Abstract

Dilatation measurements have been performed on a single-crystalline sample of the heavy-fermion superconductor URu$_2$Si$_2$ ($T_c = 1.2$ K). Thermal expansion measurements indicate a thermal electronic Grüneisen parameter $\Gamma_e = 27$. A comparison with the magnetic electronic Grüneisen parameter derived from the magnetostriction, $\Gamma_m = 26$, points to a single energy scale. Magnetostriction measurements in the superconducting state reveal hysteresis with a peculiar change of sign close to the upper critical field, $B_{c2}$.

The heavy-fermion superconductor URu$_2$Si$_2$ attracts considerable attention because of the unusual co-existence of superconductivity and antiferromagnetism [1,2]. Long-range antiferromagnetic order is found below the Néel temperature $T_N = 17.5$ K. Neutron-diffraction experiments [3] revealed that URu$_2$Si$_2$ is an antiferromagnet with an extremely small ordered moment of 0.03$\mu_B$ (on the uranium atom) oriented along the tetragonal axis (c-axis). Superconductivity is found below $T_c = 1.2$ K [1].

Dilatation measurements were performed on a single-crystalline sample of dimensions $4 \times 3 \times 5$ mm$^3$ ($a \times a \times c$) using a sensitive three-terminal parallel-plate capacitance technique. The coefficient of linear thermal expansion, $a_i = L^{-1} dL/dT$, where $i$ refers to the $a$- or the $c$-axis of the tetragonal crystal, was measured stepwise ($\Delta T \approx 40$ mK). The temperature variation of $\alpha_a$ and $\alpha_c$ of URu$_2$Si$_2$ at low temperature is shown in Fig. 1. The corresponding coefficient of volume expansion $\alpha_v = 2\alpha_a + \alpha_c$ is given by the solid line. For $T > T_c$, $\alpha_a$, $\alpha_c$, and $\alpha_v$ vary linearly with temperature as does the specific heat ($c = \gamma T$) [1]. The linear coefficients of the thermal expansion amount to

![Fig. 1. Linear thermal expansion $\alpha_a$ (○) and $\alpha_c$ (+). The volume effect divided by three is indicated by the solid line.](image-url)
$a_a = \alpha_a / T = 0.22 \times 10^{-6} \text{ K}^{-2}$ and $a_c = \alpha_c / T = -0.16 \times 10^{-6} \text{ K}^{-2}$. At the superconducting transition ($T_c = 1.18 \text{ K}$) $\alpha_a$ and $\alpha_c$ exhibit sharp jumps and change sign. The results displayed in Fig. 1 are in good agreement with previous measurements on a single-crystalline sample [6], which exhibited a much broader transition.

The linear magnetostriction, $\lambda = \frac{[L(B) - L(0)]}{L(0)}$, was measured for a dilatation (contraction) direction along and perpendicular to the magnetic field ($B \parallel c$) by recording the capacitance change while sweeping the magnetic field at a low rate ($dB/dt \approx 0.1 \text{ T/min}$). The curves of linear magnetostriction measured in the normal state at $T = 1.5 \text{ K}$ are shown in Fig. 2. The volume magnetostriction is given by $\lambda_v = 2\lambda_a + \lambda_c$. The magnetostriction in the normal state behaves like $\lambda = bB^2$, characteristic for paramagnetic systems. Previous magnetostriction data ($B \parallel c$) at 4.2 and 20 K [7] yielded a similar behaviour.

In the superconducting state, the linear magnetostriction shows a pronounced hysteresis as shown in Fig. 3 for $\lambda_v$ and $B \parallel c$. The hysteresis loop closes at $B_{c2}$. For $B > B_{c2}$ the usual $B^2$ behaviour is observed. Remarkably, at the lowest temperatures, in the superconducting state, the hysteresis changes sign at a field close to $B_{c2}$. With increasing temperature, the inversion point of the hysteresis moves to lower field values, and, finally, vanishes for a temperature close to 1.0 K. Data for $\lambda_a$ and $\lambda_c$ obtained by the discrete method, i.e. by stepwise increasing the magnetic field ($\Delta B = 0.2 \text{ T}$) at a temperature of 0.5 K, are shown in Fig. 4. In Fig. 4, a $\lambda = bB^2$ term, representing the

The quadratic field dependence of the normal state is subtracted. The magnetostrictive hysteresis for $\lambda_v$ in the superconducting state changes sign close to the upper critical field where the hysteresis loop closes. The solid lines are guides to the eye.](image)
normal-state contribution determined in the field range $B > B_{c2}$ ($\approx 2$ T), is subtracted. The results of the discrete and sweep methods are in good agreement. Note that in low fields the hysteresis in $\lambda_s$ has a different sign compared to the hysteresis in $\lambda_c$. The afore-mentioned inversion of the hysteresis close to $B_{c2}$ for $\lambda_c$ is not observed for $\lambda_s$. However, the hysteresis in $\lambda_s$ becomes negligibly small in that field region. The complex behaviour of the magnetostriction is illustrated by a sign reversal of the hysteresis loop in $\lambda_s$ by raising the temperature to 1.0 K.

In order to study the volume dependence of the thermal and magnetic energy scales of the heavy-fermion state a Grüneisen parameter analysis may be performed [8]. One can introduce an experimental effective thermal Grüneisen parameter $\Gamma_{\text{eff}}(T)$:

$$\Gamma_{\text{eff}}(T) = \frac{V_m \alpha_v(T)}{\kappa c(T)} \tag{1}$$

where $V_m$ is the molar volume, $\kappa = -V^{-1}dV/dp$ is the isothermal compressibility and $c$ is the molar specific heat at constant volume. In the low-temperature limit $\Gamma_{\text{eff}}$ attains a large constant value for heavy-fermion systems which equals the thermal Grüneisen parameter, $\Gamma$, as only the linear terms in the thermal expansion ($a_s = a_v T$) and the specific heat ($c = \gamma T$) are retained. In the case of URu$_2$Si$_2$, we obtain $\Gamma_r = 27$, where we used $a_s = 0.27 \times 10^{-6}$ K$^{-2}$, $\gamma = 67$ mJ/mol K$^2$, $V_m = 4.9 \times 10^{-5}$ m$^3$/mol and a value for the compressibility estimated at 0.73 Mbar$^{-1}$ [8]. When superconductivity sets in, $\Gamma_{\text{eff}}$ changes sign and takes the value $-27$. For a quadratic field dependence of the volume magnetostriction, $\lambda_s = b_s B^2$, the volume dependence of the molar susceptibility, $\chi = \mu_s M / B$, can be calculated from the relation: $d \ln \chi / d \ln V = 2b_s \mu_s V_m / \kappa \chi$. The molar susceptibility of URu$_2$Si$_2$ at 1.5 K is given by $\chi = 62 \times 10^{-9}$ m$^3$/mol for $B \parallel c$ [1]. Using the coefficient $b_s$ from the magnetostriction curves of Fig. 2, we obtain a value of $d \ln \chi / d \ln V = 25$. The magnetic Grüneisen parameter, $\Gamma_B$, is determined by: $d \ln \chi / d \ln V = 2\Gamma_B - \Gamma_r$ where $\chi$ is independent of temperature and magnetic field [9]. The evaluated value of $\Gamma_B$ at 1.5 K is 26. For $B \parallel c$, we find that $\Gamma_B \approx \Gamma_r$, indicating that the magnetic and thermal properties of the electronic system are strongly coupled in URu$_2$Si$_2$.

The magnetostriction in the superconducting state can be described in terms of the spontaneous and forced magnetostriction. The spontaneous magnetostriction is equal to the zero-field values of $\lambda_s$ and $\lambda_c$ in Fig. 4 and reflects the pressure dependence of the condensation energy. It can also be derived by integrating the superconducting contributions to $\alpha_s$ and $\alpha_c$. The length changes, $(\lambda_c - \lambda_s) / \lambda_s$, derived from the thermal expansion are $\Delta \lambda_s = 0.37 \times 10^{-6}$ and $\Delta \lambda_c = -0.23 \times 10^{-6}$ at 0.5 K, in good agreement with the zero-field values of Fig. 4. The forced magnetostriction is caused by the diamagnetic shielding of the external field and may show hysteresis for increasing and decreasing fields. The most obvious origin of this hysteresis is the effect of flux pinning, which leads to different flux profiles in the sample for increasing and decreasing fields. For a magnetostriction perpendicular to the direction of field, the length of the sample is smaller for increasing fields than for decreasing fields [10]. For a magnetostriction along the field the hysteresis has opposite sign. In the low-field and low-temperature range, the appropriate sign for the discussed flux pinning effects is found, while in the region close to $B_{c2}$ an opposite sign for the hysteresis is observed. An opposite sign for the magnetostrictive hysteresis has also been observed for UBe$_{13}$ [11]. The additional contribution of the magnetostriction near $B_{c2}$ may be related to an interaction of the vortices and the heavy quasiparticles.
