ABSTRACT

Context. Protoplanetary disks around young stars are the birth-sites of planets. Spectral energy distributions and direct images of a subset of disks known as transition disks reveal dust-depleted inner cavities. Some of these disks show asymmetric structures in thermal submillimetre emission and optical scattered light. These structures can be the result of planet(s) or companions embedded in the disk.

Aims. We aim to detect and analyse the scattered light of the transition disk J160421.7-213028, identify disk structures, and compare the results with previous observations of this disk at other wavelengths.

Methods. We obtained and analysed new polarised intensity observations of the transition disk J160421.7-213028 with VLT/SPHERE using the visible light instrument ZIMPOL at R'-band (0.626 μm). We probed the disk gap down to a radius of confidence of 0.1' (∼15 AU at 145 pc). We interpret the results in the context of dust evolution when planets interact with the parental disk.

Results. We observe a gap from 0.1 to 0.3' (∼15 to 40 AU) and a bright annulus as previously detected by HiCIAO H'-band observations at 1.65 μm. The radial width of the annulus is around 40 AU, and its centre is at ∼61 AU from the central star. The peak of the reflected light at 0.626 μm is located 20 AU inward of the cavity detected in the submillimetre. In addition, we detect a dip at a position angle of −46.2 ± 5.4'. A dip was also detected with HiCIAO, but located at ∼85°. If the dip observed with HiCIAO is the same, this suggests an average dip rotation of ∼12°/year, which is inconsistent with the local Keplerian angular velocity of −0.8°/yr at −61 AU.

Conclusions. The spatial discrepancy in the radial emission in J160421.7-213028 at different wavelengths is consistent with dust filtration at the outer edge of a gap carved by a massive planet. The dip rotation can be interpreted as fast variability of the inner disk and/or the presence of a warp or circumplanetary material of a planet at ∼9.6 AU.

Key words. techniques: high angular resolution – protoplanetary disks

1. Introduction

Recent observations of transition disks (TDs) have provided insight into the processes of planet formation and circumstellar disk dissipation (e.g. Espaillat et al. 2014). High-contrast imaging in the optical and near-infrared regime and observations at millimetre wavelengths not only revealed large clear inner cavities, but also several types of structures such as spiral arms, asymmetries, dips, and disk eccentricities (e.g. Garufi et al. 2013; van der Marel et al. 2013; Quanz et al. 2013; Avenhaus et al. 2014, Thalmann et al. 2014; Benisty et al. 2015). Different processes that are not mutually exclusive, can rule the disk evolution and create the observed structures, such as photoevaporation or magnetorotational instabilities (e.g. Alexander et al. 2014; Flock et al. 2015).

Spatially resolved observations at different wavelengths are required to distinguish the physical fingerprints that each of these mechanisms leaves on the dust and gas distribution of protoplanetary disks. For example, the spatial segregation between small and large particles, as observed for several TDs (e.g. Garufi et al. 2013), is a natural consequence of filtration effects caused by particle traps (e.g. Rice et al. 2006; Zhu et al. 2012; de Juan Ovelar et al. 2013). One way to form a particle trap is planet-disk interaction: at the outer edge of a planetary gap, a region with positive pressure gradient can stop the fast inward migration of large dust particles (e.g. Pinilla et al. 2012, 2015).

In this Letter, we present polarimetric differential imaging (PDI) of the transition disk around J160421.7-213028 (hereafter J1604), obtained with the subsystem ZIMPOL of the SPHERE instrument of the Very Large Telescope (VLT), at R'-band (0.626 μm). This disk is a member of the Upper Scorpius association (Preibisch & Zinnecker 1999), which is 5−10 Myr old (Pecaut et al. 2012), and it is located at...
~145 pc (de Zeeuw et al. 1999). The disk is an excellent candidate to identify structures because it has one of the largest cavities reported in TDSs and is seen almost face-on (~6°, Mathews et al. 2012). Its cavity was resolved with observations from the Submillimeter Array (SMA; Mathews et al. 2012) and was recently observed with the Atacama Large Millimeter/submillimeter Array (ALMA) in Cycle 0 (Zhang et al. 2014), with a beam size of 0.73'' × 0.46'' (106 × 67 AU at 145 pc). The observations with ALMA showed that the gas cavity is much smaller than the mm-dust cavity (radius of 31 AU inferred from CO emission vs. 79 AU from the continuum, Zhang et al. 2014). In addition, near-infrared polarised intensity images obtained with HiCIAO at 1.6 µm (Mayama et al. 2012) revealed an asymmetric ring of ~63 AU radius, with a dip located at a position angle (PA, measured from north to east) of 85°. A tentative second dip was suggested at PA of 255°.

This Letter is organised as follows. In Sect. 2 we describe the observations and data reduction. The main results from the data analysis and the comparison with previous observations of this disk is presented in Sect. 3. We conclude with the discussion and perspectives in Sect. 4.

2. Observations and data reduction

VLT/SPHERE/ZIMPOL observations of J1604 were performed on June 10, 2015, as part of the observing run 095.C-0693(A). We have used field tracking, polarimetric (P2) mode with the R′ filter (λ0 = 0.626 µm, FWHM = 0.148 µm) for both cameras. Although there is currently no alternative to ZIMPOL for polarimetric imaging of southern targets in the visible, the blocking HWP angles to obtain Stokes Q and U, and the two ordinary beams of the polarising beam splitter; and the two extra-ordinary beams of the polarising beam splitter; and the two clean instrumental polarisation (IP), for which we corrected using the method described by Canovas et al. (2011). The models of Canovas et al. (2015) show that it is possible for an astrophysical signal to appear in the U images, even when single-scattering dominates. However, this U component only occurs for disks at high inclination (i > 40°). Since the disk of J1604 has an inclination of i = 6 ± 1.5° (Mathews et al. 2012), we can use the assumption that the polarised scattered light is entirely tangential and therefore only appear in Q, while U should not contain any scattered light signal from the disk. We optimised our IP correction by minimising the U signal and found an optimum when we used an annulus of 10 ≤ r ≤ 15 binned pixels.

3. Results

3.1. Radial profile

The radial profile of the polarised surface brightness is also illustrated. This profile was obtained by calculating the mean value at each radius from the centre of the Q image, and the error bars correspond to the standard deviation at each position. As a result of poor seeing and moderate AO performance, speckle noise inside a region of 0.1″ surrounding the star still dominates. Therefore,
we only show the profile from the radius of confidence (>0.1″ corresponding to >15 AU at 145 pc).

The radial profile shows that the reflected light at 0.626 μm has a gap from 15 to 40 AU, and it has a bright annulus from 40 to 80 AU. The reflected light extends until ~120 AU. We fit a Gaussian profile to the ring emission ($a \exp\left[-(x-b)^2/2\sigma^2\right] + d$), from ~40 AU to ~80 AU. The centre of the Gaussian ($b$) and its width ($\sigma$) were obtained by $\chi^2$ minimisation, and the values are $61.5 \pm 0.3$ AU and $8.5 \pm 0.4$ AU, respectively. These findings agree with the H band scattered light observations obtained with HiCIAO (Mayama et al. 2012). A comparison between the HiCIAO and ZIMPOL data is shown in Appendix A. Compared with the ALMA observations of the 880 μm continuum and CO J = 3−2 emission, the annulus at 0.626 μm lies inside the mm-cavity which has a radius of ~79 AU (Zhang et al. 2014, Fig. 2). The gas cavity radius was inferred around 31 AU, inside the mm-cavity which has a radius of ~20–40 AU. The flux has increased by half from the minimum in the gap and with $\delta_{\text{peak}} \sim 0.65$, which suggests a massive companion of $5−10 M_{\text{Jup}}$ mass embedded around 20–40 AU distance from the star. An upper limit of $\sim 18−21 M_{\text{Jup}}$ for a companion at 20–40 AU in J1604 has been inferred from non-redundant aperture mask interferometry (Kraus et al. 2008), which does not contradict our findings. Interestingly, the location of the gas cavity inferred by observations of CO lies also in the same range.

4. Discussion

The location of the edge of the gas cavity at 31 AU inferred from observations of CO J = 3−2 of J1604 with ALMA lies inside the gap seen in scattered light (Fig. 2). In the context of planet disk interaction, when a massive planet opens a gap in the disk, a spatial segregation is expected between the location of the outer edge of the gap in gas and in dust, which is predicted to become larger at longer wavelengths (e.g. Pinilla et al. 2012). This is because the position of the pressure maximum at the outer edge of a gap (i.e. the location where the large particles do not experience radial drift) can be much farther out than the planet position, allowing the planet to pass the outer edge of the gap in gas.

Fig. 2. Left panel: overlay of the R’ band (0.626 μm) $Q_a$ reflected light (which is not scaled by $r^2$) and 880 μm map from ALMA Cycle 0 observations (contour lines every 10..90% peak of the 880 μm continuum emission) of J1604. Right panel: radial profile of the polarised surface brightness brightness (arbitrary units), and the comparison with the size of the mm-cavity observed with ALMA at 880 μm (Zhang et al. 2014). The cavity radius inferred from CO J = 3−2 emission is also displayed. The error bars correspond to the standard deviation at each position from calculating the mean value at each radius from the centre of the image.
There is a slight difference of the ring centre between HiCIAO and SPHERE data, which is within the uncertainties of our data (approximately ~1.5 pixel size, i.e. a shift of ~3 AU, Fig. A.1). The peak of emission at $R'$ and H band can change for different dust density distributions in the case of planet-disk interaction (shift of ≤5 AU for very massive planet ≥15 $M_{\text{Jup}}$, de Juan Ovelar et al. 2013).

If the dip in the ring of J1604 observed with HiCIAO in 2012 is the same structure that we observe, then the dip must be rotating quickly, with an angular speed of ~12°/year (clockwise as the disk rotation derived from the CO emission Zhang et al. 2014). The local Keplerian speed at the position of the dip (61 AU) is approximately ~0.8°/year, much lower than derived from the two observations. Instead, the dip could be the shadow of a structure orbiting much closer to the star. The derived angular velocity corresponds to a Keplerian circular orbit at a distance of only ~9.6 AU from the star (for a 1 $M_{\odot}$ star). The nature of the structure creating this shadow is unclear at the moment, it could be a warp in the inner disk regions or a more localised feature such as circumplanetary material of a planet at that location. If the secondary dip in the HiCIAO observations is confirmed, an inclined inner disk might be responsible (Marino et al. 2015). Our observations provide no direct constraints at 10 AU from the star.

If the ring-like structure is created by a planet carving a gap, this planet would be much closer to the ring itself (at 20−40 AU), orbiting more slowly than the dip. The gap-carving planet is therefore unlikely to be associated with the shadowing structure. It is of course also possible that the dips seen in 2012 and in 2015 are unrelated temporary features, or that the dip rotates in the other direction, that it has rotated over more than 360 degrees, in which cases the derived angular velocity is meaningless and the fact that we see different dips might be related to the observed variability of J1604. While no mid-infrared (MIR) excess was detected in IRS spectra taken with Spitzer (Dahm & Carpenter 2009), photometric data between 3 and 16 μm obtained with the Wide-field Infrared Survey Explorer (WISE) do show MIR excess, suggesting an optically thick narrow ring located close to the dust sublimation radius (Luhman & Mamajek 2012). The discrepancy between WISE and IRS points to variability of the inner disk. Rapid infrared variability has also been detected in several other disks (e.g. Sitko et al. 2012; Flaherty et al. 2013).

Future high-contrast observations (in a year or more from now) can confirm whether the observed dip is the same in HiCIAO and our observations and if it rotates with a constant speed; or if the two observed dips are independent events, which would suggest fast inner disk variability.

Fig. 3. Left panel: radial mapping from 0.2−0.6 arcsec of the PI image of J1604 at R’ band. The colour scale is linear and arbitrary. Right panel: azimuthal profile calculated from the mean values obtained between [0.35−0.48] arcsec (dashed lines in the left panel) and in the left panel of Fig. 1). The error bars are from the standard deviation of the data. The solid line represents the best fit of a Gaussian by χ² minimisation. The vertical lines show the location of the minimum of the dip from our observations and from HiCIAO observations (Mayama et al. 2012).
Appendix A: Comparison with HiCIAO data

Figure A.1 shows the comparison between the azimuthally averaged radial profile of the polarised surface brightness at $R'$ and $H$ band. The data are normalised to the maximum value at $r > 0.2''$. By fitting a Gaussian profile to the ring emission $(a \exp[-(x - b)^2/2c^2] + d)$, the centre of the Gaussian is at $61.5 \pm 0.3$ and $64.8 \pm 0.2$ AU (for 145 pc distance) for $R'$ and $H$ band, respectively. The width of the Gaussian is $8.5 \pm 0.4$ and $10.6 \pm 0.9$ AU for $R'$ and $H$ band respectively. The errors are from the $\chi^2$ minimisation and are much smaller than the spatial uncertainty from the observations (1 pixel size $\sim 2$ AU). Fitting a power-law to the brightness profile beyond the location of the peak, the emission drops as $\propto r^{-2.92 \pm 0.03}$ and $\propto r^{-4.70 \pm 0.06}$ for $R'$ and $H$ band, respectively.

Figure A.1. Comparison between the azimuthally averaged radial profile of the polarised surface brightness at $R'$ and $H$ band. The data are normalised to the maximum value at $r > 0.2''$. Error bars are omitted for better readability; typical values are 40% and 30% of the mean value for $R'$ and $H$ band respectively.

Appendix B: Ring shape at different azimuthal cuts

Figure B.1 shows the radial profile of the azimuthally averaged surface brightness over four bins of PA. A Gaussian profile is fitted to each case; the width and centre of the Gaussians are summarised in Table B.1. The fitting results show that there are no significant azimuthal variations of the ring within the uncertainties of the data (pixel size $\sim 2$ AU).

Table B.1. Centre and width of the Gaussians fits for the profiles in Fig. B.1.
