ABSTRACT

We report on the determination of astrometric, spin, and orbital parameters for PSR J1518+0204C, a “black widow” binary millisecond pulsar in the globular cluster (GC) M5. The accurate position and orbital parameters obtained from radio timing allowed us to search for the optical companion. By using WFC3/Hubble Space Telescope images, we identified a very faint variable star (mF390W ≳ 24.8, mF660W ≳ 24.3, mF814W ≳ 23.1) located at only 0′′.25 from the pulsar’s timing position. Due to its strong variability, this star is visible only in a subsample of images. However, the light curve obtained folding the available data with the orbital parameters of the pulsar shows a maximum at the pulsar inferior conjunction and a possible minimum at the pulsar superior conjunction. Furthermore, the shape of the optical modulation indicates a heating process possibly due to the pulsar wind. This is the first identification of an optical companion to a black widow pulsar in the dense stellar environment of a GC.

Key words: globular clusters: individual (M5, NGC 5904) – pulsars: individual (PSR J1518+0204C) – techniques: photometric

1. INTRODUCTION

According to the canonical formation scenario, millisecond pulsars (MSPs) form in binary systems that contain neutron stars (NSs), which are eventually spun up to millisecond periods by mass accretion from an evolving companion that, in turn, is expected to become a white dwarf (WD; e.g., Lyne et al. 1987; Alpar et al. 1982; Bhattacharya & van den Heuvel 1991). About 40% of known MSPs are found in globular clusters (GCs),3 though the Galaxy is 100 times more massive (2.4 × 10^11 M⊙ ≲ M/M⊙ ≲ 1.2 × 10^12; Little & Tremaine 1987; Koehanek 1996) than the entire GC system. This is partially caused by selection effects, since GCs have been searched very deeply by radio surveys. Despite this, the abundance of MSPs in GCs compared to the Galactic disk is real and very large, and provides a strong indication that dynamical interactions greatly enhance the formation of these objects. In fact, in the Galactic field, the only viable formation channel for MSPs is the evolution of various kinds of binary systems originated and/or hardened by stellar interactions (e.g., Davies & Hansen 1998). In particular, the ultradense cores of GCs are very efficient “factories” for generating exotic objects, such as low-mass X-ray binaries (LMXBs), cataclysmic variables, blue stragglers, and MSPs (e.g., Bailyn 1995; Verbunt et al. 1997; Ferraro et al. 2001a). Indeed, these objects are thought to result from the evolution of various kinds of binary systems originated and/or hardened by stellar interactions (e.g., Clark 1975; Hills & Day 1976; Bailyn 1992; Ivanova et al. 2008), and are therefore considered powerful diagnostics of GC dynamical evolution (e.g., Ferraro et al. 1995; Goodman & Hut 1989; Hut et al. 1992; Meylan & Heggie 1997; Pooley et al. 2003; Fregeau 2008; Ferraro et al. 2009, 2012).

Studying the optical emission properties of binary MSP companions is important to better constrain the orbital parameters and to clarify the evolutionary status of these systems. In GCs, it also represents a crucial tool for quantifying the occurrence of dynamical interactions, understanding the effects of crowded stellar environments on the evolution of binaries, determining the shape of the GC potential, and estimating the mass-to-light ratio in the GC cores (e.g., Phinney 1992; Bellazzini et al. 1995; Possenti et al. 2003; Ferraro et al. 2003b). Despite their importance, only eight MSP companions in six GCs have been identified thus far (Edmonds et al. 2001; Ferraro et al. 2001a; Edmonds et al. 2002; Sigurdsson et al. 2003; Ferraro et al. 2003a; Bassa et al. 2003; Cocozza et al. 2008; Pallanca et al. 2010, 2013b). Three of them are likely helium WDs, in agreement with the expectations of the MSP recycling scenario, while the other five are nondegenerate stars, which are thought to be either the result of a different evolutionary path or the product of an exchange interaction.

“Black Widows” (BWs) are MSPs characterized by an unmeasurably small eccentricity and a very small mass function (thus indicating a companion mass smaller than 0.05 M⊙; Roberts 2013). In most cases, these pulsars show eclipses in the radio signal suggesting that the companion is a nondegenerate, possibly bloated star. In particular, in some systems the radio eclipse lasts for a significant fraction of the orbit, implying that the eclipsing region at the position of the companion is larger than its Roche lobe (RL). This suggests that the obscuring material is the plasma released by the companion because of the energy injected by the pulsar.

After the discovery of the first BWs in GCs, King et al. (2003) observed that they represented a much larger fraction...
of the MSP population than in the Galactic disk. Because of this, they proposed that BWs form much more often than other types of MSPs in GCs, going even as far as to suggest that perhaps they form exclusively in GCs and that the BWs in the Galactic disk were formed in GCs and later ejected. However, in the last few years, the number of BWs discovered in the Galactic field has significantly increased, both in blind surveys (Burgay et al. 2006; Bates et al. 2011; Keith et al. 2012) and particularly in the surveys targeted at Fermi unidentified sources (e.g., Ransom et al. 2011; Keith et al. 2011) suggesting that BWs can form directly in binary systems in the Galactic field, with no need for an exchange interaction. If this view is correct, then the percentages of BWs as a fraction of the total MSP population should be similar in the Galaxy and in GCs, particularly the GCs with a low interaction rate per binary Verbunt & Freire (2014): In both environments, an LMXB, once formed, can evolve undisturbed toward the MSP binary stage. Some BWs should survive even in GCs with a high interaction rate per binary, because they have very small orbits that are unlikely to be disrupted. Hence, studying the numbers and properties of BWs both in the Galactic field and in GCs is important to test these two hypotheses (formation through dynamical interactions or the evolution of primordial binaries). This is important because their formation is still very poorly understood.

Up to now, only a few companions to BWs have been detected (Fruchter et al. 1988; Stappers et al. 1996, 1999, 2000; Reynolds et al. 2007; van Kerkwijk et al. 2011; Pallanca et al. 2012; Romani 2012; Breton et al. 2013), none of them in a GC. The companions to BWs in the Galactic field are found to be low-mass objects likely ablated and with a partially filled RL. Moreover, these objects show an IR/optical/UV modulation of a few magnitudes correlated with the orbital motion. The light curve of BW companions is usually characterized by a maximum around pulsar inferior conjunction ($\Phi \sim 0.75$) and one minimum around pulsar superior conjunction ($\Phi \sim 0.25$). This shape is thought to be due to the pulsar wind heating the side of the companion that faces the pulsar.

Here we present the first identification of an optical companion to a BW pulsar in the GC M5. M5 (NGC 5904) is a dynamically evolved GC (Ferraro et al. 2012) with intermediate central density and concentration (log $\rho_0 = 4.0$ in units of $M_\odot$/$pc^3$; Pryor & Meylan 1993; $c = 1.66$; Micocci et al. 2013) and relatively high metallicity ([Fe/H] $\sim -1.3$; Carretta et al. 2009) located at $\sim$7.5 kpc from the Earth (Ferraro et al. 1999; Harris 1996, 2010 version). M5 harbors five MSPs (Anderson et al. 1997; Hessels et al. 2007; Freire et al. 2008). Among them, PSR J1518+0204C deserves special attention since it is a BW system. This pulsar has a spin period of 2.48 ms and it is in a 2.1 hr orbit with a companion of minimum mass $\sim 0.04 M_\odot$. It shows regular eclipses for 15% of its orbit, as well as eclipse delays at eclipse ingress and egress, which can last up to 0.2 ms, and are presumably due to dispersive delays as the pulsar passes through the ionized wind of its companion (Hessels et al. 2007). If BWs are directly created in binary systems without the need for exchange interactions, then PSR J1518+0204C should resemble the BWs in the Galactic field. In fact, the very short orbital period ($\sim$2 hr) and M5’s very low interaction rate per binary both suggest that it is unlikely that PSR J1518+0204C was significantly disturbed following the LMXB stage.

In Section 2, the results of the radio timing are reported, while the optical observations and the identification of the companion to the pulsar are described in Section 3. The results are discussed in Section 4. In Section 5, we present some concluding remarks with attention to possible future studies.

2. RADIO TIMING

2.1. Observations and Data Processing

PSR J1518+0204C (hereafter M5C) was discovered as part of a series of deep 1.4 GHz observations of several GCs with the Arecibo telescope in the summers of 2001 and 2002. Details of the search observations, methodology, and follow-up timing measurements of the new pulsars are described in detail by Hessels et al. (2007), and thus we only briefly discuss the timing observations and methodology for PSR J1518+0204C here.

All observations were made using one to four Wideband Arecibo Pulsar Processors (WAPPs; Dowd et al. 2000), each of which provides 100 MHz of bandwidth. We took observations in search mode, resulting in data with 256 frequency channels per WAPP, and a time resolution of 64 $\mu$s. In order to avoid known sources of radio frequency interference (aka RFI), one WAPP was centered near 1170 MHz and the remaining 2–3 WAPPs were placed such that together they covered a continuous frequency band of 200 or 300 MHz centered near 1470 MHz.

In the early years (2002–2004), we took many observations scattered throughout the year in order to better determine the astrometric and spin parameters of all the pulsars in the cluster. Since then, we have prioritized one-week campaigns in order to improve the measurement of the rate of advance of periastron of MSB, as detailed in Freire et al. (2008), with a few scattered observations that helped improve the proper motions of all the pulsars. Given the short orbital period of M5C, we get excellent, but quasirandom orbital coverage of this pulsar, since the observing strategy has been mostly designed with MSB in mind.

The data were processed using standard techniques (e.g., Lorimer & Kramer 2012) with tools in the PRESTO software suite. We folded the lower and contiguous upper frequency bands modulo the predicted pulse period using prepold, removed strong narrowband or transient broadband RFI as identified by eye from the folds, then averaged the high signal-to-noise detections together to make a template pulse profile. We determined times of arrival (TOAs) every 3–15 minutes (based on the strength of the detection, primarily due to diffractional scintillation) by cross-correlating the template profile with the folded data using the routine get_TOAs.py, resulting in 2078 TOAs covering a period of about nine years.

We determined a phase-connected timing solution using Tempo10 by fitting for astrometric, spin, and orbital parameters, along with a single average dispersion measure. We corrected arrival times to the TT(BIPM) time standard and used the DE421 solar system ephemerides (Folkner et al. 2008). Only 1398 TOAs were actually used in the fit because we ignored those TOAs between orbital phases of 0.2–0.38 due to the regular pulsar eclipse and the pulse delays during eclipse egress, which would systematically skew orbital parameter fits. The eccentricity of the 2.08 hr orbit was too small to measure and we therefore fixed it, as well as the argument of periastris ($\omega$), both to zero.

8 http://tempo.sourceforge.net
9 The get_TOAs.py routine is based on the algorithm described by Taylor (1992).

Pallanca et al.

Figure 1. Timing residuals for PSR J1518+0204C. The top panel shows the post-fit timing residuals of the timing solution described in Table 1 as a function of date (in MJD). The weighted rms of the residuals is 12.3 μs based on 1398 arrival times. The bottom panel shows post-fit residuals as a function of the orbital phase (mean anomaly), where the radio eclipse is obvious near orbital phase 0.25 (pulsar superior conjunction). Arrival times between the orbital phases of 0.2 and 0.38 are not among the 1398 used in the timing fit, but are displayed here to illustrate the extra dispersive delay near superior conjunction, which is due to plasma emanating from the companion star.

The final timing solution, reported in Table 1 and shown in Figure 1, had weighted rms residuals of 12.3 μs and a reduced $\chi^2$ of 1.88 with 1385 dof. We estimated the errors on the fit parameters using a bootstrap error analysis with 4096 iterations.

2.2. Results

The timing solution includes a very precise position and proper motion, which are absolutely required for follow-up of the object in the crowded field of M5. The system is located at $\alpha$(J2000) = 15h18m32s788893(21) and $\delta$(J2000) = 02°04'47.8153(8), which is only 7.5″ (corresponding to ~0.27 core radii; $r_c$ = 28″) from the nominal cluster center as determined by Micocchi et al. (2013). This is well within the core radius of the cluster. The proper motion is entirely consistent with the previously measured proper motions of PSR B1516+02A and B (Freire et al. 2008), indicating that it is mostly due to the motion of the cluster as a whole. The peculiar velocities of these pulsars within the cluster are still too small to be measured with our current timing precision.

The observed spin period derivative of the pulsar is a combination of several contributions, the main ones being due to its intrinsic spin period derivative, $P_{\text{int}}$, the acceleration of the pulsar in the gravitational field of the cluster projected along the line of sight $a_t$ and the Shklovskii’s effect, due to the pulsar’s total proper motion $\mu$:

$$\left( \frac{\dot{P}}{P} \right)_{\text{obs}} = \left( \frac{\dot{P}}{P} \right)_{\text{int}} + \frac{a_t}{c} + \frac{\mu^2 d}{c},$$

where $d$ is the distance to the cluster, 7.5 kpc. The Galactic acceleration is generally small, or of the same order as the last term, which is the smallest.

Using a simple empirical model of GC interiors (King 1962; Freire et al. 2005) and the cluster’s central velocity dispersion of 5.5 km s$^{-1}$ (Harris 1996, 2010 version), we estimate that the maximum cluster acceleration along the line of sight at the location of M5C is $a_{\text{max}} = \pm 1.54 \times 10^{-9}$ ms$^{-2}$. This would need to be of the order of $\pm 2.6 \times 10^{-9}$ ms$^{-2}$ to fully account for the observed $\dot{P}$ already without the contribution from the Shklovskii effect (which amounts to $+0.5 \times 10^{-9}$ ms$^{-2}$). From this, we can infer minimum and maximum values for $\dot{P}_{\text{int}}$ of $0.9$ and $3.5 \times 10^{-20}$, which implies a magnetic field $B_0 \leq 3.0 \times 10^8$ G and a characteristic age $1.1 < \tau_c < 4.3$ Gyr. These values are typical among the Galactic MSP population.

We also detect a variation of orbital period with very high significance; its time derivative $\dot{P}_{\text{obs}}$ is $-0.914(23) \times 10^{-12}$. Considering the typical masses of such binary systems, the measured value is one order of magnitude larger than the expected contribution due to the emission of gravitational waves predicted by general relativity. Such a discrepancy is a common feature for BW systems (Lazaridis et al. 2011), where significant changes of the orbit are most likely caused by tidal dissipation leading to changes in the gravitational quadrupole moment of the companion (which are not negligible in the case of a distorted companion, or in the presence of an interaction between the companion and the pulsar; Lorimer et al. 2004, and references therein). The effect is not due to the acceleration of the pulsar in the cluster: even if it were accelerating with

Notes. Numbers in parentheses represent the formal errors in the least significant digits as determined by a bootstrap analysis of the data with 4096 iterations. The pulsar is assumed to have a mass of 1.4 \( M_\odot \).

\[ \pm a_{\text{max}}, \text{ the contribution to the orbital variation would only be } P_{\text{orb,k}} = \pm 0.04 \times 10^{-12}. \]

We also detect a variation of the apparent slowdown of the pulsar, \( \dot{\nu} \), though with much lower significance. This is likely caused by a small change in the gravitational acceleration of the cluster and nearby stars at the position of the pulsar, something to be expected considering that the pulsar is, at least in projection, very near the center of the cluster, where the stellar density is highest.

3. OPTICAL PHOTOMETRY OF THE COMPANION STAR

3.1. Observations and Data Analysis

By taking advantage of the precise position of PSR J1518+0204C obtained from the radio timing, we used high-resolution Hubble Space Telescope (HST) images to search for the optical companion to this pulsar. The photometric data set consists of a set of images obtained with the ultraviolet-visible (UVIS) channel of the WFC3. The WFC3 UVIS CCD consists of two twin detectors with a pixel scale of \( \sim 0\prime.04/pixel \) and a global field of view (FOV) of \( \sim 162\prime \times 162\prime \). Our analysis has been focused only on CHIP1, which contains the pulsar region.

The analyzed images have been acquired through four filters, in two different epochs. The first epoch images were obtained on 2010 July 5 (Prop. 11615, P.I. Ferraro). The data set consists of six images in the F390W filter with an exposure time \( t_{\text{exp}} = 500 \) s each, four images in F606W with \( t_{\text{exp}} = 150 \) s, four images in F814W with \( t_{\text{exp}} = 150 \) s, and six images in F656N (a narrow filter corresponding to H\alpha) with exposure times ranging from \( t_{\text{exp}} = 800 \) s to \( t_{\text{exp}} = 1100 \) s. The second epoch images have been obtained during four visits between 2012 June 6 and 2012 June 9 (Prop. 12517, P.I. Ferraro), using the same three wide filters as the first epoch. In particular, the data set consists of 4 images obtained through the F390W filter with an exposure time \( t_{\text{exp}} = 735 \) s each, 8 images in F606W with \( t_{\text{exp}} = 350 \) s, and 12 images in F814W with \( t_{\text{exp}} = 230 \) s and 240 s.

The photometric analysis has been performed on the WFC3 “flat fielded” (flt) images, once corrected\(^11\) for “Pixel Area Map” by using standard IRAF procedures. The photometric analysis has been carried out by using the daophot package (Stetson 1987). For each image, we modeled the point-spread function (PSF) by using a large number (\( \sim 100 \)) of bright and nearly isolated stars. The PSF model and its parameters have been chosen by using the daophot PSF routine on the basis of a Chi-squared test. A Moffat function (Moffat 1969) provides the best fit to the data in all cases. All F390W, F606W, and F814W images have been combined with daophot MONTAGE\(^2\) in order to produce a master frame. On this combined image, we then performed a source detection analysis by using daophot FIND and a 3\( \sigma \) detection limit, where \( \sigma \) is the standard deviation of the measured background. Finally, using the star list thus obtained as a reference master list, we performed the PSF fitting in each image by using the daophot packages ALLSTAR and ALLFRAME (Stetson 1987, 1994). For each star, the magnitudes estimated in different images have been homogenized (see Ferraro et al. 1991, 1992) and their weighted mean and standard deviation have been finally adopted as the star mean magnitude and its photometric error. In the final catalog, we reported both single image magnitudes and the mean magnitudes in each filter.

Since the FOV of the WFC3 images suffers heavily from geometric distortions, we corrected the instrumental positions of stars by applying the equations reported by Bellini & Bedin (2009) and Bellini et al. (2011). We then transformed the WFC3 catalog to the absolute astrometric system (\( \alpha, \delta \)) by using the stars in common with the HST WFPC2 catalog from Lanzoni et al. (2007) as secondary astrometric standards, by using the cross-correlation software CataXcorr.\(^12\) The astrometric solution has an accuracy of \( \sim 0.2\prime \) in both \( \alpha \) and \( \delta \).

Finally, the WFC3 instrumental magnitudes have been calibrated to the VEGAMAG system by using the photometric zero-points and the procedures reported on the WFC3 web page.\(^13\)

3.2. The Companion to PSR J1518+0204C

In order to identify the companion of PSR J1518+0204C, we searched for peculiar objects located within \( 1\prime \) from the nominal pulsar position (see Table 1). At a first visual inspection of the pulsar region, it was possible to identify a star showing strong variability and lying at \( \sim 0.025 \) from the pulsar, which is within the optical astrometric uncertainty. This star is very faint and visible only in a few images, while it is below the detection limit in the other frames (see Figure 2).

For this reason, we performed a visual inspection of all the 44 available images, whenever possible forcing the fitting procedure to determine the magnitude of this faint star.

\(^{11}\) For more details on the applied correction and on the Pixel Area Map definition, see the WFC3 Data Handbook.

\(^{12}\) CataXcorr is a code aimed at cross-correlating catalogs and finding astrometric solutions, developed by P. Montegriffo at INAF—Osservatorio Astronomico di Bologna. This package, available at http://davide2.bo.astro.it/~paolo/Main/CataPack.html, has been successfully used in a large number of papers by our group in the past 10 years.

\(^{13}\) http://www.stsci.edu/hst/wfc3/phot_zp_lbn
We were able to measure its magnitude in only 14 images (4 in the F390W, 3 in the F606W, and 7 in the F814W filters); however, this limited data set was sufficient to clearly assess the variability of this star, which showed quite significant luminosity variations: \( \Delta m_{F390W} \sim 0.32 \) mag (from \( m_{F390W} = 24.83 \pm 0.17 \) to \( m_{F390W} = 25.15 \pm 0.22 \)), \( \Delta m_{F606W} \sim 0.62 \) mag (from \( m_{F606W} = 24.34 \pm 0.20 \) to \( m_{F606W} = 24.96 \pm 0.19 \)), and \( \Delta m_{F814W} \sim 0.87 \) mag (from \( m_{F814W} = 23.13 \pm 0.07 \) to \( m_{F814W} = 24.00 \pm 0.28 \)). Unfortunately, the object is under the detection threshold in all F656N images, hence we do not have any \( m_{F656N} \) measure. In the other images, this star is not detected, most likely because its flux is below the detection threshold. For each band, we estimated the detection threshold as the average value of the magnitudes of the five faintest detected stars within 20\arcsec from the pulsar position, obtaining \( DTF_{F390W} \sim 26.59 \pm 0.13 \), \( DTF_{F606W} \sim 25.67 \pm 0.10 \), and \( DTF_{F814W} \sim 24.41 \pm 0.14 \). In turn, these values imply the following lower limits to the amplitudes of variation: \( \Delta m_{F390W} \geq 1.76 \), \( \Delta m_{F606W} \geq 1.33 \) and \( \Delta m_{F814W} \geq 1.28 \). Moreover, this star shows a magnitude scatter larger than that computed for objects of similar luminosity.

In order to establish whether the magnitude of variation is related to the pulsar’s orbital phase (and hence establish a physical connection between this star and the pulsar), we computed the light curve in the three bands, folding each measurement (using a magnitude upper limit for the images where the star is not detected) with the orbital period and the ascending node of the pulsar (see Table 1). Although the available data do not allow a complete coverage of the orbital period, the flux modulation of the star nicely correlates with the pulsar’s orbital phase (see Figure 3). In fact, the data are consistent with a luminosity maximum (in each band) around \( \Phi = 0.75 \), corresponding to the pulsar inferior conjunction (when we are observing the companion side facing the pulsar) and a luminosity minimum (at least a few magnitudes fainter) around \( \Phi = 0.25 \), corresponding to the pulsar superior conjunction (when we are observing the back side of the companion). Such a shape is the typical light curve expected when the surface of the companion is heated by the pulsar flux.

For reference, we overplotted sinusoidal functions \( ^{14} \) with a maximum at \( \Phi = 0.75 \) and a minimum at \( \Phi = 0.25 \) onto the observed light curve. The first important point to note is that in order to account for most of the upper limits where the star is not detected, an amplitude variation of about three magnitudes is required (see Figure 3). Such a large modulation (\( \Delta m \sim 3 \) mags) is in good agreement with what is observed for similar objects in the Galactic field (e.g., Stappers et al. 1999, 2001; Pallanca et al. 2012). Second, despite the low significance of the detection, there are some hints that

---

\( ^{14} \) Note that the light curve can be more complicated than a sinusoid, as found for a few Galactic field BWs by Breton et al. (2013).
Figure 3. Observed light curve of the companion to PSR J1518+0204C folded with radio timing orbital parameters. The arrows are the estimated upper limits to the magnitude for the images where the star is below the detection threshold. The dotted and dashed lines are sinusoidal first-guess models of the light curve, with amplitudes of two and three magnitudes, respectively. Note that the latter model is in agreement with most of the upper limits. However, the light curve does not look like a perfect sinusoid, in agreement with the models of Breton et al. (2013) calculated for similar objects.

Figure 4. Optical CMDs defined by all stars detected within 10″ from the pulsar nominal position (gray circles). The dashed lines correspond to the detection limits in the F606W and F390W bands (left and right panel, respectively). In each panel, the black dot marks the position of COM-M5C as obtained from the average of the measured values. However, such a location is biased by the undersampling of the light curve. Hence, by taking into account the magnitude modulation, we report the possible location of the companion star. In particular, the magnitude ranges between the measured maximum and a minimum assumed to be three magnitudes fainter, while the color has been calculated as the color at maximum, with an uncertainty estimated to be of the order of the standard deviation shown by objects with similar magnitudes. Therefore, COM-M5C turns out to be located between the MS and the WD loci.
4. DISCUSSION

We have constrained the mass, luminosity, and temperature of COM-M5C by comparing its position in the (mF606W, mF606W − mB18) CMD (Figure 4) with a reference isochrone reproducing the main evolutionary sequences of MS stars (Girardi et al. 2000; Marigo et al. 2008). We adopted a metallicity [Fe/H] ∼ −1.3 (Carretta et al. 2009), an age t = 13 Gyr, a distance modulus (m − M)0 = 14.37, and a color excess E(B − V) = 0.03 (Ferraro et al. 1999). In particular, for the magnitude of the companion, we assumed the value at maximum (mF606W = 24.34) as an upper limit to the luminosity and, for its color, we adopted the value at maximum (mF606W − mB18 = 1.21 ± 0.46) as a reference. The color uncertainty has been estimated from the typical photometric error of stars of similar magnitudes (see the gray shaded region in Figure 4). The resulting effective temperature, luminosity, and mass of the companion are 3440 K ≲ Teff ≲ 5250 K, L ≲ 1.19 × 10^2 L⊙, and M_{COM} ≲ 0.2 M⊙. Given that both the luminosity and temperature of the companion are overestimated, the comparison with the adopted theoretical isochrone gives an upper limit to the companion mass.

Note that if we consider the largest derived value of the mass (M_{COM} ∼ 0.2 M⊙) and we combine it with the pulsar mass function, we can rule out very small inclination angles (e.g., i ≲ 10° for a 1.4 M⊙ NS). However, as was found for other companion stars (e.g., Ferraro et al. 2003c; Pallanca et al. 2010; Mucciarelli et al. 2013), masses of perturbed stars derived from their position in the CMD might be overestimated.15 On the other hand, if we assume the lower mass limit for core hydrogen burning stars (M_{COM} = 0.08 M⊙), we would obtain an upper limit to the inclination angle of the system i < 30°. However, such inclinations would be in disagreement with the presence of a radio eclipse.

Under the assumption that the optical emission of COM-M5C is well reproduced by a blackbody (BB), the stellar radius is R_{BB} ≲ 0.30 R⊙. However, companions to BWs are expected to be affected by the tidal distortion exerted by the pulsar and consequently to be swollen up to fill their RL. Hence, to justify the presence of eclipses of the radio signal, the size of the RL might be a more appropriate value (e.g., see PSR J2051–0827 and PSR J0610–2100 Stappers et al. 1996, 2000; Pallanca et al. 2012). According to Eggleton (1983), the RL radius can be computed as

$$R_{RL} \sim \frac{0.49 q^{2}}{0.6 q^{2} + \ln (1 + q^{2})},$$

where q is the ratio between the companion and the pulsar masses (M_{COM} and M_{PSR}, respectively) and a is the orbital separation. This relation can be combined with the pulsar mass function f_{PSR}(i, M_{PSR}, M_{COM}) = (M_{COM} \sin i)^{3}/(M_{COM} + M_{PSR})^{2}. By assuming an NS mass ranging from ∼1.2 M⊙ to 2.5 M⊙ (Ozel et al. 2012) and leaving the inclination angle to span the entire range of values (between 1° and 90°), this yields R_{RL} ∼ 0.13–0.89 R⊙.

Under the assumption that the optical variation shown in Figure 3 is mainly due to irradiation from the MSP, reprocessed by the surface of COM-M5C, we can estimate how the reprocessing efficiency depends on the inclination angle and, hence, infer the companion mass. To this end, one can compare the observed flux variation (ΔF_{obs}) between the maximum (Φ = 0.75) and the minimum (Φ = 0.25) of the light curve, with the expected flux variation (ΔF_{exp}) computed from the rotational energy loss rate (E). Unfortunately, E is not measurable with the available radio observations, because the observed period derivative is likely significantly affected by acceleration of the pulsar in the gravitational potential of the cluster. However, we take as a reference the values measured for some BWs in the Galactic field, which typically have E values ranging from 10^{34} to 10^{35} erg s^{-1} (Breton et al. 2013). Actually, since we do not observe the entire light curve, ΔF_{obs} can just put a lower limit to the reprocessing efficiency.

At first, we converted the observed mF606W modulation into a flux variation. We assumed the maximum measured magnitude (mF606W = 24.34 at Φ = 0.75) and an amplitude of variation ΔmF606W = 3 between Φ = 0.75 and Φ = 0.25, thus obtaining ΔF_{obs} = 2.96 × 10^{-15} erg s^{-1} cm^{-2}. On the other hand, the expected flux variation due to irradiation between Φ = 0.75 and Φ = 0.25 is given by

$$\Delta F_{\text{exp}}(i) = \frac{E}{4 \pi d_{\text{PSR}}^{2}} R_{\text{COM}}^{2} \frac{1}{\epsilon(i)},$$

where η is the reprocessing efficiency under the assumption of isotropic emission, R_{COM} is the radius of the companion star, which we assumed to be equal to R_{RL}(i), d_{PSR} is the distance of pulsar, adopted to be equal to the GC distance (d_{PSR} = 7.5 kpc; Harris 1996; Ferraro et al. 1999), and ε(i) parametrizes the difference of the re-emitting surface visible to the observer between maximum and minimum.16 By assuming ΔF_{obs} = ΔF_{exp}(i) between Φ = 0.75 and Φ = 0.25, we can derive how η varies as a function of i. The result is shown in Figure 5. Obviously, it is important to note that all the calculations have been performed assuming a magnitude modulation of about three magnitudes and hence in case of a larger amplitude of variation the estimated reprocessing would correspond to a lower limit of the true value. As an example, the observed optical modulation can be reproduced considering a system seen at an inclination angle of about 60°, with a very low-mass companion (M_{COM} ∼ 0.04–0.05 M⊙) that has filled its RL and reprocesses the pulsar flux with an efficiency η ≳ 1%–15%. Similar results are obtained performing the same calculations in the F390W and F814W bands. It is important to note that, for simplicity, calculations have been performed assuming an RL filled companion (an upper limit to the true companion size). Consequently, in the case of a companion only partially filling its RL the reprocessing efficiency would be larger.

On the other hand, if we use R_{BB} instead of R_{RL} for the stellar radius, the efficiency increases and for several configurations it becomes larger than 100%. In such cases, the only possible scenario would be an anisotropic pulsar emission. However, given the presence of eclipses and the observed behavior of other similar objects, R_{BB} is likely too small to provide a good estimate of the companion’s true physical size. Future studies are needed to better constrain the system parameters.

15 In fact, from the measured luminosity, we can directly derive the mass through comparison with models of unperturbed MS stars, but if the star filled the RL (and thus no longer followed the hydrostatic equilibrium law) such a mass value could be overestimated.

16 In the following, we assume ε(i) = (i/180)(1 − R_{COM}/a). Note that for R_{COM} ≪ a the second term reduces to zero. For the two limit configurations, we find that in the case of a face-on system (i = 0°), the fraction of the heated surface visible to the observer is constant and hence no flux variation is expected, while in the case of an edge-on system (i = 90°) the fraction of the heated surface that is visible to the observer varies between 0.5 (for Φ = 0.75) and 0 (for Φ = 0.25) and hence ε = 0.5.
marks the physical limit (\( \Delta M \)) of the pulsar superior conjunction. The detection limit at the pulsar inferior conjunction, while it is below in 14 out of the 44 available images, whose phases nearly in a GC. Because of its faintness, the star was detected only in 17 out of the 44 available images. Finally, we estimated a lower limit to the reprocessing factor of the pulsar flux (\( \eta \)). Note that we considered upper limit estimates when the star was not visible.

5. SUMMARY AND CONCLUSION

We obtained a phase-connected radio timing solution of PSR J1518+0204C, including a very precise position and proper motion. The latter is consistent with the known proper motion of two other M5 pulsars, indicating that they are all co-moving because of the cluster motion. We also estimated the time derivative of the orbital period. As common for BW systems, it is larger than the expected contribution due to tidal dissipation. The precise position of the pulsar due to reprocessing factor of the pulsar flux (\( \eta \)).

One of the main objectives of this study is to contribute, with observational data, to the understanding of the differences between BW systems in GCs and in the Galaxy. This task is important because the formation of these systems is still poorly understood, and it is not known how much it is influenced by the local stellar density. However, given the limited statistics, particularly of systems with optical identifications, a detailed comparison of the two populations is premature at this stage. We refer the reader to a forthcoming paper with the results of a second optical identification of a BW in a GC (M. Cadelano et al. 2014, in preparation).
