Supporting Information

ABSTRACT: The fluorescence intensity of molecular rotors containing the dicyanomethylenedihydrofuran (DCDHF) motif increases strongly with solvent viscosity. Single-bond and double-bond rotations have been proposed as pathways of nonradiative decay for this and related molecular rotors. We show here that both are involved in the case of DCDHF rotors: Fluorescence is quenched by rotation around the dicyanomethylene double bond in nonpolar solvents, but in a sufficiently polar environment rotation about a formally single bond leads to a dark internal charge-transfer state.

Molecular rotors with a viscosity-dependent fluorescence deactivation pathway are widely used as molecular viscosity probes in biology,1−6 fluid dynamics,7−9 and materials science.10−15 We have recently shown that such molecules (1 and 2 in Scheme 1) comprise a unique tool in studying contact mechanics, enabling us for the first time to directly visualize contacts between solid surfaces on a molecular scale.16

The photophysics of these remarkably useful probes and functionally similar malononitriles are still incompletely understood and actively debated.10,13,15,17−24 In a model proposed by Willets,21 fluorescence deactivation of 1 occurs through an irreversible twist involving the dicyanomethylene bond (γ in Scheme 1), upon which the ground- and the excited-state potential energy surfaces (PESs) come into sufficiently close proximity to allow efficient deactivation. We have recently reported nonexponential fluorescence decays for 1 in some solvents,16 indicating that its photophysical behavior is complex. Interestingly, in the case of 9-(2,2-dicyanovinyl)julolidine (DCVJ, see Scheme 1), nonexponential fluorescence decays have also been observed. To explain this observation, Dreger proposed a model involving a dark twisted state that equilibrates with a planar locally excited (LE) state.14 In a more recent study, Gaffney and coworkers19 studied time-resolved infrared anisotropy of DCVJ in DMSO and showed that the LE state decays to a hot ground state and to a twisted intermediate species in DMSO. This branching may be different in other

from the ground-state (GS) and fast relaxation processes (with rate constant $k^a$), the molecule reaches the near-planar LE state. From there it can radiatively relax to the ground state ($k_{rad}$) or perform twisting motion around either the $\gamma$ ($k_\gamma$)21 or $\beta$ ($k_{\beta rel}$) bond (see Scheme 1). Both twists result in fluorescence deactivation. Twisting around $\gamma$ leads to a conical intersection (CI) with the ground-state PES and instantaneous nonradiative relaxation. Twisting around the $\beta$ bond yields a highly polar TICT state. This state has a finite lifetime, and it can either act as a sink (it converts to the GS directly with rate constant $k_{\gamma 0}$) or as a reservoir state (TICT back-converts to the LE state and to the GS with rate constants $k_{\gamma r}$ and $k_{\beta r}$ respectively). In the latter case delayed fluorescence occurs and causes biexponential fluorescence decays. These twists occur easily in liquid solvents but become hindered as solvent viscosity increases. In this way, the degree of confinement is reflected by a fluorescence response. Below we show that the deactivation pathway of 1 strongly depends on solvent polarity: Deactivation proceeds through CI (through $\gamma$ twist in Scheme 1) in nonpolar solvents, whereas polar solvents facilitate the formation of the TICT species and subsequent deactivation (through $\beta$ twist, Scheme 1).

In this work, we use steady-state and time-resolved fluorescence measurements and combine them with visible pump mid-IR probe transient measurements. Combination of these powerful techniques enables us to learn more about the excited-state dynamics of 1 in a range of solvents. To further deepen our fundamental understanding of the relevant processes, we supplement our experimental findings with TD-DFT calculations.

The steady-state absorption and fluorescence spectra of 1 (see Figure 1a) show significant changes in both the shape and peak positions as solvents are changed from nonpolar hexane to the highly polar DMSO, indicating charge-transfer character of the excited state. From the Stokes shifts we estimate the difference in dipole moments of $S_1$ and $S_0$ to be $\Delta \mu = 5.8 \pm 0.9 \text{ D}$.12,22,23,26 Because of efficient fluorescence deactivation, quantum yields in liquids are very low (see Figure 1a and Table 1). In the very polar solvents DMSO and MeCN the quantum yields ($\Phi_f$) are <1%. This value is somewhat higher in medium polarity EtOAc (2.9%) and peaks in the relatively nonpolar toluene (5.0%). An order-of-magnitude drop in $\Phi_f$ (~0.6%) is observed when going from toluene to the even less polar hexane (Figure 1a, inset). This trend can be explained by the presence of two different barriers with different polarity dependencies that lead to fluorescence deactivation.

The fluorescence decays show trends similar to the ones observed in steady-state measurements. In hexane, the decays are too fast to be measured with our TCSPC equipment. In toluene, fluorescence decay is monoexponential and relatively slow (120 ps). Our calculations (see below) indicate that the increase in polarity (which occurs in the case of hexane vs toluene) results in an increase in the energy barrier that separates the LE state from the CI. In EtOAc, the decay is biexponential (with time constants of $\tau_1 = 30$ and $\tau_2 = 228$ ps at quantum yields ($\Phi_f$) are <1%. This value is somewhat higher in medium polarity EtOAc (2.9%) and peaks in the relatively nonpolar toluene (5.0%). An order-of-magnitude drop in $\Phi_f$ (~0.6%) is observed when going from toluene to the even less polar hexane (Figure 1a, inset). This trend can be explained by the presence of two different barriers with different polarity dependencies that lead to fluorescence deactivation.

The fluorescence decays show trends similar to the ones observed in steady-state measurements. In hexane, the decays are too fast to be measured with our TCSPC equipment. In toluene, fluorescence decay is monoexponential and relatively slow (120 ps). Our calculations (see below) indicate that the increase in polarity (which occurs in the case of hexane vs toluene) results in an increase in the energy barrier that separates the LE state from the CI. In EtOAc, the decay is biexponential (with time constants of $\tau_1 = 30$ and $\tau_2 = 228$ ps at
room temperature, Figure 1b). Reconstructed decay-associated fluorescence spectra show two components with identical spectral profiles (Figure S14), indicating that fluorescence emission occurs from a single state. The trend obtained from calculations presented below suggests that EtOAc is just polar enough to prevent crossing at the energy barrier leading to the CI (the \( \gamma \) twist becomes hindered) and to simultaneously lower the energy barrier that separates the LE state from the \( \beta \)-twisted (TICT) state. It is, however, not polar enough to stabilize the TICT state to such an extent that it cannot convert back to the fluorescent planar LE state. As a result of this interconversion we observe delayed fluorescence. The kinetic model (see Scheme 2) can be expressed by the following equations

\[
\frac{d[P]}{dt} = k_{TP}[T] - k_{TP}[P] - k_{rad}[P] \tag{1}
\]

\[
\frac{d[T]}{dt} = k_{TP}[P] - k_{TP}[T] - k_{T0}[T] \tag{2}
\]

\[
[GS] = 1 - [P] - [T] \tag{3}
\]

(Where P, T, and GS are the planar, TICT, and ground state, respectively), which can be solved analytically, so that \( k_{TP} \), \( k_{TP} \), and \( k_{T0} \) can be obtained from our data. The \( k_{TP} \) and \( k_{TP} \) values thus obtained allow estimation of the energy of the TICT state to be \( \sim 0.9 \) kcal/mol lower than the energy of the planar LE state at room temperature for 1 in EtOAc.

Fluorescence emission spectra measured at increasing temperatures show an unusual increase in intensities with temperature (Figure 1b, inset). To further investigate this, we have measured fluorescence decays for 1 in EtOAc at different temperatures (see Figure 1b and Table S2). The twisting rates \( k_{TP} \) and \( k_{TP} \) increase with temperature, while \( k_{T0} \) somewhat counterintuitively decreases. This causes the shorter time constant (\( \tau_1 \)) to decrease (from 37 ps at 5.5 °C to 25 ps at 54.5 °C) and the longer one (\( \tau_2 \)) to increase (from 168 ps at 5.5 °C to 282 ps at 54.5 °C). Two factors contribute to the increase in \( \Phi_f \) with increasing temperature: (1) Nonradiative relaxation of 1 in EtOAc occurs through the TICT state; the decrease in \( k_{T0} \) results in less efficient nonradiative decay. (2) The simultaneous increase in \( k_{TP}/k_{TP} \) produces an increase in population of the fluorescent planar state (P). The change in \( k_{TP} \) probably originates from the fact that increasing the temperature causes the relative permittivity of EtOAc to decrease from \( \sim 6.4 \) (5.5 °C) to \( \sim 5.4 \) (54 °C), which, in turn, destabilizes the TICT state and separates it further from the GS PES rendering nonradiative decay less rapid. At the same time, the energy of the TICT state comes closer to the energy of the LE state, increasing \( k_{TP} \). The increase in \( \Phi_f \) and longer \( \tau_2 \) with temperature (Figure 1b) show that the escape through the alternative channel (\( \gamma \) twist) does not occur under these conditions.

In DMSO, the TICT state (\( \beta \)-twisted structure in Scheme 2) readily forms and does not revert back to the fluorescent LE.
Figure 3. (a) Representative time traces of 1 in toluene. (b) Species-associated spectra obtained from global analysis with sequential model assumed.

planar state. The formation of the \( \beta \)-twisted transient species in polar DMSO can be observed in vis-pump mid-IR probe measurements (time resolution \( \sim 200 \) fs). Transient IR spectral traces for 1 in DMSO measured in the C=C and CN regions are shown in Figure 2a. Representative time traces are shown in Figure 2c. In the C=C region, ground-state bleach (GSB) bands are centered at 1568 and 1608 \( \text{cm}^{-1} \). Another GSB band is centered at 1542 \( \text{cm}^{-1} \), but its strong overlap with excited-state absorption (ESA) bands originating from the planar LE state makes it visible only at later probe delays. An excited-state band rises at 1582 \( \text{cm}^{-1} \), and we attribute it to the formation of the \( \beta \)-twisted TICT state. Its rise correlates with the decay of LE ESA bands centered at 1535 and 1552 \( \text{cm}^{-1} \) (Figure 2a,c, left side), indicating sequential formation kinetics. A spectral signature of this species can also be observed in the CN stretch region (see Figure 2a,c, right side). The TICT state manifests itself here as a rise in the ESA, but very pronounced overlap between the CN bands (symmetric and asymmetric stretches) of the LE and TICT states complicates the separation of the bands associated with the two species. From a global fit of the transient data with a target sequential model \( \text{eq 4} \) and the Supporting Information for details), we reconstruct species-associated spectra (shown in Figure 2b), with rate constants of \( k_{1T} = (3.68 \pm 0.06) \times 10^{-2} \text{ps}^{-1} \) and \( k_{10} = (9.85 \pm 0.03) \times 10^{-2} \text{ps}^{-1} \) \( (k^* \) was too fast to be resolved).

\[
S_{1,\text{LE}} \xrightarrow{k_{1T}} S_{1,\text{LE}} \xrightarrow{k_{10}} S_{1,\beta(TICT)} \xrightarrow{k_{0\gamma}} S_0
\]  

Vis-pump mid-IR probe measurements for 1 in toluene do not indicate the presence of transient species. Global analysis with sequential model yields two rate constants of \( 1.31 \pm 0.07 \) and \( 8.32 \pm 0.02 \times 10^{-3} \text{ps}^{-1} \) \( (\text{Figure 3}) \). We attribute the shorter one to vibrational cooling and the longer one to the decay of the fluorescent LE state. These rates show excellent agreement with the fluorescence measurements and indicate that fluorescence deactivation of 1 indeed proceeds through CI and does not involve transient intermediates.

Relaxed scans of the excited-state PES for 1a obtained by TD-DFT (CAM-B3LYP/6-31+G(d)) calculations, where solvent effects are included using the polarizable continuum model (PCM),\textsuperscript{31} show excellent agreement with our experimental results. TD-DFT calculations find three minima \( (\text{Figure 4 and Scheme 2}) \) on the \( S_1 \) PES. One minimum belongs to the fluorescent LE planar state, which is reached upon photoexcitation and subsequent relaxation. A second minimum is reached by twisting about the \( \gamma \) bond \( (\text{Scheme 2}) \). The sudden drop in oscillator strength and the close proximity of the GS and ES PES \( (\text{Figure 4a and inset}) \) both suggest the presence of a CI near these coordinates. This is in excellent agreement with the initially proposed deactivation model\textsuperscript{12} and identifies this twist as an important fluorescence deactivation pathway. Our calculations indicate that the dipole moment decreases as the twist advances, which, in turn, results in polar solvents hindering this twist. Such a trend was observed previously by Massin et al., who used deactivation through a dicyanomethylene twist to probe medium polarity.\textsuperscript{12} Consequently, this pathway is expected to be less favorable in polar solvents \( (\text{calculated barriers are 3.1 and 5.8 kcal/mol for toluene and DMSO, respectively}) \). We have experimentally estimated \( (\text{see Supporting Information}) \) this barrier to be \( \sim 3.6 \text{ kcal mol}^{-1} \) in hexane \( (\epsilon_r = 1.89) \) and toluene \( (\epsilon_r = 2.38) \). This value is reasonably close to the calculated value of 3.1 kcal mol\textsuperscript{-1} obtained for toluene. The third PES minimum can be accessed through twisting of the \( \beta \) bond \( (\text{Scheme 2 and Figure 4b}) \). It is accompanied by a large increase in the calculated dipole moment and a gradual drop in the oscillator strength. A polar environment stabilizes this highly polar state and lowers the energy barrier that separates it from the LE planar state.

Figure 4. Potential energy surface scans of 1a with polarizable continuum model solvation. Insets show oscillator strength as a function of scanned dihedral angle. Ground-state energies are calculated at excited-state geometries. (a) Relaxed \( \gamma \)-constrained scan. (b) Relaxed \( \beta \)-constrained scan.
(from 1.3 kcal mol\(^{-1}\) in toluene to 0.1 kcal mol\(^{-1}\) in DMSO). This makes the \(\beta\)-twisted TICT state easier to reach but hinders the back conversion from the TICT to the planar fluorescent state when the environment is too polar. The energy difference between the GS and ES twisted geometries decreases as polarity increases (from 52 kcal mol\(^{-1}\) in toluene to 29 kcal mol\(^{-1}\) in DMSO), but the surfaces still remain well-separated and the oscillator strengths decrease gradually with increasing \(\beta\). We have found no evidence of a CI near these coordinates. Instead, nonradiative relaxation from this state is expected (and experimentally observed) to become more efficient as the solvent polarity increases due to the increasing proximity of the two surfaces (energy-gap law).\(^{29}\) The trends obtained from the TD-DFT calculations are in excellent agreement with our experimental observations that show that reversible \(\beta\) twist occurs in solvents of medium polarity (EtOAc) and becomes irreversible as polarity increases further (DMSO, MeCN) due to stabilization of the TICT state.

To conclude, we have shown that 1 (and by analogy, 2) can relax to the ground state via two distinct pathways. Both involve significant changes in geometry and account for the sensitivity of the fluorescence of these molecules to viscosity and free volume. The relaxation pathway depends strongly on the dielectric properties of the molecular environment: In nonpolar solvents relaxation occurs by twisting about the exocyclic C=C bond, which results in momentary deactivation. Polar solvents hinder this twist, while at the same time opening up a new deactivation pathway that leads to the dark intermediate \(\beta\)-twisted ICT state from which the nonradiative relaxation occurs. The presence of two decay pathways leads to a discontinuous dependence of the nonradiative decay rate at low viscosities on the polarity. Because the two pathways have different spatial requirements, the dependences of their rates on viscosity and free volume may be different. These factors need to be taken into account when molecular rotors similar to 1 are used as viscosity/free volume sensors.
