$. This suggests that NGC 1856 may
host two SSPs separated in age by about \( \text{FWHM}_{\text{MSTO}}/2 \approx 90 \) Myr (see Section 4.2 below).

In this context, we adopted equation (2) also to derive the value of reddening variation necessary to reproduce the observed pseudo-age distributions assuming that a cluster is formed by an SSP. Instead of age, we derived the FWHM of the observed and simulated pseudo-age distributions as a function of \( F438W - F814W \), using the appropriate extinction coefficient for the UVIS WFC3 filters we transformed the ‘Δ colour’ in \( \Delta A_V \) obtaining the following value: \( \Delta A_V = 0.27 \). The derived \( \Delta A_V \) is significantly larger than the reddening variations observed in the spatial differential reddening map in the innermost region of the cluster. Moreover, we note that due to the uniform shape of the observed pseudo-age distribution, this large reddening should affect a significant number of stars, making the possibility that the reddening can mimic the presence of a multiple population even less plausible. Therefore, taking these results at face value, they seem to suggest that an SSP is not able to reproduce the observed morphology of the MSTO region.

4.2 Comparison with a synthetic CMD of two SSPs of different age

As stated in Section 4, we also simulated synthetic CMDs combining two SSPs with different ages. One set is obtained using SSPs with ages of 300 and 410 Myr and the other with ages of 300 and 380 Myr. For both cases, we derived a set of simulations in which we varied the ratio of the number of stars in the young and the old SSP, from 10 to 90 per cent in each of them, with a step of 5 per cent. For each simulated CMD we obtained the corresponding pseudo-age distribution that we compared with the observed one.

The fact that the stars from the two SSPs are mixed together in the parallelogram used to derive the pseudo-age distribution, combined with our purely statistical approach, cause an increase in the ‘free parameters’ and introduces a sort of degeneracy in the derived results. This is reflected in the fact that we obtained more than one simulated pseudo-age distribution that reasonably reproduces the observed one. These ‘best-fitting’ pseudo-age distributions are shown in Fig. 9. In detail, the top panels show the best fit achieved from the SSPs with ages of 300 and 410 Myr (with mass fractions of ‘young’ stars of 40 and 50 per cent, respectively), whereas in the bottom panels we show the ones obtained from the SSPs with ages of 300 and 380 Myr (with mass fractions of young stars of 40 and 55 per cent, respectively). The ages of the two SSPs and the ratio between them have been reported in each panel. We note that the best-fitting mass ratios of the young to the old population seem to be around 1:1, consistent with the observed pseudo-age distribution, where we see a hint of two peaks with a similar maximum value and hence a likely number ratio of \( \approx 1:1 \) for young versus old stars in the cluster.

To constrain which combination of two SSPs provides the best solution to reproduce the observed CMD of NGC 1856, we performed two-sample Kolmogorov–Smirnov (K–S) tests. The two-tailed \( p \) values are mentioned in Fig. 9 for each pseudo-age distribution. Taking these results at face value, it seems that the combination of SSPs with ages of 300 and 380 Myr provide a better solution with respect to the SSPs with ages of 300 and 410 Myr. To further constrain the two-SSP fits, we pointed our attention to the distribution of RC stars, adopting the following approach. The left-hand panels of Fig. 10 show the CMDs zoomed in to the RC and the upper portion of the MS, with superimposed isochrones from Marigo et al. (2008), with the same ages as those adopted in the SSPs (left sub-panel: 300 and 410 Myr; right sub-panel: 300 and 380 Myr, respectively). First, we selected cluster RC stars by applying colour and magnitude cuts (shown as dotted lines in the left-hand panels of Fig. 10). Then, we divide RC stars in two parts, applying a magnitude threshold (shown as the dot–dashed lines in Fig. 10) coinciding with the brightest point of the RC of the ‘old’ isochrone (i.e. \( F438W = 19.3 \) mag for the 410 Myr isochrone and \( F438W = 19.15 \) mag for the 380 Myr isochrone). Finally, we counted the stars in the upper and lower portion of the RC, both in the observed data and in each synthetic CMD obtained from the associated Monte Carlo simulations.

The ratios between the stars in the upper portion of the RC and their total number as a function of the mass ratio of the young SSP in each simulation are shown in the right-hand panels of Fig. 10 (for SSPs with ages of 300 and 410 Myr in the top panel and for SSPs with ages of 300 and 380 Myr in the bottom panel, respectively). The ratios from the DRC CMD, obtained with the different magnitude cuts, are shown as dashed lines. The typical uncertainty on the mass ratios has been estimated to be of the order of 10 per cent, shown as an error bar in both panels. Taking these results at face value, it seems that the best match is obtained from the synthetic CMD obtained from the SSPs with ages of 300 and 380 Myr and with a fraction of young stars of 0.55 \( \pm 0.10 \) (cf. the bottom-right panel in Fig. 9).

Globally, the results presented in Sections 4.1 and 4.2 show that a single SSP fails in reproducing the observed pseudo-age distribution while a combination of two SSPs with different ages can provide a very good fit. This seems to indicate that a spread in age may be present in the cluster and cannot be categorically excluded as argued by Bastian & Silva-Villa (2013).
5 CONSTRAINTS ON ONGOING STAR FORMATION ACTIVITY

To study whether NGC 1856 presently hosts ongoing star formation, we performed a search for PMS stars by means of narrow-band imaging of the Hα line. Hα emission is a good indicator of the PMS stage: the presence of strong Hα emission (EW_{Hα} > 10 Å) in young stellar objects is normally interpreted as a signature of the mass accretion process on to the surface of the object that requires the presence of an inner disc (see Feigelson & Montmerle 1999; White & Basri 2003, and reference therein). To do this, we used the method described in De Marchi et al. (2010), which combines V and I broad-band photometry with narrow-band Hα imaging to identify all the stars with excess Hα emission and to measure their Hα luminosity.

In the top panels of Fig. 11, we show the F555W - F814W versus F555W - F658N colour–colour diagram for the stars inside the cluster core radius (top-left panel) and for the stars in the ‘control field’, the same field we used to derive the contamination by the background LMC population in Fig. 2 (top-right panel). We used the median F555W - F658N colour of stars with small (< 0.05 mag) photometric uncertainties in each of the three F555W, F814W and F658N bands, as a function of F555W - F814W, to define the reference template with respect to which excess Hα emission is identified (shown by the dashed line in Fig. 11). We selected a first candidate sample of stars with Hα excess emission by considering all those with an F555W - F658N colour at least 5σ above that reference line, where σ is the uncertainty on the F555W - F658N colour of the star in question (shown as open red squares in Fig. 11). Then we calculated the equivalent width of the Hα emission line (EW_{Hα}) from the measured colour excess, using the following equation from De Marchi et al. (2010):

\[
W_{\alpha}(H\alpha) = RW \times [1 - 10^{-0.4 (H\alpha - H\alpha_c)}]
\]

Figure 10. Left-hand panels: DRC CMDs zoomed in the upper portion of the MS with superimposed isochrones (red solid and blue dashed lines for the young and the old isochrones, respectively) from Marigo et al. (2008) along with the adopted ages (left-hand panel: 300 and 410 Myr. Right-hand panel: 300 and 380 Myr). Dotted lines represent the magnitude and colour cuts adopted to select RC stars, whereas the dot–dashed lines represent the magnitude cut, used to divide the two parts of the RC. Right-hand panels: ratios between the stars in the upper portion of the RC and their total number as a function of the ratio of the young SSP (top panel: SSPs with ages of 300 and 410 Myr; bottom panel: SSPs with ages of 300 Myr and 410 Myr). The ratio obtained in the observed DRC CMD is reported as a dashed line in both panels. The typical uncertainty (∼10 per cent) in the calculated number ratio is also shown.

Figure 11. Top panels: F555W - F814W versus F555W - F658N colour–colour diagram for the stars inside the core radius (left-hand panel) and in the control field (right-hand panel), representing the contamination from the background LMC stars (same field adopted in Fig. 2). The dashed line represents the median F555W - F658N colour, representative of stars with no Hα excess. Stars with an F555W - F658N colour at least 5σ above that reference line, where σ is the uncertainty on the F555W - F658N colour of the star, are reported as open red squares. Those among them with EW_{Hα} > 10 Å, where the equivalent width of the Hα emission line (EW_{Hα}) is calculated using the equation (4) of De Marchi, Panagia & Romaniello (2010) are reported as solid blue circles. Bottom panels: CMDs of the cluster and of the control field with overplotted stars selected from the F555W - F814W versus F555W - F658N colour–colour diagram (solid blue circles).
where RW is the rectangular width of the filter (similar in definition to the equivalent width of the line), which depends on the characteristic of the filter (for the adopted F658N filter, RW = 17.68; see table 4 in De Marchi et al. 2010). Finally, we considered as bona fide candidate PMS stars those objects with EW_Hα > 10 Å (White & Basri 2003), shown as solid blue circles in Fig. 11. The number of objects that show excess Hα emission is very low and is roughly the same in both fields. In the bottom panels of Fig. 11, we overplotted these objects (shown as solid blue circles) on the F438W − F814W versus F438W CMDs of the cluster and the control field; the majority of them are located on the fainter part of the CMD, where the photometric errors are larger and the contamination by background LMC stars is higher. In fact the number of objects that show an Hα excess is comparable within the errors in the two fields below the TO of the background SSP (i.e. F438W ≲ 23 mag). Hence, the number and the location of these objects in the CMDs suggest that they can be considered spurious detections. For what concerns the handful of objects at brighter magnitudes (i.e. F438W ≳ 22 mag), where the photometric errors are smaller and the contamination is lower, we hypothesize that these can be stars in a binary system in which mass transfer between the primary and the secondary star is occurring. We exclude the possibility that these objects are true PMS stars due to the fact that, in this case, we would have observed a significant number of these objects at fainter magnitudes (i.e. lower masses and hence longer PMS lifetime).

In this context, it is worth to note that our magnitude detection limit for stars showing Hα excess is around F438W ≃ 26.5 mag, which, at the cluster age, corresponds to stars with masses of ≲ 0.8 M⊙. The PMS lifetime for such stars is of the order of ~120 Myr, indicating that if star formation is occurring within the cluster, with our method we should be able to observe a significant number of PMS objects.

Hence, these results indicate that the level of ongoing star formation activity is negligible in NGC 1856. In fact, the lack of low-mass stars showing an Hα excess indicates that the star formation in the cluster must have stopped at least ~120 Myr ago, in agreement with the conclusions derived from the pseudo-age distribution analysis.

6 CONSTRAINTS TO THE STELLAR ROTATION SCENARIO IN PRODUCING EMSTO’S

In the literature, some alternative explanations that do not invoke the presence of an extended star formation, have been proposed to explain the EMSTO phenomenon in intermediate-age star clusters. In particular, the so-called stellar rotation scenario ( Bastian & de Mink 2009; Yang et al. 2013) suggests that EMSTOs can be explained by a spread in rotation velocity among TO stars. Yang et al. (2013) calculated evolutionary tracks of non-rotating and rotating stars for three different initial stellar rotation periods (approximately 0.2, 0.3 and 0.4 times the Keplerian rotation of ZAMS stars), and for two different rotational mixing efficiencies (‘normal’, f_R = 0.03 and ‘enhanced’, f_R = 0.20). From the isochrones, built from these tracks, they calculated the widths of the MSTO region caused by stellar rotation as a function of cluster age and translated them to age spreads. In particular, fig. 7 in Yang et al. (2013) shows the equivalent width of the MSTO of star clusters caused by rotation as a function of the cluster age, for different initial stellar rotation periods and rotational mixing efficiencies. At the age of NGC 1856, all the Yang et al. models with ‘normal’ mixing efficiency (i.e. f_R = 0.03) indicate that rotation does not cause any appreciable spread. On the other hand, for their models with ‘enhanced’ mixing efficiency (i.e. f_R = 0.20), the predictions vary from no spread for the model with the longest initial stellar rotation period to a maximum of ~100 Myr for the model with the shortest period (i.e. the model for the highest rotation velocity). In this case their model predicts a ‘negative’ spread, in the sense that the rotating model exhibits a bluer MSTO with respect to their non-rotating counterpart, thus mimicking the presence of a younger population (see the top-left panel of fig. 6 in Yang et al. 2013).

To test the prediction of this rotating model in the specific case of NGC 1856, we used the 410 Myr isochrone from Marigo et al. (2008) as a template for non-rotating stars (i.e. the same isochrone as that plotted in Fig. 5), and we derived its rotating counterpart. To do so, we calculated the shifts in colour and magnitude between the rotating and non-rotating isochrones in fig. 6 of Yang et al. (2013), and we transformed these shifts in our photometric system and we applied them to the Marigo et al. (2008) isochrone. Figure 12 shows the DRC CMD of NGC 1856 with superimposed non-rotating and rotating isochrones (blue solid and red dashed line, respectively). For the rotating isochrone, we plotted only the MS part, since the post-MS era of stellar evolution is not addressed by the Yang et al. (2013) models. Overall, the rotating model plotted in Fig. 12 seems to reproduce the observed CMD reasonably well in the upper portion of the MS, whereas the bottom portion of the MS is not as well reproduced, the rotating model being somewhat too red with respect to the observed MS. The latter is due to the fact that the rotating model bends towards red colours (lower temperatures) for stellar masses M ∼ 1–2 M⊙.

In conclusion, the rotating model of Yang et al. (2013) that involves ‘enhanced’ rotational mixing efficiency seems to provide a satisfactory fit to the observed MS of NGC 1856, indicating that a spread in rotation velocity, beside an age spread, could be a possible cause of the observed broadening of the MSTO region. However, we note that the predictions of the Yang et al. (2013) models are not consistent with the observations for intermediate-age (~ 1–2 Gyr)
star clusters featuring eMSTOs. This is especially the case for the rotating models involving enhanced rotational mixing efficiency (see discussion in G14, in particular their fig. 7). It should however also be recognized that the study of the creation of theoretical stellar tracks and isochrones for rotating stars at various stages of stellar evolution, rotation rates and ages is still in relatively early stages. To date, no stellar rotation velocity measurements have yet been undertaken in young and intermediate-age star clusters in the Magellanic Clouds. We strongly encourage such studies in the future in order to provide fundamental improvements of our understanding of the possible relation between the eMSTO phenomenon and the effects of stellar rotation.

7 INSIGHTS FROM DYNAMICAL ANALYSIS

As mentioned in the Introduction, a peculiar characteristic of eMSTOs in intermediate-age star clusters in the Magellanic Clouds is that they are not hosted by all such star clusters. To explain this phenomenon in the context of multiple SSPs, G11a proposed a scenario in which eMSTOs can only be hosted by clusters for which the escape velocity of the cluster is higher than the wind velocities of ‘polluter’ stars thought to provide the material out of which the second stellar generation is formed, at the time such stars were present in the cluster (we refer to this as ‘the escape velocity threshold’ scenario). This scenario was developed further by G14 who studied HST photometry of a sample of 18 intermediate-age (1–2 Gyr) star clusters in the Magellanic Clouds that covered a variety of masses and core radii. They found that all the clusters showing an eMSTO feature escape velocities \( V_{\text{esc}} \gtrsim 15 \text{ km s}^{-1} \) out to ages of at least 100 Myr. This age is equivalent to the lifetime of stars of \( \approx 5 \, M_{\odot} \) (e.g. Marigo et al. 2008), and hence old enough for the slow winds of massive binary stars and IM-AGB stars of the first generation to produce significant amounts of ‘polluted’ material out of which second-generation stars may be formed. Furthermore, C14 showed that this threshold on \( V_{\text{esc}} \) is consistent with HST observations of four low-mass intermediate-age star clusters (\( \approx 10^4 \, M_{\odot} \)): the two clusters that host eMSTOs have \( V_{\text{esc}} \gtrsim 15 \text{ km s}^{-1} \) out to ages of \( \approx 100 \text{ Myr} \), whereas \( V_{\text{esc}} \lesssim 12 \text{ km s}^{-1} \) at all ages for the two clusters not exhibiting eMSTOs. Hence, the critical escape velocity for a star cluster to be able to retain the material ejected by first-generation polluter stars seems to be in the range of 12–15 km s\(^{-1}\). This threshold is consistent with wind velocities of IM-AGB stars and massive binary stars (see G14 for a detailed discussion). Briefly, IM-AGB stars show wind velocities in the range 12–18 km s\(^{-1}\) (Vassiliadis & Wood 1993; Zijlstra et al. 1996), whereas observed velocities of ejecta of massive binary stars are in the range 15–50 km s\(^{-1}\) (Smith et al. 2002, 2007).\(^4\)

With this in mind, following the results presented in the previous sections where the analysis of pseudo-age distributions seems to suggest the presence of multiple SSPs in NGC 1856, we determined the structural parameters and the dynamical properties of the cluster from our new HST/WFC3 data.

\(4\) We note that this measure have been derived from one system, RY Scuti, which is in a specific case of stable mass transfer, whereas most of the mass is ejected during the unstable phase. Lower velocities are expected during unstable mass transfer or the ejection of a common envelope.

\(5\) STSDAS is a product of the Space Telescope Science Institute, which is operated by AURA for NASA.
We estimated the cluster mass and escape velocity as a function of time, going back to an age of 10 Myr, after the cluster has survived the era of violent relaxation and when the most massive stars of the first generation, proposed to be candidate polluters in literature (i.e. FRMS and massive binary stars), are expected to start losing significant amounts of mass through slow winds. The current mass of NGC 1856 was determined from its integrated-light V-band magnitude listed in Table 2. We determined the aperture correction for this magnitude from the best-fitting King model derived in Section 7.1 by calculating the fraction of total cluster light encompassed by the measurement aperture. After correcting the integrated-light V magnitude for the missing cluster light beyond the measurement aperture, we calculated the total cluster mass adopting the values of $A_V$, $[Z/H]$, and age listed in Table 2. This was done by interpolation between the $\mathcal{M}/L_V$ values in the SSP model tables of Bruzual & Charlot (2003), assuming a Salpeter (1955) initial mass function. The latter models were recently found to provide the best fit (among popular SSP models) to observed integrated-light photometry of LMC clusters with ages and metallicities measured from CMDs and spectroscopy of individual stars in the 0.2–2 Gyr age range (Pessev et al. 2008).

We calculated the dynamical evolution of the star cluster following the prescriptions of G14. Briefly, the evolution of cluster mass and radius was evaluated with and without initial mass segregation, given the fundamental role that the latter property plays in terms of the early evolution of the cluster’s expansion and mass loss rate (e.g. Mackey et al. 2008b; Vesperini, McMillan & Portegies Zwart 2009). For the case of a model cluster with initial mass segregation, we adopted the results of the simulation called SG-R1 in D’Ercole et al. (2008), which involves a tidally limited model cluster that features a level of initial mass segregation of $r_e/r_e > 1 = 1.5$, where $r_e > 1$ is the effective radius of the cluster for stars with $M > 1 M_\odot$ (see G14 for a detailed description of the reasons for this choice).

Table 3 lists the derived masses and escape velocities at an age of 10 Myr, obtained with and without initial mass segregation. Escape velocities are calculated from the reduced gravitational potential $V_{\text{esc}}(t) = 2H(t)/(r_{\text{tid}}(t) - 2r(t))^{1/2}$, at the core radius. Here $H(t)$ is the potential at the tidal (truncation) radius of the cluster. The choice to calculate the escape velocity at the cluster core radius is related to the prediction of the in situ scenario, where the second-generation stars are formed in the innermost region of the cluster (D’Ercole et al. 2008). For convenience, we define $V_{\text{esc}}(t) = V_{\text{esc}}(t, t = 10^7 \text{yr})$, and refer to it as ‘early escape velocity’. To estimate ‘plausible’ values for $V_{\text{esc}}(t)$ we used a procedure that involves various results from the compilation of Magellanic Cloud star cluster properties and N-body simulations by Mackey et al. (2008b). Briefly, they showed that the maximum core radius seen among a large sample of Magellanic Cloud star clusters increases approximately linearly with log(age) up to an age of ~1.5 Gyr, namely from ~2.0 pc at $\pm 10$ Myr to $\pm 5.5$ pc at $\pm 1$ Gyr. Conversely, the minimum core radius is ~1.5 pc throughout the age range 10 Myr–2 Gyr. Using N-body modelling Mackey et al. (2008b) showed that this behaviour is consistent with adiabatic expansion of the cluster core in clusters with different levels of initial mass segregation, in that clusters with the highest level of mass segregation experience the strongest core

On the star formation history of NGC 1856 3065

Figure 14. Cumulative completeness-corrected radial distribution of bright versus faint stars. Red solid circles and solid line represent stars with $F438W < 20.5$ mag while black open circles and dotted line represent stars with $21.0 < F438W < 23.5$ mag.
The region below $12 \text{ km s}^{-1} \approx \text{const}$ constituted an additional source of gas to form second-generation stars several tens of million years after its birth. This would have a significant amount of ‘pristine’ gas from its surroundings in the first several tens of million years after its birth. This would have constituted an additional source of gas to form second-generation stars (Conroy & Spergel 2011; G14; but see also Bastian & Strader 2014).

### 8 SUMMARY AND CONCLUSION

We presented results obtained from a study of new, deep HST/WFC3 images of the young (age $\approx 300$ Myr) massive star cluster NGC 1856 in the LMC. After correction for differential reddening, we compared the CMD of the cluster with Monte Carlo simulations, both of one ‘best-fit’ SSP and of two SSPs of different ages, in order to investigate the MSTO morphology and to quantify the intrinsic width of the MSTO region of the cluster. We studied the physical and dynamical properties of the cluster, deriving its radial surface number density distribution and determining the evolution of cluster mass and escape velocity from an age of 10 Myr to 1 Gyr, considering the possible effects of initial mass segregation.

The main results of the paper can be summarized as follows.

(i) NGC 1856 shows a broad MSTO region whose width cannot be explained by photometric uncertainties, LMC field star contamination, or differential reddening effects. Comparison with Monte Carlo simulations of an SSP shows that the observed pseudo-age distribution is significantly wider than that derived from a single-age simulation. Conversely, combining two SSPs with different ages, we obtain a set of pseudo-age distributions that reproduce the observed quite well. By considering the luminosity function of the RC feature, we conclude that a best fit is achieved with a combination of SSPs with ages of 300 and 380 Myr and a mass fraction for the younger component of $\approx 55\%$. The observed pseudo-age distribution shows two distinct peaks with a similar maximum value and an uniform decline towards younger and older ages, with respect to the peaks. However, the small separation in age between the two peaks prevents us to conclude whether the morphology of the MSTO can be better explained with a smooth spread in age or by two discrete bursts of star formation. These results do not agree with the conclusions of Bastian & Silva-Villa (2013) who conclude that the CMD of NGC 1856 is consistent with a single age to within 35 Myr. We expect that this difference is due to the fact that our data are significantly deeper, namely $\approx 6$ mag. Consequently, we suggest that the arguments of Bastian & Silva-Villa (2013) against the ‘age spread’ scenario should be considered with caution.

(ii) We use V, I and H$\alpha$ images to select and study candidate (‘putative’) pre-MS stars in NGC 1856. The numbers of ‘putative’ pre-MS stars in the cluster field and the control (background) field are found to be similar, suggesting that the detections can be considered spurious and/or associated with residual noise. This indicates that star formation is not currently ongoing in the cluster.

(iii) The ‘stellar rotation’ scenario for the nature of the eMSTO phenomenon has been tested by evaluating rotating and non-rotating isochrones of the same age with the DRC CMD. Overall, a reasonable range of rotation velocities seems to be able to reproduce the MSTO properties quite well, albeit only if the rotational
mixing efficiency is significantly higher than typically assumed values. However, several properties of MSTOs and RCs among eMSTO star clusters in the age range of 1–2 Gyr are inconsistent with such high rotational mixing efficiencies. This seems to indicate that a range of stellar ages provides a more likely explanation of the eMSTO phenomenon (including the wide MSTO of NGC 1856) than does a range of stellar rotation velocities, although, with the current data alone, the latter hypothesis cannot formally be discarded. In this context, new stellar rotation measurements in young and intermediate-age star clusters, combined with new models of theoretical tracks and isochrones for rotating stars will be of fundamental importance to address the role of stellar rotation in the eMSTO phenomenon.

(iv) The dynamical properties of NGC 1856 derived from our data suggest that the cluster has an early escape velocity of \( \approx 17 \text{ km s}^{-1} \), high enough to permit the retention of material shed by the slow winds of polluter stars (IM-AGB stars and massive binary stars). The cluster escape velocity remains above the threshold value of \( 14–15 \text{ km s}^{-1} \) for \( \approx 80–100 \text{ Myr} \), long enough for the slow winds of IM-AGB stars to have ejected their envelopes. This material would likely have been available for second-generation star formation which could have caused the wide MSTO. Furthermore, these early escape velocities are consistent with observed wind velocities of ejecta of IM-AGB stars and with those seen in massive binary star systems.

ACKNOWLEDGEMENTS

Support for this project was provided by NASA through grant HST-GO-13011 from the Space Telescope Science Institute, which is operated by the Association of Universities for Research in Astronomy, Inc., under NASA contract NAS5–26555. We made significant use of the SAO/NASA Astrophysics Data System during this project. THP acknowledges support through FONDECYT Regular Project Grant no. 1121005 and BASAL Center for Astrophysics and Associated Technologies (PFB-06).
