LOGIC PROGRAMMING AND NEGATION: A SURVEY

KRZYSZTOF R. APT AND ROLAND N. BOL

We survey here various approaches which were proposed to incorporate negation in logic programs. We concentrate on the proof-theoretic and model-theoretic issues and the relationships between them.

1. INTRODUCTION

1.1. Motivation

Nonmonotonic reasoning grew out of attempts to capture the essential aspects of common-sense reasoning. It resulted in a number of important formalisms, the most known of them being the *circumscription method* of McCarthy [101], the *default theory* of Reiter [136], and *autoepistemic logic* of Moore [104]. (For a systematic comparison of these approaches, see the recently published Marek and Truszczyński [98].)

One of the striking features of logic programming is that it can naturally support nonmonotonic reasoning—by means of negative literals. Many concepts introduced in the area of nonmonotonic reasoning have a natural counterpart within logic programming in spite of its limited syntax. The dual interpretation of logic programs—as a computational mechanism and as a formalism for knowledge representation—provided a fertile ground for a study of proof theory and semantics of programs which support nonmonotonic reasoning.

This paper attempts to survey the outcome of this research. This subject, or some fragments of it, were already discussed in no less than five previous survey articles: Shepherdson [149, 150], Przymusinska and Przymusinski [113], Bidoit [19], and Clark [37]. Moreover, while writing this paper we learned of another survey—that of Dix [46], who focuses on the nonmonotonic reasoning aspects of...
logic programming. However, this field is so fast growing—about half of the references cited here were published during the last three years—that another survey of it might be justified. We provide here an alternative overview of this area by concentrating on the main developments in the proof theory and model theory and on the relationships between them.

No unified picture emerges from this endeavor. A number of interesting proposals were made dealing with proof theory and semantics. The multifarious relationship between them, revealed by often intricate mathematical arguments, brings to light the complex nature of logic programming and of nonmonotonic reasoning in the logic programming setting.

1.2. Setting the Stage

The SLD resolution of Kowalski \[80\] allows us to derive only positive consequences (namely, conjunctions of atoms) from a (positive) program. However, in many circumstances it is also useful to derive negative consequences. As we shall see in the next subsection, this naturally leads to nonmonotonic reasoning.

A classic example of the usefulness of negative consequences is the timetable, which states connections explicitly, but the absence of connections only implicitly. In the case of positive programs, three approaches to derive negative information became most known. Each of them is treated more extensively for the case of general programs (called normal programs in Lloyd \[87\]).

1. Use the negation as finite failure rule of Clark \[38\], which states that \(\neg Q\) is a consequence of a program \(P\) if a finitely failed SLD tree for the query \(Q\) w.r.t. \(P\) exists (in short, if \(Q\) finitely fails).

2. Use program completion of Clark \[38\], which strengthens the program by—informally—interpreting implications as equivalences.

3. Use the closed world assumption (in short CWA) of Reiter \[135\], which states that for a ground atom \(A\), \(\neg A\) is a consequence of a program \(P\) if \(A\) cannot be proved from \(P\).

The relationships between these concepts for positive programs are by now well understood (see, e.g., Lloyd \[87\] or Apt \[2\] for an overview of these results).

Once negative consequences can be derived from a positive program, it is natural to extend the syntax of programs and allow negative assumptions. This leads to the class of general programs in which negative literals are allowed in the bodies of the clauses. However, when trying to extend the above approaches to the case of general programs, several complications arise. The approaches become self-referential and, thereby, potentially paradoxical. Moreover, as we shall see, a naive amalgamation of the SLD resolution and the negation as finite failure rule yields an unsound reasoning method, completion of a general program can be inconsistent, and the closed world assumption can yield an inconsistent theory. So to treat this subject, we have to carefully review the concepts it relies upon. Let us start by discussing some relevant aspects of nonmonotonic reasoning.

1.3. Nonmonotonic Inference Relations

Properties of nonmonotonic inference relations have been extensively studied, for example, by Kraus et al. \[81\]. (For an overview of this topic, see Makinson \[94\].) Dix
defined how a (proof- or model-theoretic) semantics for logic programs can be viewed as an inference relation (consequence relation). Given a particular semantics \( SEM \), he defined the inference relation \( \vdash^P SEM \) of a program \( P \) as a relation between sets of ground atoms\(^1\) and sets of ground literals:

\[
\{ A_1, \ldots, A_n \} \vdash^P SEM \{ L_1, \ldots, L_m \} \quad \text{if} \quad SEM(P \cup \{ A_1, \ldots, A_n \}) \models L_1, \ldots, L_m. \quad ^2
\]

One way of classifying semantics for logic programming is by studying which properties they satisfy (a property is satisfied by \( SEM \) if it is satisfied by \( \vdash^P SEM \) for all programs \( P \) for which \( SEM \) is defined). Eventually, if one agrees on which properties are desirable and which ones are not, this study can be one of the reasons for considering one semantics better than another (another one could be for example computability).

A very strong property of inference relations is monotonicity. Below we use the symbol \( \vdash \) to denote an arbitrary inference relation, \( \Gamma \) for a set of atoms, \( A \) for an atom, and \( L \) for a literal.

**Definition 1.1 (Monotonicity).** An inference relation is monotonic if it satisfies

\[
\Gamma \vdash L \quad \text{implies} \quad \Gamma \cup \Gamma \vdash L.
\]

Classical logic is monotonic; thus, so is the inference relation determined by the SLD resolution, because it is a subset of classical logic. The negation as finite failure rule, the program completion, and the closed world assumption all introduce nonmonotonicity when deriving negative literals from positive programs, since \( \emptyset \vdash\{ p \rightarrow q \} \rightarrow \neg p \), whereas \( \{ q \} \vdash\{ p \rightarrow q \} \rightarrow \neg p \). Consequently, all semantics for logic programs with negation considered in this paper are nonmonotonic.

The study of nonmonotonic logics is such a large area, that it is impossible to give a complete overview of it in this paper. Therefore, we limit ourselves here to observations that are relevant to logic programming. One may wonder what makes an inference relation logical when it is not monotonic. Kraus et al. [81] considered the following properties desirable (we omit a number of simple properties that are satisfied by all logic programming semantics in this paper):

- **Cut:** \( \Gamma \vdash A \) and \( \Gamma \cup \{ A \} \vdash L \) imply \( \Gamma \vdash L \),
- **Cautious monotonicity:** \( \Gamma \vdash A \) and \( \Gamma \vdash L \) imply \( \Gamma \cup \{ A \} \vdash L \),
- **Rationality:** \( \Gamma \vdash \neg A \) and \( \Gamma \vdash L \) imply \( \Gamma \cup \{ A \} \vdash L \).

Cautious monotonicity is weaker than rationality (in the presence of simple properties). A logic that satisfies cautious monotonicity and cut is called cumulative. We shall use these properties in Sections 4.3, 7.4, and 10.

Dix calls these properties *strong principles* [46, 47], as opposed to certain *weak principles* he identifies [46, 48]; these weak principles are more specific to logic programs, and should be satisfied by every reasonable semantics. Examples of weak principles are the principle of partial evaluation (PPE), which roughly means that a positive body literal can be replaced by its definition, and relevance, which means that the truth value of an atom is determined solely by the part of the program that atom depends on (the notion made precise in Definition 2.2).

\(^1\) Disjunctions of ground atoms in the case of disjunctive logic programs; see Section 10.

\(^2\) \( SEM \) can return a single model, a set of models, or a theory. In the case of a set of models, the skeptical approach is chosen: \( SEM(\Gamma) = L \) if \( L \) is true in all models in \( SEM(\Gamma) \).
There are a number of good reasons for adopting a nonmonotonic semantics for negation.

- Historically, a classical interpretation of negation was ruled out, because it would result in full first-order theorem proving, with too high a complexity. This argument is hardly valid any more, because the semantics for logic programs with negation studied in this paper are highly undecidable to various degrees in the first-order case (see, e.g., Apt and Blair [4], and Cadoli and Schaerf [27] for an overview), but some of them can be computed in polynomial time in the propositional case (see, e.g., van Gelder et al. [63]).

- In many situations, for example, in databases, it is natural to record only positive information, leaving all negative information implicit.

- Recently, researchers in artificial intelligence recognized that common-sense reasoning is nonmonotonic. Therefore, nonmonotonic logics, that is, logics with a nonmonotonic inference relation, became popular. Logic programs with nonmonotonic negation constitute a small, yet quite expressive class of nonmonotonic logics, which is of particular interest because they are implementable. We observed that most motivating examples in papers on the semantics of negation in logic programming are taken from common-sense reasoning.

We distinguish these last two reasons as "static," respectively, "dynamic" nonmonotonicity. Nonmonotonicity is used statically when the available information is complete and can be theoretically, though not practically, captured as classical logic consequences of a theory. The standard example for this case is the already mentioned timetable problem for which it is possible, though not practical, to list all existing connections and all absent connections. This form of nonmonotonicity justifies directly the closed world assumption, introduced in Section 1.2.

Nonmonotonicity is used dynamically for "jumping to conclusions" when the available information is incomplete. If, later, more information becomes available, it may turn out that the conclusion is no longer justified, and must be withdrawn. The standard example for this case is that, if we learn that Tweety is a bird, we jump to the conclusion that it can fly, but if we subsequently find out that Tweety is a penguin, we withdraw that conclusion. This use of logic, called belief revision, is clearly nonmonotonic.

In this example, there is apparently a default assumption, namely, that birds can fly, unless there is evidence to the contrary. Reiter [136] proposed default logic as a framework for formalizing such defaults. Also, the example reasons about the beliefs of an agent, for which Moore [104] proposed autoepistemic logic. In fact, some semantics for negation in logic programming are closely related to these proposals.

One way of using negation in logic programming for belief revision is by means of abnormality relations. The example of the penguin Tweety can be described by the addition of the fact penguin(Tweety) to the program TWEETY:

\[
\begin{align*}
bird(Tweety) & \leftarrow \\
fly(x) & \leftarrow bird(x), \neg abnormal_{fly,bird}(x) \\
abnormal_{fly,bird}(x) & \leftarrow penguin(x)
\end{align*}
\]

% Tweety is a bird.
% Normal birds can fly.
% Penguins are abnormal birds w.r.t. flying.
We return to this program in Section 11.1. All semantics mentioned in this paper coincide on this program: they derive fly(Tweety) from TWEETY, but not from TWEETY ∪ \{penguin(Tweety) ←\}.

1.4. Plan of This Paper
This paper is organized as follows. In the next section, we introduce the syntax and discuss the choice of the underlying first-order language. In Section 3, we introduce the basic resolution procedure used for general programs—the SLDNF resolution. Next, in Section 4, we discuss another classical concept, that of program completion, and discuss soundness and completeness of SLDNF resolution w.r.t. program completion. Then in Section 5, we return to the SLDNF resolution by discussing some of its variants and extensions.

In Section 6, we study semantics of general programs by concentrating on two-valued candidates for a natural model which were proposed in the literature. Then in Section 7, we consider three-valued options. In Section 8, we relate these special models to various modifications of program completion. Next, in Section 9, we return to the study of proof-theoretic issues and analyze another form of resolution, called SLS resolution. In particular, we discuss there soundness and completeness of SLS resolution w.r.t. the semantics considered in Section 7 and the issue of its implementation. In Section 10, we discuss disjunctive logic programs, i.e., programs built from clauses whose heads are disjunctions of atoms, and relate various approaches to their semantics to the case of general programs.

Finally, in Section 11, we summarize the results of the paper by indicating for which classes of programs all the considered approaches coincide. We also indicate there which topics were not treated in this paper.

2. PRELIMINARIES

2.1. Syntax
We recall the usual definitions. A literal is an atom or its negation. A positive literal is a synonym for an atom and a negative literal is a negated atom. Literals are denoted here by letters \(L, M\). A general query is a finite conjunction of literals. (Instead of general queries, one usually considers general goals, which are expressions \(\bot \leftarrow L\), where \(L\) is a query.) The empty general query is denoted by \(\square\). To adhere to the syntax of logical programming, we write the general query \(L_1 \land \cdots \land L_n\) as \(L_1, \ldots, L_n\).

A general clause is a construct of the form \(H \leftarrow L\), where \(H\) is an atom and \(L\) is a query; \(H\) is called its head and \(L\) its body. When the body is empty, the general clause is called a unit clause. Finally, a general program is a finite set of general clauses. We say that a relation \(p\) is defined in \(P\) if it occurs in a head of a general clause of \(P\) and that \(P\) uses a relation \(q\) if \(q\) occurs in the body of a general clause of \(P\).

We shall deal here exclusively with general queries, clauses, and programs; we omit from now on the qualification “general,” unless some confusion arises. When
all literals used in the bodies of the program clauses are positive, we call the program positive.

As in the case of queries we often use bold letters to denote finite sequence of syntactic objects. Given two sequences of terms \( s = s_1, \ldots, s_n \) and \( t = t_1, \ldots, t_n \) of the same length, we abbreviate \( s_1 = t_1 \land \cdots \land s_n = t_n \) to \( s = t \).

We recall now a number of auxiliary notions.

**Definition 2.1.** By an expression, we mean here a term, atom, literal, query, negation of a query, or a clause. \( \text{Var}(E) \) is the set of variables occurring in the expression \( E \), \( \forall E \) denotes the universal closure of \( E \), and \( \exists E \) the existential closure of \( E \).

A substitution \( \theta \) is a function from variables to terms with a finite domain. Its domain is denoted by \( \text{Dom}(\theta) \), the set of variables occurring in the terms forming its range by \( \text{Ran}(\theta) \), and its restriction to the set of variables \( V \) by \( \theta|_V \). For an expression \( F \), we abbreviate \( \theta|_\text{Var}(F) \) to \( \theta|_F \). We write \( F\theta \) for the result of applying the substitution \( \theta \) to the expression \( E \). \( \theta \) is called a renaming substitution for \( E \), if for some substitution \( \eta \), we have \( A\theta\eta = A\eta \). \( \epsilon \) denotes the identity substitution.

The application of a substitution to a (set of) expression(s) and the relation “more general than” between the substitutions is defined in the usual way. Given two atoms \( A \) and \( B \), a substitution \( \theta \) is called a unifier of \( A \) and \( B \) if \( A\theta = B\theta \), and is called a most general unifier (in short, mgu) of \( A \) and \( B \) if it is a unifier which is more general than all unifiers of \( A \) and \( B \). Finally, an mgu \( \theta \) of two atoms \( A \) and \( B \) is called relevant if \( \text{Dom}(\theta) \cup \text{Ran}(\theta) \subseteq \text{Var}(A) \cup \text{Var}(B) \).

When studying programs, the relationship between the relations used is of importance.

**Definition 2.2 (Dependency).** Consider a program \( P \).

- The dependency graph \( D_p \) for \( P \) is a directed graph with signed edges. Its nodes are the relations occurring in \( P \). For every clause in \( P \) which uses relation \( p \) in its head and relation \( q \) in a positive (resp. negative) literal in its body, there is a positive (resp. negative) edge \((p, q)\) in \( D_p \). We say then that \( p \) uses \( q \) positively (resp. negatively).
- We say that \( p \) depends positively (resp. negatively) on \( q \) if there is a path in \( D_p \) from \( p \) to \( q \) with only positive edges (resp. at least one negative edge).
- We say that \( p \) depends evenly (resp. oddly) on \( q \) if there is a path in \( D_p \) from \( p \) to \( q \) with an even (resp. odd) number of negative edges.

### 2.2. The Universal Query Problem

A simple completeness result for SLD resolution reads as follows:

Let \( P \) be a positive program, \( A \) an atom, and \( \theta \) a substitution. If \( P \models \forall A\theta \), then \( P \models_{\text{SLD}} A\sigma \), for some substitution \( \sigma \) such that \( A\sigma \) is more general than \( A\theta \).

We shall not use classical logic as the semantics for general logic programs, for reasons explained in Section 1.3. In some cases, the semantics of a program will be given by a logical theory, such as the program completion. In many other cases, the
semantics of a program will be given by some canonical Herbrand model, such as the least Herbrand model $M_p$ for a positive program $P$. The relative merits of both approaches are discussed in Wallace [163], among others. When using the canonical model approach, restricting ones attention to Herbrand models often leads to considerable technical simplifications. However, the following statement is false:

Let $P$ be a positive program, $A$ an atom, and $\theta$ a substitution. If $M_p \models \forall A \theta$, then $P \models_{SLD} A \sigma$, for some substitution $\sigma$ such that $A \sigma$ is more general than $A \theta$.

As a counterexample, take $P = \{ p(a) \leftarrow \}$, $A = p(x)$, and $\theta = \epsilon$. Since $a$ is the only term in the Herbrand universe, $M_p = \{ p(a) \} \models \forall x p(x)$. There are essentially two ways to avoid this problem.

1. Ensure that the language under consideration has sufficiently many terms. This can be done by
   - adding a clause $p(f(c)) \leftarrow$ to the program $P$, where $p$, $f$, and $c$ do not occur in $P$ (as, e.g., in Ross [138]);
   - postulating, as in Kunen [83], an infinite "universal" language in which all programs and queries are expressed.

2. Consider arbitrary models instead of only Herbrand models. This approach is taken by Kunen [82] and by Przymusinski [118], who also termed the above problem the universal query problem.

In this paper we adopt the "universal language" approach, because it gives rise to simpler formulations of results than the other approaches. It also solves the problem of how to deal formally with language elements that occur in the query but not in the program. Each approach has its merits and drawbacks. For example, in the case of the approach here adopted, taking the program $P = \{ p(a) \leftarrow \}$ again, $\neg \forall x p(x)$ holds in the least Herbrand model of $P$ w.r.t. the universal language, whereas it does not hold in all models of $P$. So now we have the "opposite" of the universal query problem: given the program $\{ p(a) \leftarrow; q \leftarrow \neg p(x) \}$, should $q$ be "true"? We leave this problem aside, and for a more detailed discussion of this issue, we refer to Shepherdson [149].

In the sequel, $B_p$ denotes the Herbrand base of $P$, $M_p$ the least Herbrand model of a positive program $P$, and $\text{ground}(P)$ the set of all ground instances of clauses from $P$, all considered w.r.t. this universal language. Finally, by $L_p$ we denote the language defined by the program $P$, that is, the language whose constants, function, and relation symbols are those occurring in $P$.

3. PROOF THEORY I: SLDNF RESOLUTION

3.1. A Discussion

In order to compute with general programs, one needs to be able to resolve negative literals. A natural idea is to use the closed world assumption, that is, to stipulate for an atom $A$ that

$\neg A$ succeeds if $A$ cannot be proved.
The problem with this rule is that it is, in general, undecidable whether an atom can (cannot) be proved, even if we restrict our attention to positive programs. Later, in Section 9 we shall consider an ineffective form of resolution which formalizes the above idea.

To make the above rule effective, Clark [38] proposed to replace the statement “A cannot be proved” by its finitary version, the negation as finite failure rule, which makes this rule decidable. So, according to Clark [38], the statement “A cannot be proved” should be interpreted as “A finitely fails.”

However, for general programs the considered trees for a query A can contain negative literals, so the question now arises when these literals fail. A natural idea is to stipulate that for an atom A,

\[ \neg A \text{ fails iff } A \text{ can be proved.} \]

Interpreting the statement “A can be proved” as “there exists a successful derivation for the query A,” we end up with a resolution method, called SLDNF resolution, which is appropriate for general programs and general queries. It should be mentioned here that another interpretation of the above statement is possible, which leads to another form of resolution. We shall consider it in Section 5.1.

Thus according to the SLDNF resolution, when the selected literal is positive, the usual SLD-like procedure is to obtain a new resolvent, and when the selected literal, say \[ \neg A, \] is negative, the following rule is used to obtain the new resolvent:

\[ \neg A \text{ succeeds if } A \text{ finitely fails,} \]
\[ \neg A \text{ finitely fails iff } A \text{ succeeds.} \]

That is, if \[ \neg A \text{ succeeds, it is deleted from the query, and if it finitely fails, the query fails.} \]

As in the case of the SLD resolution, this notion of resolution can be used not only to prove but also to compute. Let us introduce the following notation:

- \[ P \vdash_{SLDNF} \forall Q \theta \text{ if there exists a successful SLDNF derivation of } P \cup \{Q\} \text{ with computed answer } \theta. \]
- \[ P \vdash_{SLDNF} \neg Q \text{ if there exists a finitely failed SLDNF tree for } P \cup \{Q\}. \]

Without any restrictions, the above notion of SLDNF resolution becomes a problematic concept. Indeed, take the following program \[ \text{NUMBERS = } \{ \text{positive}(x) \leftarrow \neg \text{zero}(x); \text{zero}(0) \leftarrow \}. \] Then the query \[ \neg \text{zero}(x) \] succeeds, so \[ \neg \text{zero}(x) \] finitely fails and, consequently, \[ \text{positive}(x) \] finitely fails as well. Thus, \[ \text{NUMBERS} \vdash_{SLDNF} \forall x \neg \text{positive}(x). \] However, for any ground term \( t \) different from 0, \[ \text{zero}(t) \] finitely fails, so \[ \text{positive}(t) \] succeeds. Thus, \[ \text{NUMBERS} \vdash_{SLDNF} \text{positive}(t). \] This excludes any soundness results. In fact, these conclusions will be drawn by most Prolog systems. So Prolog is not “sound.”

The problem is caused by the use of variables in nonground negative literals. To ensure soundness, Clark [38] imposed the restriction that only ground negative literals can be selected.

However, the definition of the SLDNF resolution sketched above is difficult to formalize. Consider, for example, the program \[ P = \{ p \leftarrow p \}. \] The query \[ \neg p \] neither succeeds nor finitely fails, since the query \( p \) neither succeeds nor finitely fails. So it is not clear whether there is a resolvent. (This also shows that SLDNF resolution is incomplete, since neither \[ P \vdash_{SLDNF} p \] nor \[ P \vdash_{SLDNF} \neg p \] holds here.) The prob-
lem is that success and finite failure are not the only possible outcomes of an evaluation: also an unsuccessful tree which is not finitely failed can be generated.

This problem was not properly taken care of in the definition of SLDNF resolution given in Clark [38] and reproduced in Lloyd [86]. In Lloyd [87] a revised definition of SLDNF resolution was proposed according to which the SLDNF trees are constructed “bottom-up” by induction on the number of alternations through negation. Unfortunately, according to this definition for the above-mentioned example and some other problematic cases, no SLDNF trees or SLDNF derivations exist. This is clearly undesirable, especially if one reasons about “run time” properties of the SLDNF resolution, like termination.

These problems were first tackled by Martelli and Tricomi [100], who proposed a revision of the original definition in which the subsidiary trees used to resolve negative literals are built “inside” the main tree. The solution presented here is due to Apt and Doets [10].

3.2. A New Definition

Definition 3.1 (Resolvent).

(i) We say that $Q$ resolves to $Q'$ via $\alpha$ w.r.t. $\Sigma$, or $Q'$ (more explicitly, the pair $(\alpha, Q')$ is a resolvent of $Q$ w.r.t. $\Sigma$, notation $Q \Rightarrow^\alpha Q'(\Sigma)$, if:

either $\Sigma = (L, R)$, $L$ is (an occurrence of) a positive literal in $Q$, $R$ is a program clause, and for some variant $H \leftarrow L$ (the input clause) of $R$, $\alpha$ is mgu of $L$ and $H$, and $Q' = Q\alpha[L\alpha := L\alpha]$ is obtained from $Q\alpha$ by replacing $L\alpha$ by $L\alpha$,

or: $\Sigma$ is (an occurrence of) a negative literal in $Q$, $\alpha = \epsilon$, and $Q' = Q - \{\Sigma\}$ is obtained from $Q$ by removing $\Sigma$.

(ii) A clause $R$ is called applicable to an atom if it has a variant, the head of which unifies with the atom.

Definition 3.2 (Pseudoderivation). A (finite or infinite) sequence $Q_0 \Rightarrow^\alpha_1 \cdots Q_n \Rightarrow^\alpha_{n+1} \cdots$ of resolution steps is a pseudoderivation if for every step involving a program clause:

- (“standardization apart”) the input clause employed does not contain a variable from the initial query $Q_0$ or from an input clause used at some earlier step;
- (“relevance”) the mgu employed is relevant.

Intuitively, an SLDNF derivation is a pseudoderivation in which the deletion of every (ground) negative literal is justified by means of a subsidiary (finitely failed SLDNF) tree. This brings us to consider special types of trees.

Definition 3.3. A tree is called:

- successful if it contains a leaf marked as success;
- finitely failed if it is finite and all its leaves are marked as failed.

In the sequel we consider systems of trees called forests.
Definition 3.4 (Forest). A forest is a system $\mathcal{F} = (\mathcal{F}, T, \text{subs})$, where:

- $\mathcal{F}$ is a set of trees;
- $T$ is an element of $\mathcal{F}$ called the main tree;
- $\text{subs}$ is a function assigning to some nodes of trees in $\mathcal{F}$ a ("subsidiary") tree from $\mathcal{F}$.

By a path in $\mathcal{F}$ we mean a sequence of nodes $N_0, \ldots, N_i, \ldots$ such that for all $i$, $N_{i+1}$ is either a child of $N_i$ in some tree in $\mathcal{F}$ or the root of the tree $\text{subs}(N_i)$.

Thus a forest is a special directed graph with two types of edges—the "usual" ones stemming from the tree structures, and the ones connecting a node with the root of a subsidiary tree.

An SLDNF tree is a special type of a forest built as a limit of certain finite forests: pre-SLDNF trees. The nodes of these trees are labeled by queries. Below we shall identify a node with its label.

The construction begins with the main tree, which consists of just one node—the original query. During the construction new, subsidiary trees can be added. In each "round" the branches of all trees are extended in parallel. The final object is an SLDNF tree. As in the original definition of Clark [38], the subsidiary trees are kept "aside" of the "main" tree. The difference is that their construction is no longer viewed as an atomic step in the resolution process. If a subsidiary tree $T$ becomes successful or finitely failed, this information is used in the "next round" of the extension process to determine the status of the query which originated the construction of $T$.

For the rest of this section, we fix a program $P$. The next definition is crucial.

Definition 3.5 (Pre-SLDNF tree). A pre-SLDNF tree (relative to $P$) is a forest whose nodes are (possibly marked) queries of (possibly marked) literals. (For queries, there are markers failed, success, and floundered; for literals, we have the marker selected.) The function $\text{subs}$ assigns to nodes containing a marked negative ground literal $\neg A$ a tree in $\mathcal{F}$ with root $A$. The class of pre-SLDNF trees is defined inductively.

- For every query $C$, the forest consisting of the main tree which has the single node $C$ is a pre-SLDNF tree (an initial pre-SLDNF tree).
- If $\mathcal{F}$ is a pre-SLDNF tree, then any extension of $\mathcal{F}$ is a pre-SLDNF tree.

Here, an extension of a pre-SLDNF tree $\mathcal{F}$ is defined by performing the following actions for every nonempty query $C$ which is an unmarked leaf in some tree $T \in \mathcal{F}$:

First, if no literal in $C$ is marked yet as selected, mark one as selected. Let $L$ be the selected literal of $C$.

- $L$ is positive.
  - $C$ has no resolvents w.r.t. $L$ and a clause from $P$.
  - Then $C$ is marked as failed.
  - $C$ has such resolvents.
    For every clause $R$ from $P$ which is applicable to $L$, choose one resolvent $(\alpha, D)$ of $C$ w.r.t. $L$ and $R$ and add this as a child of $C$ in $T$. These
resolvents are chosen in such a way that all branches of \( T \) remain pseudoderivations.

- \( L = \neg A \) is negative.
  - \( \neg A \) is nonground. Then \( C \) is marked as flounderered.
  - \( \neg A \) is ground.
    * \( \text{subs}(C) \) is undefined.
      Then a new tree \( T' \) with the single node \( A \) is added to \( \mathcal{F} \) and \( \text{subs}(C) \) is set to \( T' \).
    * \( \text{subs}(C) \) is defined and successful.
      Then \( C \) is marked as failed.
    * \( \text{subs}(C) \) is defined and finitely failed.
      Then the resolvent \((\epsilon, C - \{L\})\) of \( C \) is added as the only child of \( C \) in \( T \).

Additionally, all empty queries are marked as success.

Note that if no tree in \( \mathcal{F} \) has unmarked leaves, then trivially \( \mathcal{F} \) is an extension of itself, and the extension process becomes stationary.

Every pre-SLDFN tree is a tree with two types of edges between possibly marked nodes, so the concepts of inclusion between such trees and of limit of a growing sequence of such trees have clear meaning.

**Definition 3.6 (SLDNF tree).**

- An SLDNF tree is a limit of a sequence \( \mathcal{T}_0, \ldots, \mathcal{T}_i, \ldots \) such that \( \mathcal{T}_0 \) is an initial pre-SLDNF tree, and for all \( i, \mathcal{T}_{i+1} \) is an extension of \( \mathcal{T}_i \).
- An SLDNF tree for \( C \) is an SLDNF tree in which \( C \) is the root of the main tree.
- A (pre-)SLDNF tree is called successful (resp. finitely failed) if the main tree is successful (resp. finitely failed).
- An SLDNF tree is called finite if no infinite paths exist in it.

Next, we define the concept of SLDNF derivation.

**Definition 3.7 (SLDNF derivation).** A (pre-)SLDNF derivation for \( C \) is a branch in the main tree of a (pre-)SLDNF tree \( \mathcal{F} \) for \( C \) together with the set of all trees in \( \mathcal{F} \) whose roots can be reached from the nodes of this branch. It is called successful if it ends with the empty query. An SLDNF derivation is called finite if all paths of \( \mathcal{F} \) fully contained within this branch and these trees is finite.

Finally, we define the notion of a computed answer substitution.

**Definition 3.8 (Computed answer substitution).** Consider a branch in the main tree of a (pre-)SLDNF tree \( \mathcal{F} \) for \( C \) which ends with the empty query. Let \( \alpha_1, \ldots, \alpha_n \) be the consecutive substitutions along this branch.

Then the restriction \((\alpha_1 \cdots \alpha_n)C\) of the composition \( \alpha_1 \cdots \alpha_n \) to the variables of \( C \) is called a computed answer substitution (c.a.s. for short) of \( C \) in \( \mathcal{F} \).

Let us illustrate the above definitions by depicting the SLDNF trees for two "difficult" cases.
Example 3.9 (Infinite SLDNF trees).

(i) Consider the "problematic" case of $P = \{ p \leftarrow p \}$ and $C = \neg p$ mentioned in Section 3.1. The only SLDNF tree has then the following form:

(ii) It is important to realize that according to this definition, the construction of a subsidiary tree can go on forever, even if the information about its "status" has already been passed to the main tree. The following program illustrates this point.

Consider $P = \{ p \leftarrow \neg q; q \leftarrow; q \leftarrow q \}$. Then the only SLDNF-tree for $p$ is the following tree:

Here the subsidiary tree with the root $q$ grows forever. However, once an extension of the initial subsidiary tree with the single node $q$ becomes successful, in the next extension the node $\neg q$ is marked as failed. Consequently, the SLDNF tree for $p$ is finitely failed, even though it is not finite.

Now note the following simple result.

Theorem 3.10 (Limit).

(i) Every SLDNF-tree is the limit of a unique sequence of pre-SLDNF trees.

(ii) If the SLDNF tree $T$ is the limit of the sequence $T_0, \ldots, T_i, \ldots$, then for all $\tau$:

(a) $T$ is successful and yields $\tau$ as c.a.s. iff some $T_i$ is successful and yields $\tau$ as c.a.s.

(b) $T$ is finitely failed iff some $T_i$ is finitely failed.

This result allows us to associate with every successful or finitely failed SLDNF tree $T$ a natural number, $\text{rank}(T, \tau)$, which is the least $i$ for which the corresponding equivalence in (ii) holds, with $\tau = \epsilon$ when $T$ is finitely failed. This measure is useful for carrying out inductive proofs about SLDNF resolution.
Finally, let us mention that it is straightforward to show that if a successful SLDNF derivation or finitely failed SLDNF tree exists according to the definition given in Lloyd [87], then it does so according to the definition presented here.

3.3. Floundering

For further discussion, it is useful to introduce the following notion. An SLDNF tree \( \mathcal{T} \) is \textit{via a selection rule} \( R \) if in the sequence of pre-SLDNF trees whose limit is \( \mathcal{T} \), all the markings of literals as selected are performed according to \( R \). A \textit{selection rule} is a function which, given a pre-SLDNF tree \( F \), selects a literal in every nonempty unmarked leaf in some tree of \( F \). A selection rule is called \textit{safe} if it never selects a nonground negative literal.

One of the complications concerning SLDNF resolution is so-called floundering— a generation of a node which consists exclusively of nonground negative literals, because then selection of any literal ends the derivation in an abnormal way. In the definition here provided, floundering is treated differently—it arises as soon as a nonground negative literal is selected. Clearly, this small change has no effect on the theory of SLDNF resolution, since the original notion of floundering can be easily defined.

\textit{Definition 3.11 (Floundering).}

- We call a query \textit{blocked} if it consists exclusively of nonground negative literals.
- We say that \( P \) and \( Q \) \textit{flounder} if some SLDNF tree for \( P \) and \( Q \) contains a blocked node.

Note the difference between a blocked node and a node marked as floundered. Thus an SLDNF tree \textit{via a safe selection rule does not flounder}. Börger [26] (see Apt [2] for a more direct proof) proved that it is undecidable whether \( P \) and \( Q \) flounder. In the literature, a number of syntactic conditions was proposed which ensure that a program and a query do not flounder. The following notion owing to Lloyd and Topor [89] (see also Lloyd [87]) has become best known.

\textit{Definition 3.12 (Allowedness).}

- A query \( L \) is called \textit{allowed} if every variable of it occurs in a positive literal.
- A clause \( H \leftarrow L \) is called \textit{allowed} if \( \neg H, L \) is.
- A program is called \textit{allowed} if all its clauses are.

Thanks to the use of the new definition, the following result of Lloyd and Topor [89] now refers to a larger class of SLDNF trees.

\textit{Theorem 3.13.} Suppose that \( P \) and \( Q \) are allowed. Then:

- \( P \) and \( Q \) do not flounder.
- If \( \theta \) is a c.a.s. of \( Q \), then \( Q\theta \) is ground.

When \( \theta \) is a c.a.s. of \( Q \) such that \( Q\theta \) is ground, we say that \( \theta \) is a \textit{ground computed answer substitution}. Actually, the definition of allowedness proposed in
Lloyd and Topor [89] is slightly more general than the one we considered. Even this stronger version excludes many natural logic programs, because every allowed unit clause is ground and every computed answer is grounding. Decker and Cavedon [42] and Decker [41] proposed more general syntactic conditions which prevent floundering.

3.4. Kunen’s Definition

Kunen [83] provided a much simpler definition of the computed answer substitutions and finitely failed queries of the SLDNF resolution and used it to prove completeness in the sense discussed in the next section for allowed programs and allowed queries. We now present his definition and compare it with the one given before.

**Definition 3.14.** The set \( F \) of queries and the set \( R \) of pairs \((C, \sigma)\) where \( C \) is a query and \( \sigma \) is a substitution for which \( \text{Dom}(\sigma) \subseteq \text{Var}(C) \), are defined by a simultaneous inductive definition as follows.

0. \( \square \epsilon \in R \).

\( R + \). If \( C \) resolves to \( D \) via \( \alpha \) w.r.t. some positive literal of \( C \) and a clause from \( P \) and \( DR \sigma \), then \( CR(\alpha \sigma) \in C \).

\( R - \). If \( A \) is a ground atom in \( F \) and \( (C, C')R \sigma \), then \( (C, \neg A, C')R \sigma \).

\( F + \). If \( L \) is a positive literal in \( C \) and for every clause \( R \) from \( P \) which is applicable to \( L \), there exist \( \alpha \) and \( D \in F \) such that \( C \overset{\alpha}{\Rightarrow} D(L, R) \), then \( C \in F \).

\( F - \). If \( A \) is a ground atom such that \( A \epsilon \), then \( (C, \neg A, C') \in F \).

Recall that for a query \( C, \theta|C \) stands for the restriction of the substitution \( \theta \) to the variables of \( C \). The intention here is that \( R \) is the set of pairs \((C, \sigma)\) such that \( \sigma \) is a c.a.s. for \( C \) and \( F \) is the set of queries \( C \) such that there is a finitely failed tree for \( C \).

Note that the formulation of \( R + \) does not ensure that the resulting answer substitutions are most general. Indeed, consider the program

\[
Q(x, y) \leftarrow Q(y, y),
Q(x, x) \leftarrow .
\]

Then \( \square \epsilon \) by clause 0, \( Q(y, y)\epsilon(x/y) \) by clause \( R + \) and the second program clause, and consequently, \( Q(x, y)\epsilon(y/x) \) by \( R + \), since \( Q(x, y) \) resolves to \( Q(y, y) \) via \( \epsilon \) and the first program clause. However, \( y/x \) is not a c.a.s. for \( Q(x, y) \), whereas \( y/x' \) is.

In order that \( R + \) produce most general answer substitutions, we amend it as follows:

\( \dagger R + \). If \( C \) resolves to \( D \) via \( \alpha \) w.r.t. some positive literal of \( C \) and a clause from \( P, DR \sigma \), and

\[
\text{Var}(C \alpha) \cap \text{Var}(D \sigma) \subseteq \text{Var}(D),
\]

then \( CR(\alpha \sigma) \subseteq C \).

The following theorem of Apt and Doets [10] shows the equivalence between the SLDNF resolution and Kunen’s definition as modified above.
**Theorem 3.15 (Equivalence).** If $C$ is a query, then:

- $C \text{R}_\tau$ iff $\tau$ is a c.a.s. for $C$.
- $C \in F$ iff $C$ has a finitely failed SLDNF tree.

### 3.5. Termination

It is natural to ask then what is the use of the definition of SLDNF resolution given in Section 3.2. To show its usefulness, we now consider the issue of termination, which cannot be handled using Kunen's approach.

**Definition 3.16 (Terminating program).** A program is called *terminating* if all its SLDNF trees for ground queries are finite.

Of course, in general, one is actually interested in proving termination of a given program not only for all ground queries, but also for a class of nonground queries constituting the intended queries. The approach to prove termination discussed here allows us to identify, for each program, such a class of nonground queries. To characterize terminating programs, following Cavedon [28] and Apt and Bezem [3], we introduce the following notions.

**Definition 3.17 (Acyclic program).**

- A *level mapping* for a program $P$ is a function $| | : B_P \rightarrow \mathbb{N}$ of ground atoms to natural numbers. For $A \in B_P$, $|A|$ is the *level of $A$*.
- Given a level mapping $| |$, we extend it to ground negative literals by putting $|-A| = |A|$.
- A clause of $P$ is called *acyclic with respect to a level mapping* $| |$ if for every ground instance $A - K, L, L$,

  $$|A| > |L|.$$  

- A program $P$ is called *acyclic with respect to a level mapping* $| |$ if all its clauses are. $P$ is called *acyclic* if it is acyclic with respect to some level mapping.

**Definition 3.18 (Boundedness).**

- A literal $L$ is called *bounded with respect to a level mapping* $| |$ if $| |$ is bounded on the set $[L]$ of ground instances of $L$. For $L$ bounded w.r.t. $| |$, we define $|L|$, the *level of $L$ w.r.t. $| |$*, as the maximum $| |$ takes on $[L]$.
- A query is called *bounded with respect to a level mapping* $| |$ if all its literals are. For $Q = L_1, \ldots, L_n$ bounded w.r.t. $| |$, we define $|Q|$, the *level of $Q$ w.r.t. $| |$*, as the multiset bag$(|L_1|, \ldots, |L_n|)$.

The following result explains why bounded queries are relevant.

**Lemma 3.19 (Finiteness).** Let $P$ be an acyclic program and let $Q$ be a bounded query. Then every SLDNF tree for $P$ and $Q$ is finite.

This leads to the following conclusion.
Corollary 3.20. Every acyclic program is terminating.

Further work on this subject was done by Ross [140], and work on termination of programs w.r.t. SLDNF resolution with the leftmost selection rule of Prolog was done by Apt and Pedreschi [5]. We return to acyclic programs in Section 11.1.

4. PROGRAM COMPLETION

4.1. Definition

In first-order logic, the soundness and completeness results equate the notions of semantic and proof-theoretic implication: for every set of formulas $T \cup \{ \phi \}$, we have

$$T \vdash \phi \text{ iff } T \vdash \phi.$$  

A similar result cannot be established for the SLDNF resolution and the programs. Indeed, using SLDNF resolution, we can prove ground negative literals, but all of them are false in the largest Herbrand model of a program, $B_P$.

Clark [38] proposed to solve this problem by strengthening a program $P$ to its completion, $\text{comp}(P)$, and comparing the SLDNF resolution with $\text{comp}(P)$. Intuitively, in the completion the implications are replaced by equivalences. The formal definition is a bit subtle, since this replacement has to be made at the right moment, and the equality relation has to be interpreted in an appropriate way. We recall here the definition.

First, assume that " = " is a new binary relation symbol not appearing in $P$. We write $s \neq t$ as an abbreviation for $\neg(s = t)$. " = " is interpreted as identity in all models.

We perform successively the following steps, where $x_1, \ldots, x_n, \ldots$ are new variables.

Step 1: Transform each clause $p(t) \leftarrow L$ of $P$ into $p(x) \leftarrow x = t \land L$.

Step 2: Transform each formula $p(x) \leftarrow F$ obtained in the previous step into $p(x) \leftarrow \exists y F$, where $y$ are the variables of the original clause.

Step 3: Let $p(x) \leftarrow \exists y F_1, \ldots, p(x) \leftarrow \exists y F_k$ be all formulas obtained in the previous step with a relation $p$ on the left-hand side. Replace them by one formula $p(x) \leftarrow F_1 \lor \cdots \lor F_k$. If $F_1 \lor \cdots \lor F_k$ is empty, replace it by $\text{true}$.

Step 4: For each relation symbol $q$ not appearing in a head of a clause in $P$, add a formula $q(x) \leftarrow \text{false}$.

Step 5: Replace each formula $p(x) \leftarrow F$ by $\forall x (p(x) \leftarrow F)$.

Step 6: In each formula replace " \leftarrow " by " \leftrightarrow ".

Additionally, we add the following free equality axioms, $EQ$, which enforce that the equality theory of $\text{comp}(P)$ is the same as that of Herbrand universe:

1. $f(x) = f(y) \rightarrow x = y$ for each function symbol $f$.
2. $f(x) \neq g(y)$ for all function symbols $f$ and $g$ such that $f \neq g$.
3. $x \neq t$ for each variable $x$ and term $t$ such that $x \neq t$ and $x$ occurs in $t$.

Call the resulting set of formulas $\text{comp}(P)$. 
Additionally, we interpret "=" in all two-valued and three-valued interpretations as identity. This allows us to dispose of the usual equality axioms.

4.2. Two-Valued Model Theory

While program completion is a natural concept in the case of positive programs, in the case of general programs things dramatically change, due to the following disturbing observation.

**NOTE 4.1.** For \( P = \{ p \leftarrow \neg p \} \), \( \text{comp}(P) \) is inconsistent.

Because inconsistent program completion allows us to derive arbitrary first-order formulas from the program, the above note seems to rule out the use of program completion to model negative information.

Before we discuss some ways of resolving this difficulty, it is useful to recall the immediate consequence operator \( T_p \) of van Emden and Kowalski [160], which acts on Herbrand interpretations of a given program. This operator plays an important role in the theory of positive programs.

**Definition 4.2 (Immediate consequence operator).** For a program \( P \) and a Herbrand interpretation \( I \) for \( P \), we define

\[
T_p(I) = \{ H \mid \exists L ( H \leftarrow L \in \text{ground}(P), I \models L) \}.
\]

The following simple observation (originally made for positive programs) by van Emden and Kowalski [160] explains the interest in this operator by characterizing the Herbrand models of \( P \) in terms of the operator \( T_p \).

**Lemma 4.3.** For every Herbrand interpretation \( I \), \( I \models P \) iff \( T_p(I) \subseteq I \).

A bit more complicated argument (originally made for positive programs) by Apt and van Emden [7] characterizes the Herbrand models of \( \text{comp}(P) \) in terms of the operator \( T_p \).

**Lemma 4.4 (Fixpoint).** For every Herbrand interpretation \( I \), \( I \models \text{comp}(P) \) iff \( T_p(I) = I \).

For positive programs, \( T_p \) exhibits a very regular behavior: w.r.t. the set inclusion, it is monotonic (\( I \subseteq J \) implies \( T_p(I) \subseteq T_p(J) \)) and continuous (for every infinite sequence \( I_0 \subseteq I_1 \subseteq \ldots \), \( T_p(\bigcup_{n=0}^{\infty} I_n) = \bigcup_{n=0}^{\infty} T_p(I_n) \)). Thanks to the first property, the least Herbrand model \( M_p \) is the \( \subseteq \)-least fixpoint of \( T_p \), and thanks to the second property, this model can be reached in \( \omega \) iterations of \( T_p \) starting with the empty Herbrand interpretation.

For general programs, both properties of \( T_p \) are lost. Indeed, consider again \( P = \{ p \leftarrow \neg p \} \). Then \( T_p(\emptyset) = \{ p \} \), whereas \( T_p(\{ p \}) = \{ \emptyset \} \), so \( T_p \) is not monotonic and a fortiori not continuous. Consequently, for general programs the well-known Knaster–Tarski theorem cannot be used to find a fixpoint of \( T_p \). In fact, the fixpoints need not exist: just take \( T_p \) for \( P = \{ p \leftarrow \neg p \} \).

A natural question is under what conditions completion is consistent. The following result was established by Sato [144].

**Definition 4.5 (Call-consistent).** A program is called call-consistent if no relation depends oddly on itself.
Theorem 4.6. If $P$ is call-consistent, then $\text{comp}(P)$ has a Herbrand model.

Further work on the subject of consistency of $\text{comp}(P)$ can be found in Kunen [83], Cavedon [29], Cortesi and Filé [39], Cortesi and Filé [40], Baratella [16] and Fages [58].

An alternative solution is to use three-valued logic.

4.3. Three-Valued Model Theory

Fitting [59] proposed to use a three-valued logic to provide semantics to programs and their completions. The idea is that a query can yield three outcomes: it may succeed, it may fail, and it may also diverge. The third value is meant to capture the last possibility.

Fitting [59] based his approach on a logic due to Kleene [79], in which three values are assumed: $\{0, \frac{1}{2}, 1\}$, $0$ representing false, $\frac{1}{2}$ representing unknown, and $1$ representing true. Assume now a mapping $\mathcal{I}$ from $B_p$ to $\{0, \frac{1}{2}, 1\}$. To define the meaning of the programs, we put for ground quantifier-free formulas,

$$|\neg A| = 1 - |A|,$$
$$|A \land B| = \min(|A|, |B|),$$
$$|A \leftarrow B| = \begin{cases} 1, & \text{if } |A| \geq |B|, \\ 0, & \text{if } |A| < |B|, \end{cases}$$

and identify the program with the set $\text{ground}(P)$. Note that “$\leftarrow$” received here a two-valued interpretation. (Actually in Fitting [59] the valuation of “$\leftarrow$” is not used. The above interpretation differs from that of Kleene [79] and was later added in Przymusinski [122].)

For the moment the meaning of other connectives is not needed. When a ground formula evaluates to 1, we say it is true relative to $\mathcal{I}$, and when it evaluates to 0, we say it is false relative to $\mathcal{I}$.

The mapping $\mathcal{I}$ can be conveniently presented in the form of a three-valued Herbrand interpretation.

Definition 4.7. A pair $I = (I^+, I^-)$, with $I^+, I^- \subseteq B_p$, is called a three-valued Herbrand interpretation. $I^+$ are atoms assumed true, and $I^-$ are atoms assumed false.

For example when $I = ((A), (B))$, then $A$ and $\neg B$ are true in $I$, $B$ and $\neg A$ are false in $I$, and $C$ and $\neg C$ are undefined in $I$.

Definition 4.8.

- $I$ is total if $I^+ \cup I^- = B_p$.
- $I$ is consistent if $I^+ \cap I^- = \emptyset$.

Note that every (two-valued) Herbrand interpretation $I$ can be identified with the three-valued, total, consistent Herbrand interpretation $(I, B_p - I)$ in the sense that truth and falsity coincide in both interpretations for all formulas.
The following natural ordering on three-valued Herbrand interpretations,
\[ I \subseteq J \iff I^+ \subseteq J^+ \text{ and } I^- \subseteq J^- , \]
formalizes the intuition: \( J \) contains more information than \( I \) (determines status of more literals). This ordering is usually called information ordering. Other natural orderings can be considered; see, e.g., Section 7.

Note that both truth and falsity behave monotonically w.r.t. the information ordering in the following sense.

**Lemma 4.9.** Let \( I \subseteq J \). Then for a ground query \( Q \), \( Q \) is true (false) in \( I \) implies that \( Q \) is true (false) in \( J \).

These two implications do not hold for two-valued Herbrand interpretations and \( \subseteq \) interpreted as set-theoretical inclusion. Also, in contrast to two-valued Herbrand interpretations, consistent three-valued Herbrand interpretations with the \( \subseteq \) ordering do not form a lattice. Indeed, if \( I \) and \( J \) are total and \( I \neq J \), then \( I \cup J \) does not exist. However, consistent three-valued Herbrand interpretations do form a cpo, that is a partial ordering in which the limits of growing chains exist. This is sufficient for building three-valued models inductively.

Following Fitting [59], we now introduce a three-valued analogue of the \( T_p \) operator (originally denoted by \( \Phi_p \)), which acts on three-valued Herbrand interpretations of a given program.

**Definition 4.10 (Immediate consequence operator).** For a program \( P \) and a three-valued Herbrand interpretation \( I \) for \( P \), we define
\[ T_{3_p}(I) = (T, F), \]
where
\[ T = \{ H | \exists L( H \leftarrow L \in \text{ground}(P), L \text{ is true in } I) \} , \]
\[ F = \{ H | \forall L( H \leftarrow L \in \text{ground}(P) \text{ implies } L \text{ is false in } I) \} . \]

The following lemma summarizes the relevant properties of the \( T_{3_p} \) operator.

**Lemma 4.11.**
- If \( I \) is consistent, then \( T_{3_p}(I) \) is consistent.
- \( T_{3_p} \) is monotonic.
- In general, \( T_{3_p} \) is not continuous.

Let us return now to the program completion. To define its meaning in three-valued logic, we need also to assign meaning to disjunction, equivalence, and quantifiers. We do it as follows:
\[ |A \lor B| = \max(|A|, |B|), \]
\[ |A \leftrightarrow B| = \begin{cases} 1, & \text{if } |A| = |B|, \\ 0, & \text{if } |A| \neq |B|, \end{cases} \]
so "\( \leftrightarrow \)" is "\( \leftarrow \)" receives a two-valued interpretation. The quantifiers are interpreted in the standard way. This definition allows us to determine when a
first-order formula $\phi$ is true in an arbitrary three-valued interpretation $I$, written as $I \models_3 \phi$. In analogy with the two-valued semantics, we also use the $\models_3$ relation to state that a formula is true in all three-valued models of a theory (e.g., $\text{comp}(P) \models_3 Q$).

The Fixpoint Lemma (Lemma 4.4) has a counterpart for the three-valued case.

**Lemma 4.12 (Fixpoint).** For every Herbrand interpretation $I$, $I \models_3 \text{comp}(P)$ iff $T_3(P)(I) = I$.

Consequently, by Lemma 4.11 and the generalization of the Knaster–Tarski theorem to cpo's, we get the following corollary.

**Corollary 4.13.** The $\subseteq$-least fixpoint of $T_3P$ is a consistent three-valued model of $\text{comp}(P)$.

For example, for the program $P = \{ p \leftarrow \neg p \}$ we now get three-valued model, namely, $(0,0)$, in which every ground atom is undefined and, consequently, in which $p \leftrightarrow \neg p$ is true. Thus the three-valued logic approach offers a solution to the problem of possible inconsistency of completion w.r.t. two-valued logic.

A natural question is for which programs do the three-valued and two-valued semantics of $\text{comp}(P)$ coincide. An answer was provided by Kunen [83].

**Definition 4.14 (Strictness).** Consider a program $P$ and a query $Q$. We say that $P$ is strict w.r.t. $Q$ if no relation occurring in $Q$ depends both evenly and oddly on a relation defined in the program.

**Theorem 4.15 (Equivalence).** Suppose that $P$ is call-consistent and $P$ is strict w.r.t. $Q$. Then $\text{comp}(P) \models_3 \text{comp}(P)$ iff $\text{comp}(P) \models Q$.

It was shown by Dix [43] that the two-valued completion semantics does not satisfy cautious monotonicity, but that the three-valued completion semantics is rational. For the first statement, consider the program $P = \{ q \leftarrow \neg p; q \leftarrow r; p \leftarrow q; p \leftarrow r; r \leftarrow r \}$. Then $\text{comp}(P) \models \{ p, q, r \}$, but $\text{comp}(P \cup \{ p \}) = \text{Th}(\{ p, q \leftarrow r \}) \neq \{ q, r \}$.

For a further discussion of the program completion, we refer the reader to Section 8.

### 4.4. Soundness and Completeness Results

Let us relate now SLDNF resolution and program completion. Clark [38] proved soundness of the SLDNF resolution w.r.t. two-valued semantics of program completion. In fact (see Shepherdson [149] for a sketch and Doets [49] for a complete proof), soundness holds also w.r.t. three-valued semantics. More precisely, we have the following result.

**Theorem 4.16 (Soundness).** Given a program $P$ and a query $Q$, we have:

- If $\sigma$ is a c.a.s. for $Q$, then $\text{comp}(P) \models_3 \forall \sigma Q r$.
- If there is a finitely failed SLDNF tree for $Q$, then $\text{comp}(P) \models_3 \forall \neg Q$.

A lot of effort has been devoted to establish some sort of completeness of SLDNF resolution. Already Clark [38] noticed that when comparing SLDNF
resolution with $\text{comp}(P)$, some restrictions are necessary. For example, for $P = \{ p \leftarrow q; p \leftarrow \neg q; q \leftarrow q \}$ we have $\text{comp}(P) \models p$, but no successful SLDNF derivation exists. In this example, $p$ depends both positively and negatively on $q$. The definition of strictness was designed to avoid this type of situation. Cavedon and Lloyd [30] established a conjecture of Apt et al. [8] and proved completeness of SLDNF resolution w.r.t. two-valued semantics of $\text{comp}(P)$ for allowed $P$ and $Q$ such that $P$ is strict w.r.t. $Q$ and $P$ is stratified (the concept to be introduced in Section 6). Independently, Kunen [83] established the following stronger result which refers to three-valued semantics.

**Theorem 4.17 (Completeness I).** Suppose that $P$ and $Q$ are allowed. Then:

- If $\text{comp}(P) \models \forall Q \circ$, then $Q \in F$.
- If $\text{comp}(P) \models \forall \neg Q$, then $Q \in F$.

A crucial lemma for establishing this completeness theorem, and numerous generalizations of it discussed further in the next, is the following result of Kunen [82], which allows us to set up induction in a proper way.

**Lemma 4.18.** For every first-order formula $\phi$ not containing $\leftarrow$ and $\leftrightarrow$, we have $\text{comp}(P) \models \exists \phi$ iff $T_{3P} \uparrow n \models \exists \phi$ for some finite $n$.

$T_{3P} \uparrow n$ denotes here the $n$-fold iteration of the operator $T_{3P}$ starting at the empty three-valued interpretation ($\mathcal{O}, \mathcal{O}$). In this lemma, non-Herbrand models of $\text{comp}(P)$ are used in an essential way. Also, as noted by Shepherdson [149], this lemma critically depends on the existence of infinitely many function symbols (counting constants as 0-ary function symbols), a property satisfied by the universal language adopted in this paper. When the used language has only finitely many function symbols, the free equality axioms have to be appropriately strengthened.

Recently, Doets [49] provided a simpler presentation of its proof. See also Stärk [152] for another proof.

When $\text{comp}(P) \models \forall Q \circ$ (resp. $\text{comp}(P) \models \forall Q \circ$), we say that $\circ$ is a two-valued (resp. three-valued) correct answer substitution for $Q$. Additionally, when $Q \circ$ is ground, we say that $\circ$ is a ground correct answer substitution. The Completeness I Theorem (Theorem 4.17), in conjunction with Theorems 3.13 and the Equivalence Theorem (Theorem 3.15), implies that three-valued correct answer substitutions for allowed programs and queries are ground. Shepherdson [148] showed that this claim also holds for the two-valued case for allowed programs whose completion is consistent.

A problem with the above completeness result is that, as already mentioned at the end of Section 3.3, the class of allowed programs is quite restricted and excludes many natural Prolog programs. So a natural question arises regarding how to generalize the above completeness result to a larger class of programs. This problem was studied by several researchers.

By providing more general conditions to prevent floundering, Decker and Cavedon [42] and Decker [41] generalized the Completeness I Theorem (Theorem 4.17) to a larger class of programs. Cavedon [29] proved completeness of SLDNF resolution for acyclic programs, which subsumes an early result of Clark [38], who (essentially) proved completeness w.r.t. two-valued completion for recursion-free
programs which satisfy a syntactic condition which prevents floundering. Numerous other extensions of the Completeness I Theorem were obtained by modifying the underlying computation mechanism, and so the SLDNF resolution.

5. PROOF THEORY II: SLDNF RESOLUTION REVISITED

We explained in Section 3.1 why in the definition of SLDNF resolution only ground negative literals are allowed to be selected. In this section we discuss how this restriction can be imposed or modified.

5.1. Modifications of SLDNF Resolution

An interesting theoretical alternative is to modify the SLDNF resolution by allowing the selection of nonground negative literals under certain circumstances. Consider the following modification of the definition of SLDNF resolution, already mentioned in Clark [38]. Let \( L = \neg A \) be the selected literal of a query \( C \). If there exists an empty c.a.s. for the query \( A \), then \( C \) is marked as failed. If the subsidiary tree \( \text{subs}(C) \) is defined and finitely failed, then \( C - \{ L \} \) is the only child of \( C \). In terms of Kunen's definition (Definition 3.14), this modification simply amounts to dropping the qualification "ground" in clauses \( R - \) and \( F - \).

Call the resulting notion SLDNFE resolution (for SLDNF extended). Then for the SLDNFE resolution, the Soundness Theorem (Theorem 4.16) still holds.

Shepherdson [147] further generalized this form of resolution by allowing a preliminary substitution \( \theta \) to be applied to nonground negative literals when trying to build a finitely failed subsidiary tree. In terms of Definition 3.14, this modification amounts to changing the clause \( R - \) to

\[ R' - \quad \text{If} \quad A \quad \text{is an atom such that for some} \quad \theta, \quad A\theta \in F \quad \text{and} \quad (C,C')R\sigma, \quad \text{then} \quad (C,\neg A,C')R\sigma\theta. \]

and dropping the qualification "ground" in clause \( F - \). He called this form of resolution SLDNFS (for SLDNF with substitution) and established its soundness in the sense of the Soundness Theorem (Theorem 4.16). Also, he proved its completeness w.r.t. a rather involved semantics.

Stärks [153] observed that the same soundness and completeness results hold for simple generalizations of SLDNF and SLDNFS resolution, called, respectively, ESLDNF and ESLDNFS resolution. In these resolution methods the qualification "ground" is dropped in clause \( R - \) and clause \( F - \) is replaced by:

\[ F' - \quad \text{If} \quad A \quad \text{is an atom such that for a renaming} \quad \theta \quad \text{for} \quad A, \quad AR\theta, \quad \text{then} \quad (C,\neg A,C') \in F. \]

He also studied transformation of proofs in the sequent calculus into proofs using these resolution methods.

Moreover, Stärk [153] proved completeness of ESLDNF resolution for a syntactically defined class of decomposable programs which includes the positive programs and allowed programs. Because allowed programs and allowed queries by Theorem 3.13 do not flounder, the ESLDNF resolution (with the selection of negative literals delayed until no more positive literals are available) coincides with
the SLDNF resolution. Consequently, this result generalizes the Completeness I Theorem (Theorem 4.17).

Recently, Stärk [156] proved a much stronger and more natural generalization of the Completeness I Theorem. The point of departure for Stärk is the observation that completeness depends on certain closure properties.

Definition 5.1. Let $\mathcal{Q}^+$ and $\mathcal{Q}^-$ be two sets of queries. A program is called a $(\mathcal{Q}^+, \mathcal{Q}^-)$-program if the following conditions are satisfied, where $\text{inst}(P)$ denotes the set of all instances of clauses from $P$

A1. If $Q \in \mathcal{Q}^+$, then $Q \theta \in \mathcal{Q}^+$.
A2. If $K, A, M \in \mathcal{Q}^+$ and $A \leftarrow L \in \text{inst}(P)$, then $K, L, M \in \mathcal{Q}^+$.
A3. If $(-A_1, \ldots, -A_k) \in \mathcal{Q}^+$, then if $i \in [1, k]$, $A_i$ is ground and $A_i \in \mathcal{Q}^-$. 
B1. If $Q \in \mathcal{Q}^-$, then $Q \theta \in \mathcal{Q}^-$. 
B2. If $K, A, M \in \mathcal{Q}^-$ and $A \leftarrow L \in \text{inst}(P)$, then $K, L, M \in \mathcal{Q}^-$. 
B3. If $K, A, M \in \mathcal{Q}^-$, then $A \in \mathcal{Q}^+$.

The following result of Stärk [156] explains the importance of this notion. Here yet another modification of the SLDNF resolution is used according to which in Definition 3.14 clause $F^-$ is replaced by $F^-$. 

Theorem 5.2 (Completeness II). Suppose that $P$ is a $(\mathcal{Q}^+, \mathcal{Q}^-)$-program. Then for a query $Q$:

- If $\text{comp}(P) \models \exists Q \theta$ and $Q \in \mathcal{Q}^+$, then for some substitution $\sigma$, $Q \sigma \sigma$ and $Q \sigma$ is more general than $Q \theta$.
- If $\text{comp}(P) \models \exists \neg Q$ and $Q \in \mathcal{Q}^-$, then $Q \in \mathcal{F}$.

This result generalizes the Completeness I Theorem (Theorem 4.17) because for $\mathcal{Q}^+ = \{Q|Q$ is allowed$\}$ and $\mathcal{Q}^-$ the set of all queries, we get that an allowed program is a $(\mathcal{Q}^+, \mathcal{Q}^-)$-program, and by Theorems 3.13 and 4.17, both computed and three-valued correct answer substitutions for allowed programs and queries are ground. Stärk found a systematic way of reducing previous completeness results to the Completeness II Theorem (Theorem 5.2) by means of modes, that is, input/output specifications.

Another modification was proposed by Di Pierro et al. [112]. Their approach is based on a rule termed "negation as instantiation" according to which, in the case of SLD resolution, a query consisting of one (possibly nonground) atom fails if all the branches in the SLD tree either fail or instantiate the atom. This rule is then incorporated into a resolution method for general programs. The resulting method, called SLDNI resolution, was proved sound w.r.t. two-valued semantics of program completion.

Finally, let us mention here Shepherdson [151], where an extension of the SLDNF resolution with unification w.r.t. an equality is studied.

5.2. Prolog and its Variants

Let us consider now Prolog. From the pure theoretical point of view, it is an implementation of SLDNF resolution with the leftmost selection rule with the exception that the selection of nonground negative literals is allowed, that is, floundering is ignored. This leads to various difficulties.
As already noted in Section 3.1, we obtain undesired conclusions for the program \( \text{NUMBERS} = \{ \text{positive}(x) \leftarrow \neg \text{zero}(x); \text{zero}(0) \leftarrow \} \), because both \( \forall x \neg \text{positive}(x) \) and \( \text{positive}(t) \), for any ground term \( t \) different from 0, can be established. However, for its completion,

\[
\text{comp}(\text{NUMBERS}) = \{ \forall x (\text{positive}(x) \leftarrow \neg \text{zero}(x)), \forall x (\text{zero}(x) \leftrightarrow x) \} = 0
\]

we do get the intended conclusions, since \( \text{comp}(\text{NUMBERS}) = \forall x (\text{positive}(x) \leftarrow x \neq 0) \).

In turn, consider the following program \( \text{SINK} \), where \( G \) is a finite graph:

\[
p(a, b) \leftarrow (a, b) \in G,
\]

\[
\text{sink}(x) \leftarrow \neg p(x, y).
\]

Then for a constant \( a \), the query \( \text{sink}(a) \) succeeds iff for no \( b, (a, b) \in G \), that is, iff \( \neg \exists y p(a, y) \). On the other hand, the completion interpretation of the \( \text{sink} \) relation is \( \forall x (\text{sink}(x) \leftarrow \exists y \neg p(x, y)) \). Thus for some programs the right interpretation is provided by its completion and for others by its computation mechanism. In general, it is not clear whether to interpret the negative literal \( \neg A \) in a clause as \( \exists y \neg A \) or \( \neg \exists y A \), where \( y \) stands for the sequence of local variables of \( \neg A \).

A natural solution is to find conditions which prevent selection of nonground negative literals in Prolog computations. This problem was studied by Apt and Pellegrini [6] and, independently, Stroetman [157]. Using the notion of modes, they introduced a syntactically defined class of programs and queries for which they proved absence of floundering w.r.t. the SLDNF resolution with the leftmost selection rule.

However, it is useful to note that in some restricted situations the choice of nonground negative literals does not lead to any complications. Namely, the following result is a direct consequence of the soundness of SLDNF resolution, where by SLDNF\(^+\) resolution we mean SLDNF resolution with floundering ignored.

**Theorem 5.3.** Given a positive program \( P \) and a general query \( Q \), we have:

- If \( P \models \text{SLDNF}^+, \forall Q_T \), then \( \text{comp}(P) \models \forall Q_T \).

The Soundness Theorem (Theorem 4.16) states that SLDNF resolution is sound for all safe selection rules, i.e., selection rules which never select a nonground negative literal. In MU-Prolog of Naish [106], a safe selection rule is used by delaying the nonground negative literals until they become ground. In other words, MU-Prolog implements SLDNF resolution with the "leftmost admissible literal" selection rule, where a literal is admissible if it is negative and ground, or positive. Even more complicated selection rules are allowed in NU-Prolog, the successor of MU-Prolog, of Naish [107] and in Gödel, the language proposed by Hill and Lloyd [73]. In these languages, so-called delay control declarations cause certain literals to be delayed until they become sufficiently instantiated. Lüttringhaus-Kappel [93] provides a thorough theoretical account of such delay declarations.

The restriction of the SLDNF resolution to the leftmost selection rule results in loss of completeness, even for very simple programs. Indeed, take \( P = \{ p \leftarrow p \} \) and \( Q = p, q \). Then \( \text{comp}(P) \models \neg Q \), but the only SLDNF derivation of \( Q \) w.r.t. the
leftmost selection rule diverges. Still, some limited forms of completeness can be obtained here by restricting attention to terminating programs; see Apt and Pedreschi [5] and Stroetman [157]. Lately, another approach to this issue was proposed in Stärk [154]; see Section 8.3.

In Prolog, negation can be applied to an arbitrary query, not only to an atom, as in the SLDNF resolution and its variants. Also, disjunction can be used in queries and bodies of the clauses. Lloyd and Topor [88] (see also Lloyd [87]) modelled these syntactic extensions by means of a more general syntax in which the queries and bodies of clauses can be arbitrary first-order formulas. These generalized queries and programs can be interpreted by means of a syntactic transformation which transforms them to a general query and a general program combined with the SLDNF-resolution. Lloyd and Topor [88] showed that this transformation preserves program completion (which is defined for the generalized programs in the expected way).

This syntactic extension of general programs allows us to deal properly with the program $\text{SINK}$ discussed above. To enforce its right interpretation w.r.t. program completion it suffices to replace its second clause by

$$\text{sink}(x) \leftarrow \neg \exists y p(x, y).$$

This extended syntax is used in the language Gödel of Hill and Lloyd [73] mentioned above.

### 5.3. Constructive Negation

In SLDNF resolution, only positive literals can generate a computed answer substitution. In SLDNFS resolution, negative literals can generate answers, as well. Unfortunately, these answer substitutions need to be guessed and subsequently verified. Chan [33] suggested a modification of SLDNF resolution in which non-ground negative literals can be selected and can generate answers, but, in contrast to the SLDNFS resolution, these answers can be effectively computed. This way of using negative literals is called constructive negation, and the resulting form of resolution is called SLD-CNF resolution.

First, let us introduce the following helpful notation. For a substitution $\theta = \{x_1/t_1, \ldots, x_n/t_n\}$, let $\bar{\theta}$ denote the formula $\exists y (x_1 = t_1 \land \cdots \land x_n = t_n)$, where $y$ is the sequence of variables from $\text{Ran} (\theta) \setminus \text{Dom} (\theta)$.

The departure point for Chan’s approach is the following property of SLD resolution (essentially proved by Clark [38]):

Consider a finite SLD tree for a query $Q$. Let $\theta_1, \ldots, \theta_k$ be all c.a.s.’s for $Q$ present in this SLD tree. Denote by $F_Q$ the formula $\bar{\theta}_1 \lor \cdots \lor \bar{\theta}_k$. Then $\text{comp} (P) \models \forall(Q \leftrightarrow F_Q)$.

Consequently $\text{comp} (P) \models \forall (\neg Q \leftrightarrow \neg F_Q)$, which suggests interpreting $\neg F_Q$ as the computed answers generated by $\neg Q$.

There are two problems which have to be solved for this interpretation. First, the formula $\neg F_Q$ cannot be interpreted as a set of substitutions anymore. Thus, what it means to apply this formula to a query must be defined. Second, $F_Q$ is not always defined. To solve the first problem, Chan [33] extended the language of logic programs by allowing equalities $s = t$ and inequalities $\forall (s \neq t)$ in the queries and
bodies of the clauses, and provided a normalization algorithm which transforms
every formula of the form \( \neg F_Q \) to a disjunction of simple equality formulas, that
is, existentially quantified conjunctions of equalities or there negations.

The second problem is that Chan's definition is based on the original definition
of SLDNF resolution due to Clark [38], according to which, as noted in Section 3.2,
for some problematic cases no SLDNF trees exists. It was adequately solved in
Marchiori [97], who provided a formal definition of SLD-CNF resolution in the
style of Apt and Doets [10].

Chan [33] noticed that SLD-CNF resolution is sound w.r.t. program completion
(for the two-valued semantics). In particular, SLD-CNF resolution allows us to
treat correctly the previously mentioned program NUMBERS—the query \( \text{positive}(x) \) succeeds with the desired answer \( x \neq 0 \).

Marchiori [97] studied termination of programs w.r.t. constructive negation and
among others proved completeness of the SLD-CNF resolution for acyclic pro-
grams w.r.t. program completion for bounded queries. Further generalizations of
constructive negation were proposed by Stuckey [158] and, more recently, by
Drabent [50]. Both of them proved completeness results which subsume the
Completeness I Theorem (Theorem 4.17).

6. TWO-VALUED ALTERNATIVES FOR THE LEAST HERBRAND MODEL

In the case of positive logic programs, the least Herbrand model of the program
exists. This model enjoys a number of natural properties. For example, it is the
least pre-fixpoint of the operator \( T_P \) and also its least fixpoint. Consequently, it is
customary to view it as the standard model of the program. In the case of general
programs, the situation dramatically changes because there is no least Herbrand
model. Just take \( P = \{ p \leftarrow \neg q \} \). Then \( \{ p \} \) and \( \{ q \} \) are the only minimal Herbrand
models, but none is the least. Thus, by Lemma 4.3, \( T_P \) may have no least
pre-fixpoint and at the end of Subsection 4.2, we already noted that \( T_P \) may have
no fixpoint at all.

So what is then the standard model of a general program? There is no generally
agreed upon answer to this question. With this section, we begin a review of some
of the plausible answers suggested in the literature.

6.1. Stratified Programs and the Standard Model

Let us first agree on the desired properties of the natural model. Clearly, for every
fact in the model, we would like to have some explanation of why it is there. The
following definition suggested by Apt et al. [8] and Bidoit and Froidevaux [20]
attempts to formalize this requirement.

Definition 6.1 (Supported interpretation). A Herbrand interpretation \( I \) is called
supported if

\[
A \in I \quad \Rightarrow \quad \exists L( A \leftarrow L \in \text{ground}(P), I \models L).
\]

Intuitively, \( L \) is an explanation for \( A \). We clearly have the following lemma.

Lemma 6.2. \( I \) is a supported model of \( P \) iff \( T_P(I) = I \).
Thus, in view of the observation on the behavior of the $T_p$ operator, we see that for some programs, no supported models exist. One possible approach is to accept that some programs have no natural, supported model and to identify classes of programs for which a "natural" supported model exists.

The following notion was first considered in the context of database queries by Chandra and Harel [34] and was introduced in the area of logic programming by Apt et al. [8] and van Gelder [16].

**Definition 6.3 (Stratified program).** A program is called **stratified** if no cycle with a negative edge exists in its dependency graph.

In other words, a program is stratified if no negative recursion, that is, recursion "through" negation, is used in it. For example, the program $P = \{p \leftarrow -q, q \leftarrow r\}$ is stratified, whereas $P = \{p \leftarrow -p\}$ is not. Note that every stratified program is call-consistent, but not conversely. The following equivalent formulation shows that in a stratified program the use of negation is restricted to already known (i.e., defined) relations.

**Definition 6.4 (Stratification).** Consider a program $P$. $P = P_1 \cup \cdots \cup P_n$ is called a **stratification of** $P$ if for $i \in \{1, n\}$, $P_i$ uses (i) positively only relations defined in $\bigcup_{j=1}^{i-1} P_j$ or (ii) negatively only relations defined in $\bigcup_{j=1}^{i-1} P_j$.

$P_1$ can be empty. For convenience, when some relations used in $P$ are not defined, we assume that they are defined (by the empty set of clauses) in $P_1$.

**Lemma 6.5.** A program is stratified iff it admits a stratification.

Note that a program can admit several stratifications. Following the intuition on the use of negation, the following model was defined for stratified programs.

**Definition 6.6 (Standard model).** Consider a stratified program $P$. Assume a stratification $P = P_1 \cup \cdots \cup P_n$. Denote by $I/R$ the restriction of the interpretation $I$ to relations in $R$. Each $P_i$ defines a set of relations $rel_i$. Define a sequence of Herbrand interpretations as follows:

$M_1$ = the least model of $P_1$,

$M_2$ = the least model of $P_2$ such that $M_2|rel_1 = M_1$,

$\vdots$

$M_n$ = the least model of $P_n$ such that $M_n|rel_1, \ldots, n-1 = M_{n-1}$.

We call $M_P = M_n$ the **standard model** of $P$.

For example, consider $P = \{p \leftarrow -q; q \leftarrow r\}$ and its stratification $P = \{q \leftarrow r\} \cup \{p \leftarrow -q\}$. Then $M_1 = \emptyset$ and $M_2 = M_P = \{p\}$.

The following result of Apt et al. [8] explains why the model $M_P$ is of interest.

**Theorem 6.7 (Standard model).** Consider a stratified program $P$. Then:

- $M_P$ does not depend on the stratification of $P$.
- $M_P$ is a minimal model of $P$.
- $M_P$ is a supported model of $P$. 
Thus, by the Fixpoint Lemma (Lemma 4.4), completion of a stratified program has a Herbrand model.

6.2. Locally Stratified Programs and Perfect Models

Still, the above theorem does not uniquely characterize the standard model $M_p$, since for some stratified programs, more than one supported model exists. Just take $P = \{ p \leftarrow -q; q \leftarrow q \}$. Then both $\{ p \}$ and $\{ q \}$ are supported.

To provide a unique characterization of the model $M_p$, Przymusinski [121] introduced the notion of preferable models. Fix a program $P$ and a well-founded ordering $<$ on $B_p$. If $A < B$, then we say that $A$ has a higher priority than $B$.

Definition 6.8 (Perfect model). Let $M, N$ be Herbrand interpretations of $P$. We call $N$ preferable to $M$, and write $N < M$, if for every $B \in N - M$ there exists $A \in M - N$ such that $A < B$. We write $N \not{<} M$ if $N - M$ or $N \not{<} M$. We call a Herbrand model of $P$ perfect if there are no Herbrand models of $P$ preferable to it.

Thus a perfect model of $P$ is a $<$-minimal Herbrand model of $P$. The intuition behind these definitions is the following. $N$ is preferable to $M$ if it is obtained from $M$ by possible adding/removing of some atoms, and an addition of an atom $(B)$ to $N$ is always compensated by the simultaneous removal from $M$ of an atom $(A)$ of higher priority. This reflects the fact that we are determined to minimize higher priority atoms even at the cost of adding atoms of lower priority. A model is then perfect if this form of minimization of higher priority atoms is achieved in it.

The following lemma clarifies the status of perfect models.

**Lemma 6.9.** Let $P$ be a program and $<$ a well-founded ordering on $B_p$.

- Every perfect model of $P$ is minimal.
- The relation "$N$ is preferable to $M$" is a partial order.

The standard model $M_p$ of a stratified program $P$ is related to perfect models by the following theorem of Przymusinski [121].

**Theorem 6.10.** Let $P$ be a stratified program and let for $A, B \in B_p$, $A < B$ iff the relation symbol of $B$ depends negatively on the relation symbol of $A$. Then $M_p$ is a unique perfect model of $P$.

In other words, $M_p$ is the $<$-smallest Herbrand model of $P$. This theorem provides an alternative proof of the first claim of the Standard Model Theorem (Theorem 6.7). Thus the notion of a perfect model turns out to be the key concept in assessing the character of $M_p$.

The previous result immediately suggests a generalization of the concept of stratification which was, again, proposed by Przymusinski [121]. He observed that some programs that are not stratified still have an intuitively clear meaning. The standard example is the program **EVEN**:

\[
\begin{align*}
even(0) & \leftarrow \\
even(s(X)) & \leftarrow \neg \even(X).
\end{align*}
\]
The program \textit{EVEN} is clearly not stratified, because the relation \textit{even} depends negatively on itself. However, if we consider all ground instances of the clauses of \textit{EVEN}, then we see that no ground atom depends negatively on itself. In other words, if we consider the ground atoms as proposition symbols, then the instantiated program is stratified (albeit infinite). A program that has this property is \textit{locally stratified}.

\textit{Definition 6.11 (Local stratification).}

- A \textit{local stratification} for a program \( P \) is a function \( \text{stratum} \) from \( B_p \) to the countable ordinals.
- Given a local stratification \( \text{stratum} \), we extend it to ground negative literals by putting \( \text{stratum}(\neg A) = \text{stratum}(A) + 1 \).
- A clause of \( P \) is called \textit{locally stratified with respect to a local stratification \( \text{stratum} \)} if for every ground instance \( A \leftarrow K, L, L, \)

\[ \text{stratum}(A) \geq \text{stratum}(L). \]
- A program \( P \) is called \textit{locally stratified with respect to a local stratification} if all its clauses are. \( P \) is called \textit{locally stratified} if it is locally stratified with respect to some local stratification.

\textit{Lemma 6.12.}

- An acyclic program is locally stratified.
- A stratified program is locally stratified.

Instead of comparing ground atoms by their relation symbols, a local stratification of a program \( P \) immediately induces a well-founded ordering on \( B_p \). The following theorem, owing to Przymusinski [121], shows that perfect models unambiguously define a semantics for locally stratified programs.

\textit{Theorem 6.13 (Unique perfect model). Let \( P \) be a locally stratified program and let for \( A, B \in B_p, A < B \iff \text{stratum}(A) < \text{stratum}(B) \). Then \( P \) has a unique perfect model.}

It was soon realized that some programs are not locally stratified, but still have a clear meaning. For example, we could rewrite the program \textit{EVEN} to \textit{EVEN'}:

\begin{align*}
even(X) & \leftarrow \text{zero}(X) \\
even(Y) & \leftarrow \text{successor}(X,Y), \neg \even(X) \\
\text{zero}(0) & \leftarrow \\
\text{successor}(X,s(X)) & \leftarrow.
\end{align*}

(In this program, we can change the representation of numbers without changing the clauses defining the relation \textit{even}.) This program is no longer locally stratified, because

\begin{align*}
even(0) & \leftarrow \text{successor}(0,0), \neg \even(0)
\end{align*}

is an instance of the second clause.
Of course, the premise \texttt{successor(0,0)} of this instance is false, but that is part of the semantics of the program, while (local) stratification is a syntactic property. There are two proposals for adapting local stratification and perfect model semantics to capture this phenomenon: \textit{weak stratification} by Przymusinska and Przymusinski [116, 117] and \textit{effective stratification} by Bidoit and Froidevaux [21].

For weak stratification, it is observed that for each iteration in the construction of the model, only the next lowest stratum must be identified. The truth values obtained for the atoms in this stratum can then be used to discard clauses with false premises. This in turn may remove some dependencies, thereby allowing identification of the next lowest stratum. We omit the formal definition. For the program \texttt{EVEN'}, the lowest stratum consists of the \texttt{zero} and \texttt{successor} atoms. Discarding clauses with false \texttt{zero} and \texttt{successor} premises yields the (already locally stratified) program

\begin{verbatim}
  even(0) ← zero(0)
  even(s(X)) ← successor(X, s(X)), ¬even(X)
  zero(0) ←
  successor(X, s(X)) ← .
\end{verbatim}

\textit{Theorem 6.14} (Przymusinska and Przymusinski [116, 117]. A locally stratified program is weakly stratified.

Bidoit and Froidevaux [21] define the notion of \textit{effective stratification}, which takes this approach even further. Because it is closely related to the (still to be introduced) well-founded models, we discuss it in Section 7.

\subsection*{6.3. Well-Supported or Stable Models}

In Section 6.2, we noted that, for a program \( P = \{p \leftarrow \neg q; q \leftarrow q\} \), both \( \{p\} \) and \( \{q\} \) are supported models. However, the support for \( q \) is unfounded, in the sense that \( q \) is the explanation of why \( q \) is true. So we would like to rule out the second supported model. The following approach of Fages [57] makes this idea precise.

\textbf{Definition 6.15 (Well-supported interpretation).} For a query \( L \), denote by \( \text{pos}(L) \) the sequence of positive literals of \( L \). A Herbrand interpretation \( I \) is called \textit{well-supported} if for some well-founded ordering \( < \) on \( B \),

\[
A \in I \text{ implies } \exists \text{pos}(L) \text{, } I \models L, \text{ and } B < A \text{ for } B \in \text{pos}(L).
\]

Intuitively, \( I \) is well-supported if every \( A \in I \) has an explanation which does not use \( A \). For example, for \( P = \{p \leftarrow \neg q; q \leftarrow q\} \), the model \( \{p\} \) is well-supported, whereas \( \{q\} \) is not. It should be noted that some programs have no well-supported models. Take, for example, \( P = \{p \leftarrow q; p \leftarrow \neg q; q \leftarrow p; q \leftarrow \neg p\} \). Its only Herbrand model, \( \{p, q\} \), is not well-supported.

By using the intuition of "rational beliefs" from autoepistemic logic, Gelfond and Lifschitz [65] introduced an important notion of a stable model. We begin with the following auxiliary notions.
Definition 6.16 (Gelfond–Lifschitz transformation). For a query \( L \), denote by \( \neg(L) \) the sequence of negative literals of \( L \). Let \( P \) be a program and \( I \) an interpretation. Let
\[
H(P, I) = \{ H \leftarrow pos(L) \mid H \leftarrow L \in \text{ground}(P), I \models \neg(L) \}.
\]

Now define
\[
\Gamma_p(I) = M_{H(P, I)}.
\]

Thus \( H(P, I) \) is the positive program obtained from \( P \) by removing all clauses that contain one or more negative literals that are false in \( I \) and by deleting all negative literals that are true in \( I \). In turn, \( \Gamma_p(I) \) is a Herbrand model equal to the least Herbrand model of the positive program \( H(P, I) \).

Definition 6.17 (Stable model). A Herbrand interpretation \( I \) of a program \( P \) is called stable if \( \Gamma_p(I) = I \).

Gelfond and Lifschitz [65] explain the intuition behind the definition of a stable model as follows. Consider a “rational agent” with a set of beliefs \( I \) and a set of premises \( P \). Then any clause that has a literal \( \neg A \) with \( A \in I \) in its body is useless, so it can be removed. Moreover, any literal \( \neg A \) with \( A \notin I \) is trivial, so it can be deleted. This yields the simplified program \( H(P, I) \). If now \( I \) happens to be precisely the set of atoms that follow logically from this simplified set of premises, then the set of beliefs \( I \) is stable. Thus stable models are “possible sets of belief a rational agent might hold”.

The following theorem of Fages [57] shows that the concepts of well-supported and stable models coincide. It was independently established by Elkan [55] for the case of propositional programs.

Theorem 6.18. Suppose that \( I \) is a model of \( P \). Then \( I \) is stable iff it is well-supported.

Thus, a fortiori stable models of a program \( P \) are supported models and, consequently, by the Fixpoint Lemma (Lemma 4.4), they are also models of \( \text{comp}(P) \). The converse is, in general, not true (see the beginning of this section), but for certain programs the Herbrand models of \( \text{comp}(P) \) and stable models coincide. Namely, we have the following corollary to the above theorem, owing to Fages [58] and, independently, Ben-Eliyahu [18].

Corollary 6.19. Suppose that no cycle with only positive edges exists in the dependency graph of \( P \). Then the Herbrand models of \( \text{comp}(P) \) coincide with the stable models of \( P \).

The following results of Gelfond and Lifschitz [65] clarify the relation between stable models and the notions introduced in Sections 6.1 and 6.2.

Theorem 6.20 (Unique stable model). Consider a program \( P \). Then:

- Any stable model of \( P \) is a minimal model of \( P \).
- If \( P \) is locally stratified, then it has a unique stable model which coincides with its perfect model considered in the Unique Perfect Model Theorem (Theorem 6.13).
In particular, if $P$ is stratified, then by Theorem 6.10 it has a unique stable model which coincides with its standard model $M_P$. Thus, similarly to the notion of a perfect model, the concept of a stable model allows us to characterize the notion of a standard model for stratified programs in a unique way.

The second result also shows that a sufficient condition for the existence of a stable model of a program is that it is locally stratified. Dung [52] proves that call consistency is also sufficient. More results can be found in Dung [52] and Fages [58].

7. THREE-VALUED ALTERNATIVES FOR THE LEAST HERBRAND MODEL

Stable model semantics allows more than one stable model, or none at all. This reflects some uncertainty about the conclusions that should be drawn from a program. In some cases, a "local" uncertainty can destroy too much information. For example, if $P$ is a stratified program in which the relation symbol $p$ does not occur, then $P \cup \{p \leftarrow , p\}$ has no stable models. Thus the information contained in $P$ is not reflected in the stable model semantics, although it is not related to the uncertainty about the truth value of $p$.

Well-founded semantics (WFS) avoids this problem, by producing one three-valued model, instead of multiple two-valued models. In contrast to Section 4.3, three-valued logic (that is, a three-valued interpretation of the connectives) is not needed to obtain these three-valued models. There are numerous characterizations of the well-founded semantics; we present here a few of them. Apart from the information ordering $\subseteq$ on three-valued interpretations, as defined in Section 4.3, we sometimes use the truth ordering: $I$ is truth less than $J$ iff $I^+ \subseteq J^+$ and $I^- \supseteq J^-$. 

7.1. Iterated Least Fixpoint Characterization of WFS

Suppose that one prefers the least Herbrand model/closed world assumption (rather than the completion or classical negation) to decide whether a negative literal holds w.r.t. a positive program. Then, given a general program, one can observe that regardless of the semantics of negative literals in clause bodies, some atoms must be true in its semantics (e.g., facts in the program) and some must be false (e.g., atoms that do not unify with the head of any clause). One of the weaknesses of the proposals in Section 6 is that such information is lost if no model is produced. When "guessing" an interpretation to see if it is a stable model, we know what guess to make for those atoms. We can also use those atoms to simplify the program, as in the example on weak stratification. As a result of this simplification, more atoms may become certainly true or certainly false.

If the truth value of all atoms can be decided in this way, then the program is called effectively stratifiable by Bidoit and Froidevaux [21]. If some atoms remain undecided, then we might start guessing, in order to find stable models. However, another interesting option is to stop just there and to return a three-valued model. This model shows which atoms are true, respectively false, regardless of the semantics of negation, and which atoms cannot be decided in this way. It is called the well-founded model.
The original definition of the well-founded semantics is usually attributed to van Gelder et al. [63]. Here, we loosely follow the somewhat more constructive definition of Bidoit and Froidevaux [21]. Two significantly different characterizations of the well-founded model are presented in the next sections.

The first step of our definition is to derive from a program $P$ which atoms are certainly true, respectively false, in its semantics. An atom is certainly true if it can be derived without using clauses that contain negative literals. An atom is possibly true, if it can be derived when ignoring all negative premises. An atom is certainly false if it is not possibly true. We collect the "certain" atoms in a three-valued interpretation $I_3(P)$, leaving the "uncertain" atoms unknown.

**Definition 7.1.** Let $P$ be a program. By $P^+$ we denote the program obtained from $P$ by deleting all clauses that contain a negative literal. By $P^-$ we denote the program obtained from $P$ by deleting all negative literals. Let $I_3(P) = (M_{P^+}, M_{P^-})$.

Here $M$ denotes the complement of $M$ w.r.t. the set of ground atoms in the considered universal language, which is larger than the language $L_0$ defined by $P$.

Bidoit and Froidevaux [21] call $M_{P^+}$ the set of defined atoms (Def$(P)$) and $M_{P^-}$ the set of potentially defined atoms (PotDef$(P)$). van Gelder et al. [63] call the atoms in $M_{P^+}$ well founded and $M_{P^-}$ an unfounded set (see below).

In this section, we use a simplification of a program w.r.t. a set of certain literals that differs from the Gelfond–Lifschitz transformation (Definition 6.16) in a significant way: not only negative literals, but also positive literals are considered for simplification. A generalization of Definition 6.16 to three-valued interpretations is considered in the next section.

**Definition 7.2.** Let $P$ be a program and let $I$ be a three-valued interpretation. By $P \setminus I$, we denote the program that is obtained from ground$(P)$ by deleting all clauses that contain one or more body literals that are false in $I$ and by deleting all body literals that are true in $I$. Furthermore, $\Phi_p(I) = I_3(P \setminus I)$.

**Lemma 7.3** (Przymusinski [122]). The $\Phi_p$-operator is monotonic w.r.t. the information ordering.

This lemma implies that the least fixpoint of $\Phi_p$ exists and that it can be reached by iterating the $\Phi_p$-operator from $(\emptyset, \emptyset)$, taking the pairwise union at limit ordinals.

**Definition 7.4** (Well-founded model). The information-least fixpoint of $\Phi_p$ is called the well-founded model of $P$, $WFM(P)$.

Because $\Phi_p$ is, in general, not continuous, more than $\omega$ iterations are usually needed to reach the least fixpoint. However, if the number of atoms in the language is finite, say $n$, then the computation of $WFM(P)$ in this way takes $O(n^2)$ iterations, as shown by van Gelder et al. [63].

The original definition of the well-founded model by van Gelder et al. [63] slightly differs from this one. Instead of $\Phi_p$, they define and iterate the operator $V_p(I) = \left(\text{the set of facts in } (P \setminus I)^+ M_c(P \setminus I)^-\right)$. 
Thus, the derivation of positive facts using $V_p$ goes much “slower” than using $\Phi_p$. Moreover, they define $M_{(P \setminus I)}$ in another, nonconstructive way, namely, as the largest unfounded set, where an unfounded set is a set of ground atoms $U$ such that for all atoms $A \in U$, all instances of clauses that conclude $A$ have a premise in $U$ (thus, if we assume the atoms in $U$ to be false, no clause that could derive them remains applicable, which justifies the assumption).

We can now define the generalization of the notion of weak stratification, already mentioned in Section 6.2, due to Bidoit and Froidevaux [21].

**Definition 7.5 (Effective stratification).** A program $P$ is effectively stratifiable if $WFM(P)$ is total.

**Theorem 7.6 (Bidoit and Froidevaux [21]).** A weakly stratified program is effectively stratifiable.

The well-founded model is related to program completion, stable models, and, hence, to the other models in Section 6, in the following way.

**Theorem 7.7 (Extension; van Gelder et al. [63]).**
- The well-founded model of a program is a (three-valued) model of its completion.
- All stable models of a program extend\(^3\) its well-founded model.

**Corollary 7.8.** If the well-founded model of a program is total, then it is its unique stable model.

The converse of this implication is not true: the program $\{p \leftarrow \neg p; p \leftarrow \neg q; q \leftarrow \neg p\}$ has $\{p\}$ as its unique stable model, but its well-founded model is $(\emptyset, \emptyset)$. However, Theorems 6.14 and 7.6 imply that the well-founded model of a locally (weakly) stratified program is total.

**Corollary 7.9.** The well-founded model of a locally stratified program coincides with its unique perfect model.

### 7.2. Stationary Models and Stationary Expansions

In this section we present an alternative characterization of the well-founded model, due to Przymusinski [127], which relies somewhat more on three-valued logic, but stays closer to the definition of stable models. Moreover, this characterization also suggests other interesting three-valued models of the program, which extend the well-founded model.

Definition 6.16 presents a function $H(P, I)$ that simplifies a program $P$ with respect to a two-valued interpretation $I$. In fact, this function replaces each negative literal in the program by the truth value it has in the interpretation. The result is a positive program, except that the logical constants $\text{true}$ and $\text{false}$ occur in it. When considering the semantics of such a program, i.e., its least Herbrand model, the constants $\text{true}$ can be ignored. A constant $\text{false}$ in a clause body means

\(^3\)That is, the well-founded model is lower in the information ordering than any stable model. This notion of extension should not be confused with another one: a semantics $\mathcal{S}$ defined for a class of programs $\mathcal{F}$ is sometimes said to extend a semantics $\mathcal{S}'$ defined for a smaller class $\mathcal{F}' \subseteq \mathcal{F}$ if $\mathcal{S}$ and $\mathcal{S}'$ coincide on $\mathcal{F}'$. To avoid confusion, we shall not use the word “extend” in this sense.
that this clause is never applicable, so the whole clause can be ignored. By syntactically removing the parts of the program that can be ignored, we bypassed the introduction of the logical constants and defined the result of the function to be a positive program.

It is straightforward to generalize this function so that it simplifies a program with respect to a three-valued interpretation. The result is a positive program, in which the constants true, false, and unknown occur. We can get rid of the constants true and false again, but the constants unknown remain. This is not a problem: the truth-least partial Herbrand model of such programs is well defined.

Definition 7.10 (u-program). A u-program is a positive program in which the constants true, false, and unknown may occur. $M_3(P)$ denotes the truth-least three-valued Herbrand model of a u-program $P$.

Let $P$ be a program and let $I$ be a three-valued interpretation. The u-program $H_3(P, I)$ is obtained from ground($P$) by replacing every negative literal in $P$ by the truth value it has in $I$:

$$
\Gamma_{3P}(I) = M_3(H_3(P, I)).
$$

Analogously to the stable models of Section 6.3, the fixpoints of $\Gamma_{3P}$ are considered as possible “meanings” of the program $P$. Przymusinski called these models partial, extended, or three-valued stable models, or stationary models [124, 127, 126, 120, 129]. From now on, we shall refer to them as stationary models; by “stable models” we shall always mean two-valued models.

Definition 7.11 (Stationary model). Let $P$ be a program. A stationary model of $P$ is a three-valued Herbrand interpretation $I$ such that $\Gamma_{3P}(I) = I$.

In contrast to stable models, each program has at least one stationary model. Moreover, the set of stationary models of a program has an information-least element, which happens to coincide with the well-founded model.

Theorem 7.12 (Least stationary model; Przymusinski [127]). Let $P$ be a program. The information-least stationary model of $P$ exists and coincides with WFM($P$).

If $I$ is a two-valued interpretation, then $\Gamma_{3P}(I)$ obviously coincides with $\Gamma_P(I)$. Thus all stable models of a program are also (information-maximal) stationary models of it. This clarifies the second clause of the Extension Theorem (Theorem 7.7).

Instead of considering the information-minimal stationary model, we can also consider information-maximal ones as plausible “belief states” associated with the program. Among these are stable models of a program, if it has any. However, while the stable model semantics of a program is easily destroyed by local “impossibilities,” maximal stationary model semantics is much more robust. A local impossibility simply means that some atoms remain unknown in all models; it does not affect the (global) existence of the models.

Neither the definition of a stable model nor of a stationary model is constructive—it involves a “guess” of an interpretation which is then checked whether it is a

\[ \text{Note that } M_3(P) \text{ coincides with } I_3(P) \text{ if we get rid of occurrences of } \text{true} \text{ and } \text{false} \text{ as before, and treat occurrences of } \text{unknown} \text{ as negative literals.} \]
stable, respectively, stationary, model. Saccà and Zaniolo [141] characterized all stable models by means of fixpoints of a backtracking operator which generates all stable models of a program. This work was further extended and generalized by Teusink [159], who characterized all stationary models by means of fixpoints of another nondeterministic, nonmonotonic operator.

The following characterization of stationary models, proposed by Przymusinski [119], stays within two-valued logic. First we identify a program with the program obtained by replacing every occurrence of a negative literal \( \neg A \) by the new atom \( \text{not} \_ A \). This gives a positive program, in which the atoms of the form \( \text{not} \_ A \) occur only in the bodies of clauses. A stationary expansion is obtained by adding to such a program a suitable set of \( \text{not} \_ A \) atoms; these fully determine a stationary model.

**Definition 7.13 (Stationary expansion).** Let \( P \) be a positive program with \( \text{not} \_ A \) atoms in bodies of clauses. Let \( C \) be a set of \( \text{not} \_ A \) atoms.

- A Herbrand interpretation for \( P \) is a set of atoms (containing both ordinary atoms and \( \text{not} \_ A \) atoms, in general).
- By the minimal models of \( P \cup C \), we mean the Herbrand interpretations that are minimal w.r.t. set inclusion for the ordinary atoms (but not necessarily w.r.t. \( \text{not} \_ A \)-atoms) among those interpretations \( I \) that satisfy (i) \( I \models P \cup C \) (in the classical sense) and (ii) if \( P \cup C \models A \), then \( \text{not} \_ A \notin I \).
- For a negative literal \( \neg A \), \( P \cup C \models_{\text{min}} \neg A \) if \( \neg A \) is true in all minimal models of \( P \cup C \).
- A stationary expansion of \( P \) is a consistent theory \( E(P) \) which satisfies
  \[ E(P) = P \cup \{ \text{not} \_ A | E(P) \models_{\text{min}} \neg A \} \].
- The least stationary expansion of \( P \) is called its stationary completion.

**Theorem 7.14 (Correspondence; Przymusinski [119]).** Let \( P \) be a program. There is the following one-to-one correspondence between stationary models and stationary expansions of \( P \):

- If \( M \) is a stationary model of \( P \), then \( P \cup \{ \text{not} \_ A | M \models_{\text{min}} \neg A \} \) is a stationary expansion of \( P \).
- If \( E(P) \) is a stationary expansion of \( P \), then \( \{ A | E(P) \models A \} \cup \{ \neg A | E(P) \models_{\text{min}} \neg A \} \) is a stationary model of \( P \).

In this way, the well-founded model of \( P \) corresponds with the stationary completion of \( P \).

The information-least stationary model (i.e., the well-founded model) of a program can be computed by iterating \( \Gamma P \) from \( (\emptyset, \emptyset) \). This corresponds to the following theorem.

**Theorem 7.15 (Przymusinski [119]).** Let \( P \) be a program.

Let \( P_0 = P \).

For a successor ordinal \( \alpha + 1 \), let \( P_{\alpha+1} = P_\alpha \cup \{ \text{not} \_ A | P_\alpha \models_{\text{min}} \neg A \} \).

For a limit ordinal \( \beta \), let \( P_\beta = \bigcup_{\alpha < \beta} P_\alpha \).
The sequence $P_0, P_1, \ldots, P_n, \ldots$ has a fixpoint which coincides with the stationary completion of $P$.

We shall discuss a generalization of stationary expansions to the class of general disjunctive programs in Section 10.3.

### 7.3. The Alternating Fixpoint Characterization of WFS

Yet another characterization of the well-founded model is the one given by van Gelder [62]. It is based solely on two-valued interpretations, which only in the end are combined into a three-valued model.

As observed by van Gelder [62], $\Gamma_P$ is an antimonotonic operator (on two-valued interpretations, thus w.r.t. the truth ordering). Thus $\Gamma_P^2$, i.e., $\Gamma_P$ iterated twice, is monotonic and, on the lattice we work on, has a least fixpoint, say $I_P$. Then $\Gamma_P(I_P)$ is the greatest fixpoint of $\Gamma_P^2$.

**Theorem 7.16 (Alternating fixpoint I; van Gelder [62]).** Let $P$ be a program. Then the least fixpoint $I_P$ of $\Gamma_P^2$ exists and

$$\text{WFM}(P) = (I_P, \Gamma_P(I_P)).$$

The second clause of the Extension Theorem (Theorem 7.7) is also a corollary of this theorem. The following theorem is a more general version of the Alternating Fixpoint Theorem (Theorem 7.16).

**Theorem 7.17 (Alternating fixpoint II; Przymusinska and Przymusinski [114]).** Let $P$ be a program and let $I$ be a two-valued interpretation. $(I, \Gamma_P(I))$ is a stationary model of $P$ iff $\Gamma_P^2(I) = I \subseteq \Gamma_P(I)$.

Note that for $P = \{ p \leftarrow \neg p; q \leftarrow \neg q \}$, $\Gamma_P$ oscillates between $\{ p \}$ and $\{ q \}$, but that there is no corresponding stationary model, because the interpretations $(\{ p \}, \{ q \})$ and $(\{ q \}, \{ p \})$ are inconsistent.

Such pairs of interpretations are generalized to finite sets by Baral and Subrahmanian [15].

**Definition 7.18 (Stable class).** Let $P$ be a program. A stable class of $P$ is a finite set of (two-valued) interpretations $A$ such that $A = \{ \Gamma_P(I) | I \in A \}$.

If a program $P$ has a stable model $M$, then $(M)$ is a stable class of $P$. An interpretation $I$ is a fixpoint of $\Gamma_P^2$ iff $(I, \Gamma_P(I))$ is a stable class of $P$.

This approach of van Gelder has been generalized in another direction by Fitting [60], namely, to the case of programs interpreted over four-valued models, or more generally, bilattices.

### 7.4. Properties of the Well-Founded Semantics and Its Extensions

Well-founded semantics has as the drawback that it does not infer all atoms that one would expect to be true. Consider, for example, the program $P = \{ p \leftarrow \neg q; q \leftarrow \neg p; r \leftarrow p; r \leftarrow q \}$. It has two stable models: $p$ is true in one and $q$ is true in the other. In both, $p \lor q$, and therefore $r$, is true. However, $r$ is unknown in the well-founded model.
Numerous semantics have been proposed that extend the well-founded semantics: WFS', WFS+, and EWFS by Dix [45], GWFS by Baral et al. [12], WFS_E by Schlipf [145] (equivalent to WFS+), WFS_E by Hu and Yuan [74], WFS_S by Chen and Kundu [35]; and, finally, the O-semantics by Pereira et al. [111]. The properties of these semantics were investigated in Dix [47, 48].

**Theorem 7.19 (Properties; Dix [47, 48]).**

- The well-founded semantics WFS' and WFS+ are rational.
- EWFS and O-semantics are cautious, but not rational.
- EWFS, WFS_E, and WFS_S do not satisfy the cut rule.
- GWFS is not cautious and, moreover, does not satisfy the principle of partial evaluation.

8. PROGRAM COMPLETION REVISITED

In the previous two sections, we have defined semantics for negation by means of canonical models: stable models and well-founded models. The question arises whether these semantics can be characterized by some form of completion as well—the stationary completion (Definition 7.13) is technically a logical theory, but, because all negative conclusions are stated as facts, it is still very close to a model. Wallace [164] answered this question affirmatively. In this section we summarize his results, which are obtained by defining two simple program transformations and considering the completion of the transformed programs. Then we discuss briefly recent results of Stärk [155, 154].

8.1. Tightened Completion

The standard program completion, as discussed in Section 4 results in a “loose” interpretation of negation, corresponding to the negation as finite failure rule (the Soundness Theorem (Theorem 4.16) and the Completeness Theorem (Theorem 4.17)). In order to obtain a “tight” interpretation of negation, Wallace encoded the iterations of the T^-operator into the program.

**Definition 8.1 (Tightened program).** Let P be a program. The tightened program PT is derived from P as follows, where N is a variable:

- The language of PT consists of LP augmented with a new relation symbol p of arity n + 1 for every relation symbol p of arity n in LP. A new unary function symbol s is also added.
- In each clause of P, the head p(t) is replaced by p(t, s(N)) and each positive literal p(t) in the body is replaced by p(t, N).
- For each relation symbol p in LP, the clause p(x) ← p(x, N) is added.

The tightened completion of a program P is defined as the completion of PT. The following result clarifies the relation between the stable models of a program and its tightened completion.
Theorem 8.2 (Tightened completion; Wallace [163]). The stable models of a program $P$ are precisely the restrictions of the Herbrand models of $\text{comp}(P_T)$ to $L_P$.

8.2. Rounded Completion

As a special case of the previous theorem, one can observe that the tightened completion of a program is inconsistent if and only if the program has no stable models.

One of the motivations for considering three-valued models of the completion in Section 4.3 and well-founded semantics in Section 7 was avoiding inconsistency. The following program transformation, suggested independently by Drabent and Martelli [51] and Wallace [163], results always in a call-consistent program; thus, by Theorem 4.6 its completion is consistent.

Definition 8.3 (Doubled program). Let $P$ be a program. The doubled program (called split program in [51]) $P_D$ is derived from $P$ as follows:

- The language of $P_D$ consists of $L_P$ augmented with a new relation symbol $p'$ of arity $n$ for every relation symbol $p$ of arity $n$ in $L_P$.
- Each clause of $P$ is replaced by two new clauses:
  - In the first clause, each occurrence of a relation symbol $p$ in a negative literal is replaced by $p'$.
  - In the second clause, each occurrence of a relation symbol $p$ in a positive literal or the head of a clause is replaced by $p'$.

The doubled completion (called strict completion in [51]) of a program $P$ is defined as the completion of $P_D$. There is a close connection between the doubled completion of a program and the three-valued interpretation of its standard completion.

Theorem 8.4 (Doubled completion; Drabent and Martelli [51]). Let $P$ be a program and let $L$ be an atom or a ground negative literal. Then

$$\text{comp}(P_D) \models L \iff \text{comp}(P) \models_3 L.$$ 

The tightening and doubling program transformations are orthogonal: $(P_T)_D = (P_D)_T$ is called the rounded program derived from $P$; its completion is called the rounded completion. The following result clarifies the relation between the well-founded model of a program and its rounded completion.

Theorem 8.5 (Rounded completion; Wallace [163]). The well-founded model of a program $P$ consists exactly of those ground literals from $L_P$ that are true in all Herbrand models of the rounded completion of $P$.

Intuitively, one can explain this relation between the rounded completion of a program and its well-founded model through the alternating fixpoint characterization of the latter. We can split a Herbrand model of the rounded completion into two sets, one containing the dashed atoms; the other containing the undashed atoms. By removing the dashes in the first one, two interpretations are obtained. It can be easily seen that $\Gamma_P$ oscillates between them.
Finally, Wallace describes yet another completion—the full completion of a program—which is obtained from the rounded completion by dropping the free equality axioms and adding, for each relation \( p \), the induction axiom

\[

\neg p(x, 0) \land \forall N \left( \neg p(x, N) \rightarrow \neg p(x, s(N)) \right) \rightarrow \forall N \neg p(x, N).
\]

The result is that the effect of the counter in the tightened program is weakened: a loop still leads to failure, but an infinite descending chain does not. For example, the full completion of the program \( \{ p(f(x)) \leftarrow p(x) \} \) entails \( \neg p(t) \) for each ground term \( t \), but it does not entail \( \forall x p(x) \), because there exists a model with infinitely many individuals \( a_1, a_2, \ldots \) such that, for all \( i \), \( a_i = f(a_{i+1}) \). This semantics coincides with the one presented by van Gelder [161].

8.3. Other Approaches

We conclude this section by mentioning two other modifications of completion proposed by Stärk. The first one is called partial completion. As in the definition of a doubled program (Definition 8.3), for each relation symbol \( p \), a new relation symbol \( p' \) of the same arity is introduced. The relations \( p' \) are used in a modified Step 6 of building the completion. Now instead of replacing \( \leftarrow \) by \( \leftarrow \), the formulas \( \forall x (\neg p(x) \leftarrow \neg F) \) are added. Here \( \neg \) behaves like the classical negation with the exception that \( \neg p(t) \) is \( p'(t) \) and \( \neg p'(t) \) is \( p(t) \).

The resulting theory is called partcomp(\( P \)) for partial completion. The usual completion is obtained by adding the axiom \( \forall x (p'(x) \leftarrow \neg p(x)) \) for each relation \( p \). Stärk [155] showed that the Completeness II Theorem (Theorem 5.2) holds when comp(\( P \)) \( \models \) is replaced by partcomp(\( P \)) \( \models \). This result generalizes Theorem 5.2 because Stärk also showed that for all queries \( Q \), we have partcomp(\( P \)) \( \models \forall Q \) iff comp(\( P \)) \( \models \forall \neg Q \) and partcomp(\( P \)) \( \models \forall \neg Q \) if comp(\( P \)) \( \models \forall Q \).

Then, in Stärk [154], a modification of this approach dealing with Prolog is proposed. To this end the SLDNF resolution with the leftmost selection rule is related to a theory called \( \mathcal{S} \)comp(\( P \)). This theory is a modification of comp(\( P \)) obtained by introducing for each relation symbol \( p \), three new relation symbols, \( p^s \), \( p^f \), and \( p' \), with the intuitive meaning "\( p \) succeeds," "\( p \) (finitely) fails," and "\( p \) terminates." \( \mathcal{S} \)comp(\( P \)) is build in a similar way as partcomp(\( P \)), but now the construction involves three operators, \( S \), \( F \), and \( T \), which transform the queries of the original language into formulas of the enriched language which includes the relation symbols \( p^s \), \( p^f \), and \( p' \). A typical and crucial law is \( F(L_1 \land L_2) = FL_1 \lor (TL_1 \land FL_2) \), which intuitively expresses when the query \( L_1 \lor L_2 \) finally fails w.r.t. the SLDNF resolution with the leftmost selection rule. The corresponding result connects this resolution method with \( \mathcal{S} \)comp(\( P \)) in a way analogous to the Completeness II Theorem (Theorem 5.2). This generalizes, in an essential way, a completeness result of Stroetman [157], where only terminating programs are considered.

9. PROOF THEORY III: SLS RESOLUTION

SLS resolution is a modified version of SLD resolution that can deal with stratified programs rather than just definite (i.e., positive) programs (hence the second "S" relacing the "D"). In fact, similar resolution methods for all general programs are
also called SLS resolution. First, we present the definition for stratified programs
due to Przymusinski [118] (or more precisely a mild generation to locally stratified
programs adapted from Bol [23]).

The main difference with SLDNF resolution is that the computation-oriented
negation as finite failure rule is replaced by the more idealistic negation as (not
necessarily finite) failure rule. As a consequence, SLS resolution is not effective: an
implementation can only approximate it. In contrast, SLDNF resolution can be
implemented, but not in a straightforward way: the sets of SLDNF successful and
finitely failed queries are recursively enumerable, but not by building SLDNF trees
via all (possibly infinitely many) selection rules.

Example 9.1 (SLDNF versus SLS resolution). Let \( P = \{ p \leftarrow \neg q; q \leftarrow \neg r, \neg s; r \leftarrow s \} \). For the query \( p \), we have the following trees (where needed, selected
literals are underlined; \( \rightarrow \) denotes the subs relation between nodes and trees):

\[
\begin{align*}
\text{unsuccessful SLDNF tree} & & \text{successful SLDNF tree} & & \text{SLS tree} \\
p & & p & & p \\
\neg q \rightarrow q & & \neg q \rightarrow q & & \neg q \rightarrow q \\
\neg r, \neg s \rightarrow r & & \neg r, \neg s \rightarrow s & & \neg r, \neg s \rightarrow r \\
r & & \text{fail} & & s \leftarrow \neg s, r \\
r & & & & \text{fail} \\
\vdots & & & & \vdots
\end{align*}
\]

We see (in the middle picture) that using the rightmost selection rule yields a
finite and successful SLDNF tree, which is also an SLS tree. However, using the
leftmost selection rule yields an infinite and unsuccessful SLDNF tree (left picture).
Thus the value of the completeness results for SLDNF resolution, stating the
existence of a successful SLDNF tree, is limited. The rightmost picture shows that
the SLS tree via the leftmost selection rule is successful, although infinite.

9.1. SLS Resolution for Locally Stratified Programs

We now provide a formal definition of SLS resolution for locally stratified pro-
grams using the concepts introduced in Section 3.2 when defining SLDNF resolu-
tion.
Definition 9.2 (Stratum). Let \( P \) be a program that is locally stratified w.r.t. \( \text{stratum} \).
- For an atom \( A \), not necessarily ground, we define \( \text{stratum}(A) = \sup\{ \text{stratum}(Ag) \mid Ag \text{ is a ground instance of } A \} \).
- For a negative literal \( \neg A \), not necessarily ground, we define \( \text{stratum}(\neg A) = \text{stratum}(A) + 1 \).
- We define \( \text{stratum}(\Box) = 0 \) and for a query \( Q = L_1, \ldots, L_n (n > 0) \), \( \text{stratum}(Q) = \max\{ \text{stratum}(L_i) \mid i \in [1, n] \} \).

Definition 9.3 (SLS tree). An SLS tree is a forest \( \mathcal{F} \), whose nodes are (possibly marked) queries of (possibly marked) literals. (The markers are the same as in SLDNF trees.) The function \( \text{subs} \) assigns to nodes containing a marked negative ground literal \( \neg A \) a tree in \( \mathcal{F} \) with root \( A \).

A tree is successful if it has a leaf marked as success. A tree is floundered if it has a leaf marked as floundered. Hence a tree may be both successful and floundered. A tree is failed if it is neither successful nor floundered.

Let \( P \) be a locally stratified program and let \( R \) be a selection rule. For every query \( Q \), we define the SLS tree \( \mathcal{F} \) for \( P \) and \( Q \) via \( R \) by induction on \( \text{stratum}(Q) \). The root of the main tree \( T \) of \( \mathcal{F} \) is \( Q \). For any node \( N \) in \( T \) we have:
- If \( N \) is the empty query, then \( N \) is marked as success and has no children.
- If \( R \) selects a positive literal \( L \) in \( N \), then \( N \) has as children the nodes that are obtained by extending \( T \) at \( N \) in the sense of Definition 3.5. If no children can be obtained in this way, then \( N \) is marked as failed.
- If \( R \) selects a negative literal \( \neg A \) in \( N \), then:
  - If \( A \) is nonground, then \( N \) has no children and is marked as floundered.
  - If \( A \) is ground, then \( \text{stratum}(A) < \text{stratum}(Q) \); thus, the SLS tree \( (\mathcal{F}', T', \text{subs}') \) for \( P \) and \( A \) via \( R \) is already defined. Then set \( \text{subs}(N) \) to \( T' \), extend \( \text{subs} \) by \( \text{subs}' \), and extend \( \mathcal{F} \) by \( \mathcal{F}' \).
    * If \( T' \) is successful, then \( N \) has no children and is marked as failed.
    * Otherwise, if \( T' \) is floundered, then \( N \) has no children and is marked as floundered.
    * Otherwise, \( T' \) is failed and the resolvent \( (e, N - \{ \neg A \}) \) is the only child of \( N \). (Thus, in contrast to SLDNF trees, finiteness of \( \mathcal{F}' \) is not required here.)

Definition 9.4 (Computed answer substitution). Let \( P \) be a locally stratified program and \( Q \) a query. Consider a branch in the main tree \( T \) of an SLS tree for \( P \) and \( Q \) which ends with the empty query. Let \( \alpha_1, \ldots, \alpha_n \) be the consecutive substitutions along this branch.

Then the restriction \( (\alpha_1 \cdots \alpha_n)Q \) of the composition \( \alpha_1 \cdots \alpha_n \) to the variables of \( Q \) is called an SLS computed answer substitution (c.a.s. for short) for \( Q \) in \( T \).

We saw in Section 4.4 that SLDNF resolution is sound w.r.t. the program completion, \( \text{comp}(P) \). A natural question arises: w.r.t. which semantics is SLS
resolution sound? The answer was provided by Przymusinski [118]—it turns out that SLS resolution is a proof-theoretic counterpart of the perfect model semantics. More precisely, he established the following results.

**Theorem 9.5 (Soundness).** Let $P$ be a locally stratified program, $Q$ a query, and $R$ a selection rule. Let $M_P$ be the unique perfect Herbrand model of $P$. Consider the main tree $T$ of the SLS tree for $P$ and $Q$ via $R$.

- If $\tau$ is a c.a.s. for $Q$ in $T$, then $M_P \models \forall Q\tau$.
- If $T$ is failed, then $M_P \not\models \forall \neg Q$.

**Corollary 9.6.** SLS resolution for locally stratified programs is also sound w.r.t. the unique stable model semantics and well-founded semantics.

**Theorem 9.7 (Completeness).** Let $P$ be a locally stratified program, $Q$ a query, and $R$ a selection rule. Let $M_P$ be the unique perfect model of $P$. Consider the main tree $T$ of the SLS tree for $P$ and $Q$ via $R$. Suppose $T$ does not flounder.

- If $M_P \models \forall Q\tau$, then there is a c.a.s. $\alpha$ for $Q$ in $T$ such that $Q\alpha$ is more general than $Q\tau$.
- If $M_P \models \forall \neg Q$, then $T$ is failed.

**Corollary 9.8.** SLS resolution for locally stratified programs is also complete in the absence of floundering w.r.t. the unique stable model semantics and well-founded semantics.

### 9.2. SLS-Resolution for General Programs

Although its name suggests that SLS resolution can only be used for stratified programs, several proposals for top-down computation of the well-founded semantics are also called SLS resolution. The one we found in the literature, which we discuss in this section, all have the disadvantage of requiring a *positivistic* selection rule. This means that a negative literal is selected only if no more positive literals are available.

Przymusinski [122] observed that (a suitable variant of) the iterated least fixpoint definition of the well-founded semantics suggests a *dynamic stratification* of the program: if a ground atom $A$ is decided (becomes true or false) in iteration $\alpha$, then $\alpha$ is the dynamic stratum of $A$. An SLS derivation for an atom $A$ in stratum $\alpha$ is defined by induction on $\alpha$ and consists now of two phases.

In the first phase, positive literals are selected and the derivation proceeds like an SLD derivation. This derivation *fails* if it is finitely failed or diverges. If the derivation does not fail in this phase, then it ends in a query with only negative literals (possibly none).

In the second phase, ground negative literals $\neg B$, for which the stratum of $B$ is less than $\alpha$, are selected one by one. By induction on the stratum, the SLS tree $T$ for $B$ is already defined. This case is handled as in Definition 9.3:

- If $T$ is contains the empty query, then the derivation fails.
- Otherwise, if $T$ contains a floundering derivation, then the derivation flounders.
Otherwise, \( \neg B \) is removed; the derivation continues with the remaining negative literals.

If the derivation completes both phases, then there are three possible outcomes:

- If the derivation ends in the empty query, then it is successful.
- If the derivation ends in a query containing a nonground negative literal, then it flounders.
- Otherwise, the derivation ends in an undefined leaf.

In addition to the ineffective negation as failure rule, here also the criteria for the selection rule seem to be very ineffective: how can we compare the strata of atoms without computing their truth value in the well-founded model? Przymusinski remarks ([122], Remark 9.1) that the requirement translates into “no negative recursion is allowed in the derivation.” Thus, an interpreter implementing this form of resolution may select a “wrong” negative literal, find that it leads to negative recursion, and “backtrack” over the selection. A problem with this approach is that in this way, part of the search of the interpreter is not represented in the resulting SLS tree.

In later versions [115, 131], a sequence of “SLS-trees of rank \( \alpha \)” is created, in which negative literals are decided on the basis of an SLS tree of a one lower rank, if possible, and skipped otherwise. Skipping here means that another literal is selected. The selection rule is not explicitly required to be positivistic, but in the SLS tree of rank 1, all negative selected literals will be skipped; thus, the effect is that of a positivistic selection rule. (An SLS tree of rank \( \alpha + 1 \) extends the tree of rank \( \alpha \) only at its nodes that contain exclusively skipped negative literals.)

Another hidden property of this selection mechanism is that negative literals are effectively selected in parallel: for each of them, resolution is tried at each rank (until one fails or until they have all succeeded). A positivistic selection rule that is negatively parallel (selects all negative literals at once) is explicitly used by Ross [138]; it is called preferential.

Ross defines SLP trees (the “P” stands for “positivistic”) as the result of the first phase described above. Then he defines global SLS resolution by means of global SLS trees as follows.

**Definition 9.9 (Global SLS tree).** A global tree \( \Gamma \) for a query \( Q \) has three types of nodes:

- Tree nodes, which are labeled by SLP trees for intermediate goals.
- Negation nodes, which are labeled by a query with only negative literals (possibly none).
- Nonground nodes, which have no label.

The root of \( \Gamma \) is the SLP tree for \( Q \).

Each tree node \( T \) in \( \Gamma_G \) has negation nodes as its children: if \( Q \) is a leaf of \( T \) that contains only negative literals, then \( Q \) is a child of \( T \) in \( \Gamma_G \).

Each negation node \( Q = \neg A_1, \ldots, \neg A_n(n \geq 0) \) has \( n \) children: for \( i \in [1, n] \), if \( A_i \) is ground, then the child is a tree node, namely, the SLP tree for \( A_i \); otherwise the child is a nonground node.
Every node in a global tree has a *status*: successful, failed, indeterminate, or floundered.

**Definition 9.10 (Status of nodes).** Consider a global tree:

- A nonground node is always **floundered**.
- A negation node is **failed** if one of its children is successful, **successful** if all its children are failed, **floundered** if none of its children is successful, and at least one is floundered.
- A tree node is **failed** if all its children are failed, **successful** if one of its children is successful, **floundered** if one of its children is floundered.
- Nodes that are not assigned a status according to these rules are **indeterminate**.

A tree node can be both successful and floundered, but no other status pair is possible for a single node.

**Definition 9.11.** Let $Q$ be a query. Let $T$ be the root node of a global SLS tree $\Gamma$ for $Q$ (thus $T$ is an SLP tree for $Q$). A *successful branch* of $T$ is a branch that ends in a leaf labeled $N$, such that the corresponding negation node labeled $N$ is successful. The *computed answer substitution* of a successful branch is, again, the composition of the consecutive substitutions along the branch, restricted to the variables of $Q$.

Ross [138] proved the following results.

**Theorem 9.12 (Soundness).** Let $P$ be a program and $Q$ a query. Let $\Gamma$ be a global SLS tree for $Q$.

- If $\theta$ is a computed answer substitution in $\Gamma$, then $\mathsf{WFM}(P) \models \forall(Q\theta)$.
- If the root of $\Gamma$ is failed, then $\mathsf{WFM}(P) \models \forall(\neg Q)$.

**Theorem 9.13 (Completeness).** Let $P$ be a program and $Q$ a query. Let $\Gamma$ be a nonfloundering global SLS tree for $Q$.

- If $\mathsf{WFM}(P) \models \exists Q$, then the root of $\Gamma$ is successful.
- If $\mathsf{WFM}(P) \models \forall(\neg Q)$, then the root of $\Gamma$ is failed.
- If $\mathsf{WFM}(P) \models \forall(Q\theta)$, then there is a computed answer substitution $\sigma$ in $\Gamma$ such that $G\sigma$ is more general than $G\theta$.

### 9.3. SLS Resolution for General Programs via all Selection Rules

In this section, we present a definition of SLS resolution that deals with all general programs and all selection rules; it is new, to the best of our knowledge. As the first step, we define *oracle* SLS trees. In these trees, we resolve selected positive literals...
against program clauses, as usual, but ground negative literals are resolved by using the well-founded model as an oracle. Thus we eliminate all negative recursion. The oracle produces one of the answers true, false, and unknown. In order to record the last case properly, substitutions may be annotated by u in the following definitions.

**Definition 9.14 (Oracle SLS tree).** Let $P$ be a program and $R$ a selection rule. For a query $Q$, we define the oracle SLS tree $T$ for $P$ and $Q$ via $R$ as follows. The root of $T$ is $Q$. For any node $N$ in $T$ we have:

- If $N$ is the empty query, then $N$ is marked as success and has no children.
- If $R$ selects a positive literal $L$ in $N$, then $N$ has as children those nodes that can be obtained by extending $T$ at $N$ in the sense of Definition 3.5. If no children can be obtained in this way, then $N$ is marked as failed.
- If $R$ selects a negative literal $\neg A$ in $N$, then:
  - If $A$ is nonground, then $N$ has no children and is marked as floundered.
  - If $A$ is ground, then:
    * If $A$ is true in $WFM(P)$, then $N$ has no children and is marked as failed.
    * If $A$ is false in $WFM(P)$, then the resolvent $(\epsilon, N - \{\neg A\})$ is the only child of $N$.
    * If $A$ is unknown in $WIMP$), then the resolvent $((u, \epsilon), N - \{\neg A\})$ is the only child of $N$.

**Definition 9.15 (Oracle answer substitution).** Let $P$ be a program and $Q$ a query. Consider a branch in an oracle SLS tree $T$ for $P$ and $Q$ which ends with the empty query. Let $\alpha_1, \ldots, \alpha_n$ be the consecutive substitutions along this branch.

Then the restriction $(\alpha_1 \cdots \alpha_n)\langle Q$ of the composition $\alpha_1 \cdots \alpha_n$ to the variables of $Q$ is called an oracle SLS-computed answer substitution (o.c.a.s. for short) for $Q$ in $T$, if none of the substitutions $\alpha_i$ is annotated by $u$; otherwise it is called an oracle SLS-unknown answer substitution (o.u.a.s. for short) for $Q$ in $T$.

An oracle SLS tree $T$ for a query $Q$ is:

- Successful if it gives an o.c.a.s. for $Q$.
- Floundered if it contains a leaf marked as floundered.
- Indeterminate if it is not successful and not floundered, and gives an o.u.a.s. for $Q$.
- Failed, otherwise.

The following results relate oracle SLS trees to the well-founded semantics.

**Lemma 9.16 (Soundness).** Consider an oracle SLS tree $T$ for a program $P$ and a query $Q$.

- If $\tau$ is a o.c.a.s. for $Q$ in $T$, then $WFM(P) \models_3 \forall Q\tau$.
- If $\tau$ is a o.u.a.s. for $Q$ in $T$, then $WFM(P) \not\models_3 \neg \forall Q\tau$.
- If $T$ is failed, then $WFM(P) \not\models_3 \forall \neg Q$.
Lemma 9.17 (Completeness). Consider an oracle SLS tree $T$ for a program $P$ and a query $Q$. Suppose $T$ does not flounder.

- If $\text{WFM}(P) \vdash_3 \forall Q\tau$, then there is an o.c.a.s. $\sigma$ for $Q$ in $T$ such that $Q\sigma$ is more general than $Q\tau$.

- If $\text{WFM}(P) \nvdash_3 \neg \forall Q\tau$, then there is an o.c.a.s. or an o.u.a.s. $\sigma$ for $Q$ in $T$ such that $Q\sigma$ is more general than $Q\tau$.

- If $\text{WFM}(P) \vdash_3 \forall \neg Q$, then $T$ is failed.

Proving these lemmas is straightforward: negative literals are given their correct truth value by definition; positive literals are treated as in SLD resolution.

These results allow the second step of the construction of the SLS tree. For all nodes $N$ where a ground negative literal $\neg A$ is selected and the oracle is used, we can “justify” the outcome of the oracle by a subsidiary oracle SLS tree for $A$. Either this tree produces the same answer as the oracle or it flounders. In the latter case, the descendants of $N$ are removed and $N$ becomes a flounder leaf. By recursively adding subsidiary trees for all nodes where the oracle was used, no step involving a selected ground negative literal will remain unjustified.

Definition 9.18 (SLS tree). Let $P$ be a program, $Q$ a query, and $R$ a selection rule.

An SLS tree for $P$ and $Q$ via $R$ is defined as the limit of a sequence of oracle SLS trees of depth $n$ ($n \geq 1$). These are defined by induction. An oracle SLS tree of depth 1 for $P$ and $Q$ via $R$ consists of only one tree, which is the oracle SLS tree for $P$ and $Q$ via $R$. For $n > 1$, an oracle SLS tree of depth $n$ for $P$ and $Q$ via $R$ is a forest $(\mathcal{F}, T, \text{subs})$ obtained as follows.

The main tree $T$ is the oracle SLS tree for $P$ and $Q$ via $R$, of which some nodes can be removed. From the root, follow each branch and for every ground negative literal $\neg A$ selected in a node $N$ in $T$, let $(\mathcal{F}', T', \text{subs}')$ be the oracle SLS tree of depth $n - 1$ for $P$ and $A$ via $R$, set $\text{subs}(N)$ to $T'$, and extend $\text{subs}$ by $\text{subs}'$ and $\mathcal{F}$ by $\mathcal{F}'$. If $T'$ is floundered and not successful, then mark $N$ as floundered and remove the children of $N$, if any.

The following results relate SLS trees to the well-founded semantics.

Theorem 9.19 (Soundness). Consider the main tree $T$ of an SLS tree for a program $P$ and a query $Q$.

- If $\tau$ is an o.c.a.s. for $Q$ in $T$, then $\text{WFM}(P) \vdash_3 \forall Q\tau$.

- If $\tau$ is an o.u.a.s. for $Q$ in $T$, then $\text{WFM}(P) \nvdash_3 \neg \forall Q\tau$.

- If $T$ is failed, then $\text{WFM}(P) \vdash_3 \forall \neg Q$.

Theorem 9.20 (Completeness). Consider the main tree $T$ of an oracle SLS tree for a program $P$ and a query $Q$. Suppose $T$ does not flounder.

- If $\text{WFM}(P) \vdash_3 \forall Q\tau$, then there is an o.c.a.s. $\sigma$ for $Q$ in $T$ such that $Q\sigma$ is more general than $Q\tau$.

- If $\text{WFM}(P) \nvdash_3 \neg \forall Q\tau$, then there is an o.c.a.s. or an o.u.a.s. $\sigma$ for $Q$ in $T$ such that $Q\sigma$ is more general than $Q\tau$.

- If $\text{WFM}(P) \vdash_3 \forall \neg Q$, then $T$ is failed.
Remark 9.21. Instead of the well-founded model of the program, any stationary model can be used as the oracle in the above definitions. The (oracle) SLS trees, obtained using the stationary model $M$ as the oracle, will be sound and complete (in the above sense) w.r.t. $M$.

Although we have defined SLS trees in such a way that they are sound and complete w.r.t. the well-founded semantics, it is not at all clear how an interpreter could construct these trees in a top-down way. This brings us to the issue of implementation.

9.4. Implementation

As mentioned before, SLS resolution is not effective; thus, it is not fully implementable. However, it is possible to make a sound implementation that is complete for a limited class of programs, e.g., programs without function symbols. It is then essential to capture those infinite derivations that have the form of a loop. This can be done by simple loop checking techniques or by tabulation (also known as memoization or lemma resolution).

For locally stratified programs, loop checking was studied by Bol [23]. Tabulation for stratified programs was studied by Kemp and Topor [78] and by Seki and Itoh [146]. By definition, in this setting only positive loops have to be dealt with. So their approach can remain close to tabulation for positive programs by maintaining a table for each stratum.

Chen and Warren [36] added a tabulation mechanism to the form of SLS resolution proposed by Przymusinski and Warren [123, 131] in order to detect positive loops. Negative loops are detected by maintaining a negative context: the set of negative literals that may be assumed undefined because they are encountered in a loop. In this way the tables must be constructed for all relevant negative contexts. This gives many redundant computations and a rather complex result (the final construction is a forest of forests . . . ). Bidoit and Legay [22] proposed a similar system, computing the defined atoms and the potentially defined atoms separately.

Recently, Bol and Degerstedt [24] proposed a simpler method that uses tabulation to detect both positive and negative loops. Only one table needs to be constructed, but their definition of failure is somewhat complicated.

Finally, it should be mentioned that a top-down computation of the well-founded semantics for ground programs is described by Pereira et al. [110]; instead of tabulation, it uses both positive and negative contexts. Such use of positive contexts does not generalize to the nonground case (as was shown by Apt et al. [9]).

10. DISJUNCTIVE PROGRAMS

In a disjunctive logic program, the heads of clauses can be disjunctions of one or more atoms. Numerous semantics were proposed for such programs. They are classified in Dix [44].

Positive disjunctive programs allow the expression of indefinite (incomplete) knowledge, which is impossible in definite programs. As examples, consider the
following natural statements:

\[
\text{mother}(X) \lor \text{father}(X) \leftarrow \text{parent}(X),
\]

\[
\text{red}(X) \lor \text{blue}(X) \lor \text{green}(X) \leftarrow \text{primary\_colour}(X).
\]

The addition of negation allows us to express indefinite knowledge as well, so one may wonder whether there is any use in allowing disjunctions in general logic programs. Indeed there is: because negation in logic programming is not classical negation, the effect of a clause \( p \leftarrow \neg q \) is quite different from \( p \lor q \). The pair \( \{ p \leftarrow \neg q; q \leftarrow \neg p \} \) is a better approximation—at least it retains the symmetry between \( p \) and \( q \)—but it is still not adequate. It introduces a loop through negation, which renders some semantics inapplicable and causes obvious problems in the proof theory. Furthermore, the well-founded model of the program \( \{ p \leftarrow \neg q; q \leftarrow \neg p; r \leftarrow p; r \leftarrow q \} \) does not contain \( r \), as one might expect.

10.1. Positive Disjunctive Programs

Lobo et al. [92] recently published a book about the foundations of disjunctive logic programming, of which the larger part deals with positive programs. We shall briefly recall some semantics for positive disjunctive programs; for a more elaborate discussion, motivation, and proof theory, we refer to this book.

An important distinction, which can be made already for positive disjunctive programs, is that between an inclusive and exclusive interpretation of disjunctions. For example, if we have the program \( \{ p \leftarrow p \lor q \} \), then the exclusive reading concludes that \( q \) is false, whereas the inclusive reading does not conclude anything about \( q \).

Recall that, for definite programs, the negation as (finite or infinite) failure rule can be viewed as the application of the closed world assumption (see Section 1.2)

\[
P \models_{CWA} \neg A \text{ iff } P \not\models A.
\]

This rule must be rephrased for disjunctive programs, because in this form it gives rise to inconsistencies. Indeed, we have \( p \lor q \models_{CWA} \neg p \) and \( p \lor q \models_{CWA} \neg q \), so \( P \cup \{ \neg A \mid P \models_{CWA} \neg A \} \) is inconsistent.

The generalized closed world assumption (GCWA) of Minker [102] is such a rephrasing. It says

\[
P \models_{GCWA} \neg A \text{ iff } \neg A \text{ is true in all minimal models of } P.
\]

GCWA gives rise to an exclusive interpretation of disjunctions.

The weak generalized closed world assumption (WGCWA) was developed independently by Lobo et al. [132] and by Ross and Topor [139]. It was originally defined as a computational simplification of GCWA that infers less negative literals. Let \( P^* \) be the program obtained from \( P \) by replacing \( \lor \) by \( \land \), i.e., a clause \( A_1 \lor \cdots \lor A_n \leftarrow B \) in \( P \) yields the clauses \( A_1 \leftarrow B \cdots A_n \leftarrow B \) in \( P^* \). Then

\[
P \models_{WGCWA} \neg A \text{ iff } P^* \models_{CWA} \neg A.
\]

WGCWA gives rise to an inclusive interpretation of disjunctions. Notice that CWA, GCWA, and WGCWA coincide on definite programs.

Even less negative literals than from WGCWA can be inferred from the completion of a disjunctive program, which was defined by Lobo et al. [91, 92]. It
consists of $P$, augmented with $EQ$ and the only-if (i.e., $\rightarrow$) part of the completion of $P^*$.

Theorem 10.1 (Dix [44]). WGCWA is rational and GCWA is cumulative, but not rational.

The program $P = \{ p \lor q \leftarrow r \leftarrow p ; s \leftarrow q, r \}$ is a counterexample against the rationality of GCWA. The minimal models of $P$ are $\{p, r\}$ and $\{q\}$; thus, $P \not\models_{GCWA} \neg r$ and $P \models_{GCWA} \neg s$. However, $P \cup \{r\}$ has the minimal models $\{p, r\}$ and $\{q, r, s\}$; thus, $P \cup \{r\} \not\models_{GCWA} \neg s$. Notice that $P \not\models_{WGCWA} \neg s$.

10.2. Locally Stratified Disjunctive Programs

The definition of locally stratified programs can be generalized to disjunctive programs: if two atoms are disjuncts in the head of a ground instance of a program clause, then these atoms must be in the same stratum. The definition of perfect models (Definition 6.8) generalizes immediately to locally stratified disjunctive programs. Of course, a disjunctive program may have more than one perfect model.

Definition 10.2 (Perfect model semantics; Przymusinski [126]). The perfect model semantics of a disjunctive program $P$ is defined by putting, for a ground atom $A$,

$A$ is true (false), if $A$ is true (false) in all perfect models of $P$.

Definition 10.3 (Weak perfect model semantics; Dix [44]). The weak perfect model semantics of a disjunctive program $P$ is defined by putting, for a ground atom $A$,

$A$ is true (false), if $A$ is true (false) in all perfect models of $P$ and in the perfect model of $P^*$. $^5$

Again, perfect model semantics interprets disjunctions exclusively, whereas weak perfect model semantics interprets inclusively. Perfect model semantics extends GCWAS, the generalized closed world assumption for stratified programs, which was defined by Rajasekar and Minker [133]. A weak version of GCWAS, called WGCWAS, was defined by Dix [44]; weak perfect model semantics extends it.

Theorem 10.4 (Dix [44]).

- Perfect model semantics and GCWAS coincide with GCWA on positive disjunctive programs.
- Weak perfect model semantics and WGCWAS coincide with WGCWA on positive disjunctive programs.
- Perfect model semantics, GCWAS, weak perfect model semantics, and WGCWAS are cumulative.
- Of these semantics, only WGCWAS is rational.

$^5$ Notice that $P^*$ is a locally stratified program, because $P$ is a locally stratified disjunctive program.
10.3. General Disjunctive Programs

Semantics for all general disjunctive programs that coincide with the well-founded semantics on general programs, and that also coincide with the perfect (or weak perfect) model semantics on locally stratified disjunctive programs, have been proposed by Przymusinski [119] and by Dix [44].

Przymusinski defines stationary expansions of disjunctive programs by generalizing Definition 7.13 in the following ways.

- Instead of a set of not \_A atoms, a set C of disjunctions of not \_A atoms is added to the program \( P \).
- The second condition on interpretations that are considered when determining minimal models is generalized to the disjunctive inference rule:

  \[
  \text{if } P \cup C \models A_1 \lor \cdots \lor A_n, \\
  \text{ then } I \models \text{not}_A \lor \cdots \lor \text{not}_A \rightarrow A_{k+1} \lor \cdots \lor A_n,
  \]

  where \( 1 \leq k \leq n \) and the empty disjunctive is interpreted as false.
- For a negative disjunction \( F = \neg A_1 \lor \cdots \lor \neg A_n \), \( P \cup C \models_{min} F \) if \( F \) is true in all minimal models of \( P \cup C \) (according to this particular notion of minimality).
- The fixpoint equation that defines stationary expansions becomes

  \[
  E(P) = P \cup \{\text{not}_A \lor \cdots \lor \text{not}_A \mid E(P)^{\leq_{min} \neg A_1 \lor \cdots \lor \neg A_n}\}. 
  \]

In another version of the semantics, Przymusinski used

\[
\text{if } P \cup C \models_{min} \neg A_1 \lor \cdots \lor \neg A_n, \\
\text{ then } I \models A_1 \land \cdots \land A_k \rightarrow \text{not}_A \lor \cdots \lor \text{not}_A
\]

as the disjunctive inference rule (which implicitly makes the definition of \( \models_{min} \) recursive). Dix [44] reformulates and compares these two versions, together with a third version (using essentially the first disjunctive inference rule, restricted to \( k = n \)). This third version is weaker than the perfect model semantics on locally stratified disjunctive programs.

Dix also defines weak stationary semantics: a weak stationary extension satisfies the fixpoint equation

\[
E(P) = P \cup \{\text{not}_A \lor \cdots \lor \text{not}_A \mid E(P)^{\models_{min} \neg A_1 \lor \cdots \lor \neg A_n}\}. 
\]

(This disjunctive inference rule is the third one of those mentioned above.) Weak stationary semantics interprets disjunctions inclusively.

**Theorem 10.5 (Dix [44]).**

- Stationary semantics for disjunctive programs is not cumulative.
- Weak stationary semantics is cumulative, but not rational.
- For locally stratified disjunctive programs, weak stationary semantics decides more atoms than WGCWAS, but less than weak perfect semantics.

Finally, Dix [44] defines a semantics, DWFS, which coincides with the well-founded semantics on general programs, and with the perfect model semantics on
locally stratified disjunctive programs. It is weaker than the stationary semantics, and cumulative. A weak version of it, WDWFS, also coincides with the well-founded semantics on general programs and with the weak perfect model semantics on locally stratified disjunctive programs. It is stronger than weak stationary semantics, and cumulative.

A rather different approach is taken by Ross [137]: he defines a semantics for general disjunctive programs through a top-down procedure generalizing Definition 9.9. He defines three versions: strong well-founded semantics, with an exclusive interpretation of disjunctions; weak well-founded semantics, with an inclusive interpretation of disjunctions; and finally optimal well-founded semantics, where the program(mer) defines the inclusive or exclusive nature separately for each clause. On general programs, these semantics coincide with the well-founded semantics. However, when restricted to locally stratified disjunctive programs, the strong version is weaker than perfect model semantics and the weak version is weaker than weak perfect model semantics.

Two fixpoint semantics that extend the stationary semantics are GDWFS and WF^3 by Baral et al. [13, 14] and Lobo et al. [93]. WF^3 extends GDWFS; both coincide with GWFS on general programs (thus they are not cautious and do not satisfy PPE, the properties defined in Section 1.3). They are incomparable with perfect model semantics on locally stratified disjunctive programs.

Sakama and Inoue [143] defined GCWA→ and WGCWA→, based on an extension of stable models to disjunctive programs. These semantics coincide with perfect, respectively weak perfect, model semantics on locally stratified disjunctive programs.

Clearly, the issue of what is the right semantics for general disjunctive programs is far from being decided. Its seems that the weaker semantics have some advantages:

- They are cumulative and satisfy Dix's weak principles.
- The complexity of computing them is sometimes lower (for example WGCWA has lower complexity than GCWA, but the complexity of perfect and weak perfect model semantics is the same; see also Müller and Dix [105]),
- Uncertainty is safe, that is, if the semantics draws more conclusions from the program than the programmer intended, then the results are probably worse than when some intended conclusions are missed.

11. FINAL REMARKS

We introduced in this paper two lines of research dealing with semantics of general programs. The first one was considered in Section 4 and focused on the completion of a program. The second line was considered in Sections 6 and 7 and focused on various attempts to extend the concept of a “special” Herbrand model to general programs. In each category we studied a number of proposals which resulted in quite an array possibilities.

11.1. Reconciliation

It is useful to characterize a class of programs for which these approaches coincide. This problem was considered by Apt and Bezem [3], who showed that for acyclic
programs, practically all approaches considered in this paper coincide. More specifically, they proved the following result:

**Theorem 11.1.** Let $P$ be an acyclic program. Then:

- The $T_p$ operator has a unique fixpoint, $N_p$.
- $N_p$ is a unique fixpoint of the $T_{3p}$ operator.
- $N_p$ is a unique perfect model of $P$.
- $N_p$ is a unique Herbrand model of $\text{comp}(P)$.
- SLDNF and SLS trees coincide for bounded queries.

Consequently, by the Fixpoint Lemma (Lemma 4.12), $N_p$ is also a unique three-valued Herbrand model of $\text{comp}(P)$. Additionally, because every acyclic program is locally stratified, by the Unique Stable Model Theorem (Theorem 6.20), $N_p$ is also a unique stable model of $P$ and, consequently, by Corollary 7.9 it is the well-founded model of $P$, as well.

These results were generalized by Apt and Pedreschi [51] to a larger class of programs corresponding to termination w.r.t. the leftmost selection rule, as opposed to termination w.r.t. all selection rules (in the sense of the Terminating Program Definition (Definition 3.16)). Recently, Fitting [61] provided an alternative proof of these results by means of metrics and the Banach contraction theorem.

A number of interesting programs turn out to be acyclic. By the above theorem, all approaches to their semantics coincide. For instance, the program `TWEETY` of Section 1.3 and the programs `SINK`, `NUMBERS`, and `EVEN` of Sections 3.1, 5, and 6.2 are acyclic. Another example is a natural formalization of the so-called Yale shooting problem of Hanks and McDermott [72], which is an example of temporal reasoning, an instance of nonmonotonic reasoning. This problem was extensively discussed in the literature and its formalizations in various formalisms for nonmonotonic reasoning were studied. In relation to logic programming, we note three independent references—that of Apt and Bezem [3], who proved that the translation of the Yale shooting problem to logic program results in an acyclic program, Elkan [54], who showed that this translation results in a locally stratified program, and Evans [56], who observed that SLDNF resolution can be used to compute desired consequences of the original formulation of the problem in first-order logic.

In contrast, the program `EVEN'` of Section 6.2 is not locally stratified, so a fortiori not acyclic. However, it is possible to apply to it a result of Apt and Pedreschi [5] and draw the same conclusions as for the above programs.

### 11.2. Topics Not Treated

The range of topics that fall within "logic programming and negation" is so enormous that inevitably we have to refrain from treating them all. Here follows a short list of topics we left out.

**Deductive databases** form an extension of relational databases in which some of the relations are implicitly defined. Ignoring the built-in relations, their syntax coincides with that of logic programs. In the area of deductive databases, negation also formed an important research subject. Parts of this research (like stratification and the use of perfect model semantics) overlap with that of logic programming.
Some other topics are more intrinsic for the field, in particular query processing (see, e.g., Kemp and Topor [78] and Balbin et al. [11]), integrity constraint checking (see, e.g., Lloyd et al. [90] and Sadri and Kowalski [142]), handling of updates (see, e.g., Naqvi and R. Krishnamurthy [108]), and comparison of expressive power between various query languages (see, e.g., Chandra and Harel [34]). More recent research in this area is surveyed in Kanellakis [77] and Bidoit [19].

Classical negation, also called explicit or strong negation, was introduced by Gelfond and Lifschitz [67, 68]. It involves a second kind of negation that may occur both in the head and in the body of clauses. Their motivation was to capture, in logic programming, forms of temporal reasoning more complicated than the one exemplified in the usual formalization of the Yale shooting problem.

When both kinds of negation are present, ￢ usually denotes classical negation; negation by failure is then denoted by ￢. Semantically, classically negated atoms are usually treated as new atoms. However, in the process of selecting “intended” models, the “inconsistent” ones (that is, the ones containing an atom A and its classical negation ￢A) are discarded. Overviews of this area can be found in Alferes and Pereira [1], Wagner [162], and Minker and Ruiz [103].

Abductive logic programming views, roughly speaking, the query as an observation, which must be explained by means of additional hypotheses. Explanations can be found by following the rules of the program “backwards,” as in SLD resolution and its generalizations. A survey on abductive logic programming, by Kakas et al. [76] appeared recently.

Truth maintenance systems can be viewed as an extension of (propositional) general logic programs, where some clauses (called constraints) have the constant false as the head. Semantics have been proposed for truth maintenance systems by generalizing stable and well-founded semantics to deal with constraints. We mention here work by Elkan [53], Reifenruck [134], Giordano and Martelli [70], Wittedeveen [164], and Jonker [75]. The area is related to classical negation and to abduction.

Relations with other nonmonotonic formalisms are abundant (see, e.g., Nerode et al. [109] and Przymusinski [123, 125]). Because negation as failure is nonmonotonic inference rule, there has been a cross-fertilization between semantics for nonmonotonic logics and logic programming.

In one direction, stable expansions of autoepistemic logic (Moore [104]) inspired Gelfond [64, 65] to define the stable semantics. A parallel work on connections between the default logic of Reiter [136] and stable model semantics was carried out by Marek and Truszczynski [99] and by Bidoit and Froidevaux [20]. Recently, Przymusinski [127, 121] explained the stationary semantics by means of autoepistemic logic (see also Bonatti [25]).

In the other direction, Przymusinski [130] introduced three-valued versions of default logic and autoepistemic logic, based on the well-founded semantics for logic programs. For default logic, this semantics was generalized further by Baral and Subrahmanian [15], Li and You [84], and Przymusinska and Przymusinski [114]. A unifying framework for the semantics of autoepistemic logic, based on stationary semantics for logic programs, was presented by Przymusinski [128].

The relation between logic programming and circumscription (McCarthy [101]) was studied by Lifschitz [85], Gelfond and Lifschitz [66], and Gelfond et al. [69].

Recursion theoretic analysis of the concepts discussed here attracted a lot of interest. The complexity of the syntactic notions (like (local) stratifiability), of the
proof theory (like SLS resolution), and of semantics (like well-founded model) were studied both in the propositional and first-order case. These results are surveyed in Cadoli and Schaerf [27].

Intensional negation is an approach to negation that transforms a program \( P \) (without local variables) into a program \( \bar{P} \), defining a relation \( \bar{p} \) for every relation \( p \) in \( P \), such that \( \bar{p}(t) \) succeeds from \( \bar{P} \) iff \( p(t) \) finitely fails from \( P \), and vice versa. Intensional negation was mainly studied by Mancarella et al. [95, 96, 17].

Linear logic is a modification of the classical Gentzen sequent calculus which was developed by Girard [71] to capture reasoning about resources. In particular, linear logic is sensitive to how many times a formula is used as hypothesis in a proof. Cerrito [31, 32] showed that linear logic can be used to reason about logic programs and Prolog.

We would like to thank all five referees for useful comments, Rachel Ben-Eliyahu and Jürgen Dix for extensive suggestions, and Kees Doets, Marco Schaerf, and Robert Stürk for helpful discussions on the subject of this paper.
