Well-Defined Dinuclear Gold Complexes for Preorganization-Induced Selective Dual Gold Catalysis

Vincent Vreeken, Daniël L. J. Broere, Anne C. H. Jans, Marianne Lankelma, Joost N. H. Reek, Maxime A. Siegler, and Jarl Ivar van der Vlugt*

Abstract: The synthesis, reactivity, and potential of well-defined dinuclear gold complexes as precursors for dual gold catalysis are explored. Using the preorganizing abilities of the ditopic PN\(^{\text{PPPr}}\)

\((L^\text{H})\)

ligand, dinuclear Au\(^{I}–Au^{I}\) complex 1 and mixed-valent Au\(^{III}–Au^{III}\) complex 2 provide access to structurally characterized chlorido-bridged cationic species 3 and 4 upon halide abstraction. For 2, this transformation involves unprecedented two-electron oxidation of the redox-active ligand, generating a highly rigidified environment for the Au\(^{III}\) core. Facile reaction with phenylacetylene affords the \(\alpha,\pi\)-activated phenylacetylide complex 5. When applied in the dual gold heterocycleaddition of a ura-functionalized alkyne, well-defined precatalyst 3 provides high regioselectivities for \(\alpha,\pi\)-activation with bifunctional substrates.

Gold catalysis has flourished over the past 15 years, enabling a wide range of transformations.\(^{[1]}\) More recently, dual gold catalysis has been developed successfully.\(^{[2]}\) Whereas “traditional” mono-gold catalysis relies on \(\pi\)-activation of a substrate by a cationic Au\(^{I}\) center, dual gold catalysis typically involves both \(\sigma\)- and \(\pi\)-activation (of one or two functionalities, such as C=C bonds) by two gold centers. The prevailing strategy utilizes mononuclear Au\(^{I}\) complexes to induce \(\sigma,\pi\)-activation. However, this strategy offers no handles to induce preorganization of both gold centers to specifically target well-defined \(\alpha,\pi\)-activation of, for example, unsaturated hydrocarbon C=C multiple bonds whilst avoiding \(\pi\)- or \(\sigma\)-coordination. Furthermore, no control over the selective binding of bifunctional substrates (such as heterocyclizations) can be achieved in this manner.

The synthesis, coordination chemistry and catalytic applications of dinuclear Au\(^{I}\) complexes are well-developed.\(^{[3,4]}\)

The proximity of both gold centers has occasionally been credited to enhance reactivity.\(^{[5]}\) However, to the best of our knowledge the competence of well-defined \(\alpha,\pi\)-alkynide complexes in dual gold catalysis has never been reported, despite the potential benefits of two preorganized gold centers with respect to chemoselectivity and activity for this type of reaction. Additionally, facile access to dinuclear mixed-valent gold complexes might be an interesting target in the context of cascade and Au\(^{I}/Au^{III}\) cooperative catalysis.\(^{[7]}\)

The ditopic tridentate ligand PN\(^{\text{PPPr}}\)

\((L^\text{H})\); Scheme 1) displays versatile coordination chemistry with respect to a wide range of transition metals,\(^{[8]}\) including Cu\(^{[9]}\) and Ag\(^{[10]}\). Strikingly, no single complex of gold with this type of ditopic framework is known to date. Furthermore, chemistry related to the redox-active nature of \(L^\text{H}\) has been well-established in nickel, manganese, and thiemium complexes,\(^{[11]}\) but ligand redox-activity with Group 11 metals is limited to one example with Cu\(^{[12]}\), leading to dimerization on one of the \(\eta\)-positions of the \(L\) backbone.\(^{[13]}\) New avenues for gold coordination chemistry and catalysis may become accessible by developing strategies to preorganize and stabilize multiple gold centers on suitable ligand platforms and to selectively bind and activate bifunctional substrates. To address these challenges, we herein 1) uncover the versatile coordination chemistry of gold using the redox-active ditopic PN\(^{\text{PPPr}}\)

\((L^\text{H})\), 2) disclose the interesting ligand and metal-based reactivity of (mixed-valent) dinuclear species, and 3) establish well-defined precatalyst systems ideally suited for \(\alpha,\pi\)-activation of alkynes and demonstrate their use in highly selective dual gold catalysis.

The straightforward reaction of PNIPip with AuCl(SMe₂) in a 1:2 ratio provides white solid 1 (¹³P NMR: δ 40.9 ppm) with a ¹H NMR spectrum suggestive of a C₂ symmetric species (Scheme 2). Single crystal X-ray diffraction analysis reveals an intramolecular Au1–Au2 distance of 3.23791(17) Å, which suggests an aurophilic d²–d¹⁰ interaction in the solid state (Figure 1). Reaction of 1 with one equivalent of dichloro-λ¹-(iodanyl)benzene (PhICl₂) in CH₂Cl₂ instantaneously generates a dark purple solution that shows two signals in the ³¹P NMR spectrum at δ 44.3 (P2) and 105.3 ppm (P1). The strongly downfield shifted signal for P1 supports coordination to a Au¹¹ center by site-selective two-electron Au¹ oxidation with formation of Au¹¹–Au¹ derivative 2. Mass spectrometry supports an overall Au₂Cl₂(L) configuration. The ¹H NMR spectrum contains one strongly upfield shifted aromatic signal at δ 5.90 ppm but no -NH signal could be identified. X-ray structure determination confirms the sole formation of species 2, with the central deprotonated amido nitrogen coordinating to the square-planar Au¹¹ center (Figure 1).

The PNP-ligand backbone in 2 is severely twisted, with a C6-C1-C7-C8 torsion angle of 76.4(8)°. This distortion relates to the upfield shifted aromatic signal in the ¹H NMR spectrum, which corresponds to the shielded C(6)-H hydrogen that is positioned on top of the second phenyl ring. The intramolecular Au–Au distance of 4.641 Å excludes an aurophilic d²–d¹⁰ interaction. Cyclic voltammetry does not indicate reversible oxidation of the potentially redox-active ligand scaffold in 2.

A prerequisite for catalysis with a AuX(L) precursor (X is a halide) is the generation of a vacant coordination site by halide abstraction with, for example, Ag⁺ salts or a suitable Lewis acid. Addition of one equivalent of AgNTf₂ (or related silver salts or GaCl₃; see the Supporting Information) to 2, which bears multiple chlorido fragments, leads to a mixture of species according to ³¹P NMR spectroscopy. However, addition of two equivalents results in rapid decoloration of the reaction solution and generation of a single symmetric product (³¹P NMR: δ 40.4 ppm), suggestive of the presence of only Au¹¹-phosphine fragments. The ¹H NMR spectrum shows only one methyl signal for the ditolylamine backbone and chemically identical isopropyl groups at phosphorus. Most notably, only two instead of the anticipated three aromatic hydrogen signals are observed, together with a downfield signal at δ 10.53 ppm. This signal integrates for one hydrogen and is attributed to an -NH fragment. ESI-MS data suggest that the dinuclear complex, bearing only one chlorido ligand, remains intact during this transformation. The structure of complex 3 could be elucidated by X-ray structure determination of single crystals grown from CH₂Cl₂–pentane (Figure 2).

Clearly, halide abstraction by AgNTf₂, related silver salts, or GaCl₃, induces a highly unusual metal-based reduction of mixed-valent species 2 to yield Au¹–Au¹ species 3.

Figure 1. Displacement ellipsoid plots (50% probability level) of 1 (left) and 2 (right). For clarity, the counterion and hydrogen atoms are not shown. Selected bond lengths (Å) and angles (°), for 1: Au1–P1 2.2495(8), Au1–Cl1 2.3010(7), Au1–Au2 3.23791(17), P1-Au1-Cl1 173.45(3), C6-N1-C12 126.3(3). For 2: Au1–P1 2.2655(21), Au1–N1 2.041(7), Au1–Cl1 178.39(8), P1-Au1-N1 84.51(19), N1-Au1-C6 176.4(7), torsion φ: C6-C1-C7-C8 75.8(8).

Figure 2. Displacement ellipsoid plot (50% probability level) for the cationic part of 3. The NTf₂ counterion, lattice solvent molecules, and hydrogen atoms are omitted for clarity. Selected bond lengths (Å) and angles (°): Au1–P1 2.2500(12), Au2–P2 2.2500(12), Au1–Cl1 2.3484(12), Au1–Au2 3.0758(3), C2–C8 1.449(7), P1-Au1-Cl1 178.53(4), Au1–Cl1–Au2 81.74(4).
to Au(2) (Figure 3). This is the first crystallographically characterized intramolecular Au$_2$(o,σ-acetylide) complex with a diphosphine ligand, and serves to illustrate that preorganization of two gold centers may lead to selective substrate coordination. Complex 4 reacts in a similar fashion, leading to the well-defined species 8 that was characterized by NMR spectroscopy and mass spectrometry (see the Supporting Information).

Having established that dinuclear complex 3 engages in well-defined o,σ-activation of C–C triple bond systems, the heterocyclization (intramolecular hydroamination) of urea-functionalized alkyne 6 was selected as a proof-of-concept reaction to probe the catalytic competence of this well-defined Au$_2$ species. Markovnikov addition to generate a six-membered ring (8) involves π-activation by a single gold species, whereas dinuclear o,τ-activation results in anti-Markovnikov addition to give a five-membered ring (7; Scheme 3). Using 2.5 mol% of 3 in DMF at 60°C for five hours leads to full conversion and high regioselectivity for the five-membered indole 7 (85%), in accordance with a selective o,σ-acetylide mechanism. External base (such as K$_2$CO$_3$) inhibits the reactivity, while addition of one equivalent of AgNTf$_2$ with respect to the catalyst provides slightly higher regioselectivity for 7 (90%): presumably this is due to faster generation of the o,σ-acetylide species. In the absence of additives (Ag$^+$ or base), bis(chlorido)-bridged tetranuclear complex 4 displays a similar preference for formation of 7. The high regioselectivity achieved with dinuclear catalysts 3 and 4 is attributed to the ligand-enforced proximity of both Au centers. Stoichiometric reaction of 3 and 6 shows sole formation of the o,π-activated substrate by ESI-MS (Supporting Information, Figure S27).

Dilution studies were performed to investigate the effect of decreased catalyst loading on the level of regiocontrol for the conversion of 6 to 7 and 8. The findings clearly validate our hypothesis, as the high regioselectivity for 7 obtained with catalyst 3 is independent of the catalyst concentration (Figure 4). In contrast, dilution experiments with mononuclear AuCl(PBu$_3$) —reported as the best catalyst to form 7 by o,π-activation$^{[17]}$—result in a sharp drop in selectivity.$^{[18]}$ These results demonstrate the benefits of well-defined preorganization of two gold centers to enforce selective o,π-activation and to mediate regioselective dual gold catalysis with functionalized alkynes, even at low catalyst loadings.

In summary, we have demonstrated that the redox-active PNP$^{[19]}$P$_2$ ligand is a suitable framework to preorganize two gold centers for selective o,σ-activation of functionalized alkynes. Halide abstraction from mixed-valent Au$^+$/Au$^{III}$ complex 2 using AgNTf$_2$ results in highly unusual reactivity
involving two-electron ligand oxidation, generating chlorido-bridged Au$_1$-Au$_5$ species 3 bearing a highly rigidified carbazolyl backbone. Reaction with phenylacetylene enabled the first crystallographically characterized intramolecular dual gold π,π-acylide complex (5) supported by a single diphenylphosphine. The well-defined dinuclear Au$_4$ complexes are excellent precatalysts for dual gold catalysis involving selective π,π-activation, inducing high regioselectivity in the gold-catalyzed heterocyclization of urea 6, without the need to add base or silver salts. Dilution experiments show that dinuclear catalyst 3 retains high selectivity at decreased catalyst loadings, unlike mononuclear Au$_1$ catalysts typically employed for this reaction. These results illustrate the benefits of reorganization of gold centers to invoke selective substrate activation in dual gold catalysis. The detailed mechanism behind the surprising conversion of 2 into 3 is currently under investigation. This ligand-to-dual two-electron transformation appears to involve several digold intermediates, including the dinuclear “monomer” of complex 4, as well as a unique Au$^{III}$–Au$^{III}$ species supported by one PNP ligand.[19]

Figure 4. Comparison of regioselectivity toward indole 7 with dinuclear catalyst 3 vs. mononuclear benchmark catalyst AuCl(PBu$_3$)$_2$ under dilution conditions.
[19] Because of the anticipated complexity associated with this multi-step “cascade” process, which converts 2 into 3, a detailed mechanistic investigation of this transformation is deemed beyond the scope of this study and will be reported elsewhere.
