Abstract

The gas-phase reactions of the O$^{−}$ ion with ($\eta^5$-cyclopentadienyl)tricarbonylmanganese(I), $CpMn(CO)_3^−$, and ($\eta^5$-methylcyclopentadienyl)tricarbonylmanganese(I), $CH_3CpMn(CO)_3^−$, have been studied with Fourier transform ion cyclotron resonance. The main reactions are (i) proton abstraction, (ii) loss of $CO_2$, and (iii) expulsion of two or three CO molecules from the collision complex. Initial attack on a CO ligand is the main process as indicated by experiments with $^{18}O^{−}$ and the ion/molecule reactions of the product ions resulting from the loss of three CO molecules with water, aliphatic alcohols, methanethiol and $SO_2$. The attack on a CO ligand followed by loss of three CO molecules is suggested to yield $C_5H_5MnO^−$ ions with a (cyclopentadienone)MnH$^−$ structure in the reaction with $CpMn(CO)_3^−$ and (methylcyclopentadienone)MnH$^−$ ions if $CH_3CpMn(CO)_3^−$ is the substrate. A possible mechanism for the process leading to the indicated transformation of the Cp and $CH_3Cp$ ligands into $C_5H_4O$ and $CH_3C_2H_3O$ ligands, respectively, is discussed together with the formation of (fulvene)Mn(OH)$^−$ ions following attack of O$^{−}$ on $CH_3CpMn(CO)_3^−$. The (cyclopentadienone)MnH$^−$ and (methylcyclopentadienone)MnH$^−$ ions react with $N_2O$ by oxygen atom abstraction to form $C_5H_5MnO_2^−$ and $C_6H_7MnO_2^−$ ions, respectively.

Key words: FT-ICR; Organomanganese compounds; Nucleophilic additions; Atomic oxygen radical anion; Ion/molecule reactions

1. Introduction

Nucleophilic addition reactions are studied extensively in organometallic chemistry and are often applied for synthetic purposes [1]. A central topic in the studies of these processes concerns the regioselectivity in the attack of nucleophiles on species containing unsaturated ligands, such as CO, cyclopentadienyl, ethene or benzene [1,2]. In general terms, the site of attack of a nucleophile on an organometallic compound can depend on the coordinative saturation of the metal centre, the nature of the metal atom and ligands as well as on the properties of the medium in which the reactions occur. The presence of

*Corresponding author.
indirect reactants such as solvent molecules and counter ions can obscure, however, studies aimed at obtaining fundamental mechanistic insight into nucleophilic addition reactions. In this respect, several reports have demonstrated that these reactions can be studied in the gas phase thus avoiding the influence of the indirect reactants, which are inevitably present in the condensed phase [3–5]. The main part of the reported studies concerned with gas-phase nucleophilic additions describes reactions of anions with transition metal carbonyl compounds, e.g. Fe(CO)₅ [6–8]. These reactions proceed by loss of one or more CO molecules from the collision complex and are viewed as involving initial attack on a CO ligand followed by migration of the nucleophile to the metal atom succeeded to some extent by the loss of a second CO molecule. Nucleophilic attack on an organic ligand has been described for the gas-phase reaction of H⁻ with \((\eta^6\text{C}_6\text{H}_6)\text{Cr(}\text{CO})_3\), which is reported to proceed in part by initial attack on the benzene ring and subsequent migration of a hydrogen atom to the metal centre followed by loss of \text{C}_6\text{H}_6 [9]. Recently, we reported that anions such as alkoxide ions react with \text{CpCo(}\text{CO})_2 in the gas phase at a carbonyl ligand and/or directly at the metal centre, whereas the reaction with the O⁻ radical anion involves competing attack on the Cp ligand and one of the CO ligands prior to the loss of two CO molecules [10]. Attack on the Cp ligand was proposed to yield mainly a (cyclopentadiene)CoH⁻ ion, whereas initial attack on a CO ligand was suggested to generate a metallacyclopentadiene species with a CO as well as a hydride ligand and/or a (cyclobutadiene)Co(\text{CO})H⁻ species. These structural assignments were based on a study of the reactions between the product ions generated by attack of O⁻ on \text{CpCo(}\text{CO})_2 and a series of substrates including NO, \text{SO}_2, water, aliphatic alcohols and carboxylic acids. For example, the competing losses of CO and C₃H₄O from the collision complex in the reaction with \text{SO}_2 was taken as an indication of the presence of these ligands in the reactant cobalt containing ions.

The possibility for attack of a negative ion on an organic ligand with the formation of new metal containing species motivated us to extend the study of the gas-phase reactions between the O⁻ ion and organometallic compounds with a Cp ligand. In the present paper we are concerned with the regioselectivity of the reactions of the O⁻ radical anion with the two manganese compounds, \text{CpMn(}\text{CO})_3 and \text{CH}_3\text{CpMn(}\text{CO})_3. These compounds were chosen for a closer study in order to investigate whether competing attack of the O⁻ ion on a Cp ligand and a CO ligand is a general phenomenon. Moreover, we wanted to examine whether ions comparable to those derived from \text{CpCo(}\text{CO})_2 [10] are generated in the reaction with the manganese compounds. To gain this insight, we applied the Fourier transform ion cyclotron resonance (FT-ICR) [11,12] method in combination with stable isotopic labelling and probed the structures of the initial product ions by investigating their ion/molecule chemistry.

2. Experimental

The experiments were performed with an FT-ICR instrument constructed and designed at the University of Amsterdam [13–15]. In a typical experiment the primary negative ions were formed by a pulsed electron beam with a duration of 0.1 s and trapped in a magnetic field of 1.24 T by applying a negative voltage of \(-1\) V to the trapping plates of the cubic inch cell. The O⁻ ions were formed by dissociative capture of electrons with an energy of about 1.2 eV by \text{N}_2\text{O} [16], whereas the \(^{18}\text{O}⁻\) ions were generated by reacting O⁻ with \text{H}_2^{18}\text{O} [17]. The ions of interest were isolated.
by removing all other ions from the cell by a series of r.f. pulses, which were adjusted such that unwanted translational excitation of the remaining ions was minimized [18]. In the experiments with \(^{18}\text{O}^-\), minor amounts of \(\text{O}^-\) ions were formed by the reaction of the \(^{18}\text{O}^-\) ions with the \(\text{N}_2\text{O}\) molecules present in the cell [19,20]. These \(\text{O}^-\) ions were ejected continuously from the cell during the entire reaction period. Continuous ejection of a product ion during the reaction period proved necessary also in other experiments and was achieved normally by applying an r.f. pulse of low amplitude to the excitation plates of the cell during the reaction time. The reactions of the ions of interest with a given substrate were followed as a function of time by varying the delay between the selection of the reactant ions and the detection of the ions present in the cell. Dissociative capture of electrons with a kinetic energy of \(\leq 1\text{ eV}\) by \(\text{CpMn(CO)}_3\) and \(\text{CH}_3\text{CpMn(CO)}_3\) gave rise to abundant \(\text{CpMn(CO)}_2\) and \(\text{CH}_3\text{CpMn(CO)}_2\) ions, whereas \(\text{CpMn(CO)}^-\) and \(\text{CH}_3\text{CpMn(CO)}^-\) ions were generated in a relatively low abundance. The formation of these ions by dissociative capture of low kinetic energy electrons present in the cell during the reaction time was prevented by ejecting the electrons as described in a previous paper [21].

The partial pressure of a neutral compound in the instrument was normally \(\approx 2 \times 10^{-5}\text{ Pa}\). The partial pressure of nitrous oxide was \(\approx 4 \times 10^{-5}\text{ Pa}\) in the experiments concerned with the chemistry of the \(\text{C}_5\text{H}_3\text{MnO}_2^-\) and \(\text{C}_6\text{H}_7\text{MnO}_2^-\) ions generated in the reactions of the respective \(\text{C}_5\text{H}_3\text{MnO}^-\) and \(\text{C}_6\text{H}_7\text{MnO}^-\) ions with \(\text{N}_2\text{O}\) (vide infra). The pressures were measured on an uncalibrated ionization gauge placed in a side arm of the main pumping line. The inlet lines and the main vacuum vessel of the instrument were at room temperature, while the temperature of the trapping plate opposite the filament side was measured to be 300–340 K in a typical experiment.

3. Materials

Most of the chemicals were commercially available and used without further purification. The \(\text{CH}_3\text{CpMn(CO)}_3\) compound contained \(\leq 10\%\) \(\text{CpMn(CO)}_3\). The presence of \(\text{CpMn(CO)}_3\) in the sample of the methyl substituted compound had no apparent effect on the results of the experiments described in the present paper. The \(\text{CH}_3\text{CH}_2\text{CD}_2\text{OH} (> 95\% d_2)\) compound was prepared by a \(\text{LiAlD}_4\) reduction of propionic acid and purified by distillation [22].

4. Results

4.1. Reactions of \(\text{O}^-\) with \(\text{CpMn(CO)}_3\) and \(\text{CH}_3\text{CpMn(CO)}_3\)

The \(\text{O}^-\) radical anion reacts with \(\text{CpMn(CO)}_3\) and \(\text{CH}_3\text{CpMn(CO)}_3\) in the gas phase by a number of competing processes including proton abstraction, loss of \(\text{CO}_2\) and the expulsion of two or three \(\text{CO}\) molecules from the collision complex (Table 1). In addition, hydrogen atom abstraction and formal abstraction of \(\text{H}_2\text{O}^+\) occur to a minor extent. The latter processes are observed commonly in the reactions of \(\text{O}^-\) with organic compounds such as alkenes, aromatic compounds and halogen substituted methanes [23,24].

The overall reactivity of the \(\text{O}^-\) ion towards the two manganese compounds is similar although proton abstraction is somewhat more important in the reaction with \(\text{CH}_3\text{CpMn(CO)}_3\) than with \(\text{CpMn(CO)}_3\) suggesting that the methyl substituted compound is more acidic than \(\text{CpMn(CO)}_3\) \((\Delta H_{\text{acid}} \approx 1556\text{ kJ mol}^{-1})\) [5] in the gas phase. In addition, loss of two \(\text{CO}\) molecules from the collision complex is less important in the reaction with \(\text{CH}_3\text{CpMn(CO)}_3\) than with \(\text{CpMn(CO)}_3\). The present results for the reactions of the \(\text{O}^-\) ions

\textsuperscript{a}Ions with an elemental composition of C\textsubscript{6}H\textsubscript{5} and C\textsubscript{6}H\textsubscript{7} are also observed. The yields of these ions vary from experiment to experiment indicating that they arise by proton abstraction from cyclopentadiene and methyl substituted cyclopentadiene generated by thermal decomposition of the respective metal compounds.

\textsuperscript{b}The sample of CH\textsubscript{3}CpMn(CO)\textsubscript{3} contained \approx 10\% CpMn(CO)\textsubscript{3} (see Experimental).

\textsuperscript{c}Assumed structure or assigned elemental composition.

\textsuperscript{d}See text for possible structures of these ions.

\textsuperscript{e}The C\textsubscript{2}H\textsubscript{5}MnO\textsuperscript{−} and C\textsubscript{2}H\textsubscript{5}MnO\textsuperscript{−} ions react with N\textsubscript{2}O to form C\textsubscript{6}H\textsubscript{5}MnO\textsubscript{2−} and C\textsubscript{6}H\textsubscript{7}MnO\textsubscript{2−} ions, respectively (see text). The relative yields given of the C\textsubscript{2}H\textsubscript{5}MnO\textsuperscript{−} and C\textsubscript{6}H\textsubscript{7}MnO\textsuperscript{−} ions have been obtained by adding the relative abundance of a given dioxide ion to that of the related monoxide ion.

\textsuperscript{f}The structures of these ions have not been ascertained, see text.

with the two manganese compounds are in contradiction to a recent study of VanOrden and Buckner [25]. According to their FT-ICR experiments, the O\textsuperscript{−} ion reacts with CH\textsubscript{3}CpMn(CO)\textsubscript{3} in the gas phase only by the loss of CO\textsubscript{2} from the collision complex as observed for the reactions with transition metal carbonyl compounds such as Cr(CO)\textsubscript{6} and Fe(CO)\textsubscript{5} [25,26]. The present experiments as well as our previously reported findings for CpCo(CO)\textsubscript{2} demonstrate [10], however, that the O\textsuperscript{−} ion can react in a complex manner with organometallic species containing a Cp or a CH\textsubscript{3}Cp ligand.

Loss of CO\textsubscript{2} from the collision complex yields CpMn(CO)\textsubscript{2} and CH\textsubscript{3}CpMn(CO)\textsubscript{2} ions (Table 1). These species can be formed also by capture of low energy electrons by the neutral manganese compounds (see Experimental Section) and in order to ascertain the origin of the CpMn(CO)\textsubscript{2} and CH\textsubscript{3}CpMn(CO)\textsubscript{2} ions generated in the experiments with O\textsuperscript{−}, we ejected the latter ion from the cell prior to the reaction period. Under these conditions, the CpMn(CO)\textsubscript{2} and CH\textsubscript{3}CpMn(CO)\textsubscript{2} ions are not observed revealing that the ejection of low energy electrons from the cell is sufficiently efficient for an unambiguous study of the reactions of O\textsuperscript{−} with the neutral manganese species. The CpMn(CO)\textsubscript{2} and CH\textsubscript{3}CpMn(CO)\textsubscript{2} ions may be formed also in the reaction between the manganese compounds and the NO\textsuperscript{−} ions, which are generated by attack of O\textsuperscript{−} on the N\textsubscript{2}O molecules present in the cell. However, continuous ejection of NO\textsuperscript{−} during the reaction period discloses that only a very minor part of the manganese containing ions are formed by this pathway. In other words, the CpMn(CO)\textsubscript{2} and CH\textsubscript{3}CpMn(CO)\textsubscript{2} ions are generated predominantly by the reaction of the O\textsuperscript{−} ion with CpMn(CO)\textsubscript{3} and CH\textsubscript{3}CpMn(CO)\textsubscript{3}, respectively.

The loss of two carbon monoxide molecules from the collision complex following attack of O\textsuperscript{−} leads to C\textsubscript{6}H\textsubscript{5}MnO\textsubscript{2−} and C\textsubscript{7}H\textsubscript{7}MnO\textsubscript{2−}.
ions, whereas ions with the elemental composition of C$_5$H$_5$MnO$^-$ and C$_6$H$_7$MnO$^-$ are generated by the loss of three CO molecules (Table 1). The occurrence of these processes raises the questions as to (i) whether the attacking O$^-$ ion is incorporated in the product ions, and (ii) whether attack occurs initially at a CO ligand, the organic ligand or the metal centre. In order to answer these questions, we studied the reactions of the 18O$^-$ ion with the two manganese compounds.

The ions generated by loss of carbon dioxide from the collision complex in the reaction of 18O$^-$ with either of the two manganese compounds do not incorporate the label as illustrated by the exclusive loss of CO$_{18}$O in the reaction with CH$_3$CpMn(CO)$_3$ (Eq. (1)):

$$18O^- + CH_3CpMn(CO)_3 \rightarrow 100\% CH_3CpMn(CO)_2^- + CO_{18}O \quad (1)$$

In the reaction of 18O$^-$ with CpMn(CO)$_3$, ≈ 85% of the ions formed by loss of two carbon monoxide molecules incorporates the label as indicated in Eq. (2):

$$18O^- + CpMn(CO)_3 \rightarrow 85\% C_6H_5MnO_{18}O^- + 2CO \quad (2a)$$
$$\approx 15\% C_6H_5MnO_2^- + CO + 18O \quad (2b)$$

In the reaction of 18O$^-$ with CH$_3$CpMn(CO)$_3$, more than 95% of the product ions generated by loss of two carbon monoxide molecules retains the 18O atom (Eq. (3)):

$$18O^- + CH_3CpMn(CO)_3 \rightarrow 95\% C_7H_7MnO_{18}O^- + 3CO \quad (3a)$$
$$\leq 5\% C_7H_7MnO_2^- + CO + 18O \quad (3b)$$

The extent of incorporation of the 18O atom in the product ions resulting from the loss of three carbon monoxide molecules is lower than for the product ions due to the loss of two carbon monoxide molecules as can be seen by comparing the results in Eqs. (4) and (5) with those given in Eqs. (2) and (3).

$$18O^- + CpMn(CO)_3 \rightarrow 55\% C_5H_5MnO_{18}^- + CO + 3CO \quad (4a)$$
$$45\% C_5H_5MnO^- + 2CO + 18O \quad (4b)$$

$$18O^- + CH_3CpMn(CO)_3 \rightarrow 70\% C_6H_7MnO_{18}^- + 3CO \quad (5a)$$
$$30\% C_6H_7MnO^- + 2CO + 18O \quad (5b)$$

The relative abundances of the C$_5$H$_5$MnO$_{18}$O$^-$ and C$_5$H$_5$MnO$^-$ ions (Eq. (4)) and of the C$_6$H$_7$MnO$_{18}$O$^-$ and C$_6$H$_7$MnO$^-$ ions (Eq. (5)) are significantly different from the abundance ratio of 25:75, which is predicted for a statistical process in which all four oxygen atoms have become equivalent prior to loss of three carbon monoxide molecules. This implies that the four oxygen atoms do not become structurally identical prior to product formation as indicated also by the exclusive loss of carbon dioxide molecules containing the 18O atom (Eq. (1)).

4.2. Reactions of the C$_5$H$_5$MnO$^-$ ions

The O$^-$ ion reacts relatively readily with CpMn(CO)$_3$ and a sufficient yield of the C$_5$H$_5$MnO$^-$ ions is obtained after 0.2 s for the study of the reactions between these ions and various substrates. In the reaction of the C$_5$H$_5$MnO$^-$ ions with the parent compound, a CO molecule is expelled from the collision complex (Eq. (6)). This reaction is very slow indicating that its occurrence does not hamper the study of the reactions

with other substrates.

C5H5MnO- + CpMn(C0)3 → C12H10Mn2O3 + CO (6)

With N2O, the main part (> 85%) of the C5H5MnO- ions reacts by oxygen atom transfer to generate C5H5MnO2- ions (Eq. (7)) [27,28]. This process is relatively facile although it is not capable of competing effectively with the reactions between the C5H5MnO- ions and the selected substrates. In most of the experiments concerned with the ion/molecule chemistry of the C5H5MnO- ions, the C5H5MnO2- ions were ejected continuously from the cell during the entire reaction period (see Experimental Section).

C5H5MnO- + N2O → C5H5MnO2- + N2 (7)

Dioxide ions are formed also by the loss of H2 from the collision complex in the reaction with H2O. If D2O is the substrate, only HD is expelled as shown in Eq. (8):

C5H5MnO- + HDO → C5H4DMnO2- + HD (8)

Loss of a hydrogen molecule from the collision complex is also the only reaction observed with unlabelled aliphatic alcohols. In the reaction with the deuterium labelled alcohols, CD3OH and CH3CH2CD3OH, only H2 is eliminated, whereas with CD3OD, CH3OD and CH3CH2OD, HD is expelled from the collision complex (Eq. (9)). These findings reveal that the generated hydrogen molecule consists of one of the hydrogen atoms of the reactant ion and the hydrogen atom of the hydroxy group of the alcohol:

C5H5MnO- + CD3OD → C5H4D3MnO2- + HD (9)

Notwithstanding the low pressures commonly applied in FT-ICR experiments, the primary product ions formed by loss of a hydrogen molecule in the reaction with the aliphatic alcohols and water react further with these substrates to form stable adduct ions (Eq. (10); see also Appendix A):

C5H5MnO- + ROH → [C5H4MnO2R]- + ROH → [C5H5MnO3R2]-

(R = H, CH3, C2H5, 1-C3H7, 2-C3H7, 1-C4H9) (10)

A minor fraction of the C5H5MnO- ions is observed to be unreactive towards the
aliphatic alcohols. This is disclosed by the results of experiments in which the ions react with an alcohol for 1–1.5 s after which the remaining C$_5$H$_5$MnO$^-$ ions are isolated by ejecting all other ions from the cell. In the subsequent collisions between the remaining ions and the neutral species present in the FT-ICR cell, no products from a reaction with the alcohol are generated. Based on such experiments we estimate that roughly 20% of the C$_5$H$_5$MnO$^-$ ions are unreactive towards aliphatic alcohols and water.

Expulsion of a hydrogen molecule from the collision complex is the only reaction occurring with methanethiol. With acetic acid as the substrate, proton abstraction with formation of acetate ions occurs in addition to the loss of a H$_2$ molecule. With NO no reaction is observed, whereas the C$_5$H$_5$MnO$^-$ ions react readily and completely with SO$_2$ by a number of competing processes (Table 2). The most important of these reactions involves the loss of a neutral species with the elemental composition of C$_5$H$_4$O as shown in Eq. (11):

$$\text{C}_5\text{H}_5\text{MnO}^- + \text{SO}_2 \rightarrow \text{MnHSO}_2 + \text{C}_5\text{H}_4\text{O}$$

(11)

4.3. Reactions of the C$_6$H$_7$MnO$^-$ ions

The O$^-$ ion reacts readily with CH$_3$Cp-Mn(CO)$_3$ and in most experiments the C$_6$H$_7$MnO$^-$ ions are isolated after a reaction time of 0.25 s. Subsequently, the ions are allowed to react with a selected substrate in the presence of the neutral organometallic compound and N$_2$O. With the parent compound, the C$_6$H$_7$MnO$^-$ ions react slowly by loss of a CO molecule from the collision complex, whereas the reaction with N$_2$O proceeds by oxygen atom transfer (Eq. (12)). As observed also for the C$_5$H$_5$MnO$^-$ ions, some of the C$_6$H$_7$MnO$^-$ ions (30%) appear not to react with N$_2$O. In most experiments, the C$_6$H$_7$MnO$_2^-$ ions formed in the reaction with N$_2$O are ejected continuously from the cell during the entire reaction period, thus allowing the reactions of the C$_6$H$_7$MnO$^-$ ions with the substrates to be studied selectively.

$$\text{C}_6\text{H}_7\text{MnO}^- + \text{N}_2\text{O} \rightarrow \text{C}_6\text{H}_7\text{MnO}_2^- + \text{N}_2$$

(12)

Ions with the elemental composition of C$_6$H$_7$MnO$_2^-$ are formed also in the reaction with H$_2$O, which involves only the loss of H$_2$ from the collision complex (Eq. (13)):

$$\text{C}_6\text{H}_7\text{MnO}^- + \text{H}_2\text{O} \rightarrow \text{C}_6\text{H}_7\text{MnO}_2^- + \text{H}_2$$

(13)

In the reaction with D$_2$O, some of the C$_6$H$_7$MnO$^-$ ions react to expel HD from the collision complex with the formation of C$_6$H$_6$DMnO$_2^-$ ions (Eq. (14)):

$$\text{C}_6\text{H}_7\text{MnO}^- + \text{D}_2\text{O} \rightarrow \text{C}_6\text{H}_6\text{DMnO}_2^- + \text{HD}$$

(14)

The product ions formed by loss of a hydrogen molecule react further with D$_2$O by exchange of three hydrogen atoms for deuterium atoms (Eq. (15)) and to afford stable adduct ions (see Fig. 1 and Appendix A). The occurrence of this exchange prevents a determination of the extent to which H$_2$ is expelled in the primary reaction between C$_6$H$_7$MnO$^-$ and D$_2$O, whereas the loss of a D$_2$ molecule is not occurring as revealed by the absence of formation of C$_6$H$_7$MnO$_2^-$ ions (see Fig. 1).

$$\text{C}_6\text{H}_6\text{DMnO}_2^- \xrightarrow{\text{D}_2\text{O}} \text{C}_6\text{H}_3\text{D}_4\text{MnO}_2^-$$

(15)

A minor part of the C$_6$H$_7$MnO$^-$ ions react readily with D$_2$O by exchange of hydrogen atoms for deuterium atoms as shown in Fig. 1. Only three of the seven hydrogen atoms are exchanged for deuterium atoms in the presence of D$_2$O (Eq. (16)):

$$\text{C}_6\text{H}_7\text{MnO}^- \xrightarrow{\text{D}_2\text{O}} \text{C}_6\text{H}_4\text{D}_3\text{MnO}^-$$

(16)

The distribution of the ions containing deuterium atoms is: 40% (C$_6$H$_6$DMnO$^-$), 40%

*Delay between the start of the electron beam and the isolation of the \( \text{C}_6\text{H}_7\text{MnO}^- \) ions. The duration of the electron beam pulse was 0.1 s; see text.

Fig. 1. Hydrogen–deuterium exchange in the \( \text{C}_6\text{H}_7\text{MnO}^- / \text{CH}_3\text{CpMn(CO)}_3 / \text{D}_2\text{O} \) system followed as a function of reaction time. The group of peaks indicated by I in the figure represents the \( \text{C}_6\text{H}_7\text{MnO}^- \) ions \( (d_6) \) and the fraction of these ions which exchanges up to three hydrogen atoms for deuterium atoms. The group of peaks indicated by II represents the ions formed by loss of \( \text{HD} \) in the reaction with \( \text{D}_2\text{O} \) and in the subsequent exchange with \( \text{D}_2\text{O} \). The group of signals indicated by III corresponds to stable adduct ions formed in the reactions of the latter ions with \( \text{D}_2\text{O} \) (see text).
(C₆H₅D₂MnO⁻) and 20% (C₆H₄D₃MnO⁻) after a reaction time of 0.3 s, whereas this distribution is displaced in favour of the ions containing three deuterium atoms at prolonged reaction times (see Fig. 1). The ions with three deuterium atoms remain in the cell even after reaction times of 2 s indicating that the C₆H₇MnO⁻ ions which undergo hydrogen/deuterium exchange with D₂O do not react to expel HD or H₂ from the collision complex. As can be seen in Fig. 1, some of the C₆H₇MnO⁻ ions do not react with D₂O either by exchange or to expel HD/H₂. In conclusion, the results of the experiments with D₂O indicate that at least three isomeric C₆H₇MnO⁻ ions are formed in the reaction of O⁻⁻ with CH₃CpMn(CO)₃.

Loss of a hydrogen molecule is observed also in the reactions with aliphatic alcohols and yields product ions which react further with an alcohol molecule to form stable adduct ions (Eq. (17); see also Appendix A):

\[
\text{C}_6\text{H}_7\text{MnO}^- + \text{ROH} \rightarrow \text{ROH} + \text{C}_6\text{H}_6\text{MnO}_2\text{R}^- + \text{H}_2 \quad (17)
\]

(R = CH₃, C₂H₅)

In addition to the loss of a hydrogen molecule, a water molecule is expelled from the collision complex (Eq. (18)):  

\[
\text{C}_6\text{H}_7\text{MnO}^- + \text{ROH} \rightarrow \text{C}_6\text{H}_6\text{MnOR}^- + \text{H}_2\text{O} \quad (18)
\]

The ratio between the abundances of the product ions resulting from H₂ and H₂O loss is 90:10 after the ions have reacted with methanol for 0.6 s as indicated in Table 3. This ratio is obtained if the C₆H₇MnO⁻ ions are isolated 0.25 s after the start of the electron beam pulse (the duration of this pulse was 0.1 s; see Experimental Section). A ratio of 70:30 is obtained, however, if the reactant C₆H₇MnO⁻ ions are isolated after a delay of 0.65 s and subsequently allowed to react with methanol for 0.6 s. Concurrent with this change in the product ratio in favour of the ions arising by H₂O loss, the overall reaction becomes slower as indicated by the conversions into products given in Table 3. With a delay of 1.65 s prior to the isolation of the C₆H₇MnO⁻ ions, loss of H₂ is no longer observed and in the subsequent reaction with methanol only H₂O elimination occurs. After still longer delay times, roughly 15% of the initially generated C₆H₇MnO⁻ ions remains in the FT-ICR cell. These residual C₆H₇MnO⁻ ions display no reactivity towards methanol. Combining these observations, the results of the experiments with methanol suggest that the main fraction of the C₆H₇MnO⁻ ions react relatively fast by loss of H₂ from the collision complex, whereas a minor part of the ions reacts relatively slowly to expel an H₂O molecule. In addition, a minor fraction of the ions appears unreactive towards methanol.

Elimination of a hydrogen molecule is likewise the main reaction with methanethiol, which also proceeds by loss of a water molecule from the collision complex (Eqs. (19) and (20)):

\[
\text{C}_6\text{H}_7\text{MnO}^- + \text{CH}_3\text{SH} \rightarrow \text{C}_7\text{H}_9\text{MnSO}^- + \text{H}_2 \quad (19)
\]

\[
\rightarrow \text{C}_7\text{H}_9\text{MnS}^- + \text{H}_2\text{O} \quad (20)
\]

No reaction was observed with NO as the substrate, whereas the C₆H₇MnO⁻ ions react completely with SO₂ by a number of processes including the competing losses of C₆H₆O and C₆H₆ (Table 2).

4.4. Reactions of the C₅H₅MnO₅⁻ and C₆H₇MnO₅⁻ ions

The C₅H₅MnO⁻ and C₆H₇MnO⁻ ions react with N₂O and H₂O to incorporate an
oxygen atom thus forming $\text{C}_5\text{H}_5\text{MnO}_2^-$ and $\text{C}_6\text{H}_7\text{MnO}_2^-$ ions (see Eqs. (7), (8), (12) and (13)). Both of the latter two ions react with water to generate stable adduct ions (see Appendix A). Significantly, the $\text{C}_5\text{H}_5\text{MnO}_2^-$ ions formed in the reaction with $\text{H}_2\text{O}$ exchange one oxygen atom for an $^{18}\text{O}$ atom in the presence of $\text{H}_2\text{O}^{18}$ (Eq. (21)) indicating that the two oxygen atoms in the dioxide ions are structurally distinguishable. Moreover, the $\text{C}_5\text{H}_5\text{MnO}_2^{18}\text{O}^-$ ions formed in the reaction of $\text{C}_5\text{H}_5\text{MnO}^-$ with $\text{H}_2\text{O}^{18}$ do not exchange the $^{16}\text{O}$ atom for an $^{18}\text{O}$ atom in the presence of $\text{H}_2\text{O}^{18}$.

$$\text{C}_5\text{H}_5\text{MnO}_2^- + \text{H}_2\text{O}^{18} \rightarrow \text{C}_5\text{H}_5\text{MnO}_2^{18}\text{O}^- + \text{H}_2\text{O}$$

(21)

The two dioxide ions react with aliphatic alcohols ($\text{ROH}, \text{R} = \text{CH}_3, \text{C}_2\text{H}_5$ and $\text{n-C}_3\text{H}_7$) and methanethiol mainly by simple adduct formation and the loss of a water molecule from the collision complex as exemplified for methanol in Eqs. (22) and (23):

$$\text{C}_6\text{H}_7\text{MnO}_2^- + \text{CH}_3\text{OH} \rightarrow \text{C}_7\text{H}_{11}\text{MnO}_3^-$$

(22)

$$\rightarrow \text{C}_7\text{H}_9\text{MnO}_2^- + \text{H}_2\text{O}$$

(23)

Adduct formation and loss of a water molecule occur also in the reactions of both of the $\text{C}_5\text{H}_5\text{MnO}_2^-$ and $\text{C}_6\text{H}_7\text{MnO}_2^-$ ions with $\text{SO}_2$. In addition to these reactions, loss of a neutral species with the elemental composition of $\text{C}_6\text{H}_6\text{O}$ from the collision complex is observed in the reaction of the $\text{C}_6\text{H}_7\text{MnO}_2^-$ ions with $\text{SO}_2$ in line with the results for the related monoxide ions (see Table 2). The reactivity of the dioxide ions appears to be independent of whether they are formed in the reactions of the corresponding monoxide ions with $\text{N}_2\text{O}$ or $\text{H}_2\text{O}$. The pronounced formation of adduct ions restricts, however, the insight into the structures of the $\text{C}_5\text{H}_5\text{MnO}_2^-$ and $\text{C}_6\text{H}_7\text{MnO}_2^-$ species, which could be derived from their bimolecular chemistry.

5. Discussion

5.1. Site of attack by the $\text{O}^-$ ion

The main concern in the present study is an experimental determination of the regioselectivity in the gas phase reactions of the atomic oxygen radical anion with $\text{CpMn(CO)}_3$ and $\text{CH}_3\text{CpMn(CO)}_3$. In principle, the $\text{O}^-$ ion can react at either site of the manganese containing molecules, that is, competing attack on a CO ligand, the organic ligand and the metal centre cannot be excluded a priori. If initial attack on a CO ligand occurs in the reaction of the $^{18}\text{O}^-$ ion with $\text{CpMn(CO)}_3$ this may be expected to yield intermediate 1 in Scheme 1. This species can expel $\text{CO}^{18}\text{O}$ in agreement with the result in Eq. (1) or eliminate two CO molecules with formation of ion 2 in Scheme 1. Initial attack of the $^{18}\text{O}^-$ ion on the organic ligand or at the

\[
\text{CpMn(CO)}_3 \xrightarrow{^{18}\text{O}^-} \left[ \begin{array}{c} \text{CpMn(CO)}_2^{18}\text{O}^- \\ 1 \end{array} \right] \\
\xrightarrow{2 \text{CO}} \left[ \begin{array}{c} \text{CpMn}^{18}\text{O}^- \\ 2 \end{array} \right] \\
\xrightarrow{\text{-CO}} \left[ \begin{array}{c} \text{C}_6\text{H}_7\text{MnO}^+ \\ \text{50%} \end{array} \right] \\
\xrightarrow{\text{-CO}} \left[ \begin{array}{c} \text{C}_5\text{H}_5\text{MnO}^+ \\ \text{50%} \end{array} \right]
\]

Scheme 1. Possible mechanism for initial attack of the $^{18}\text{O}^-$ ion on a carbonyl ligand and the predicted extent of incorporation of the $^{18}\text{O}$ atom in the ions formed by loss of two and three carbon monoxide molecules, respectively.
metal centre could proceed as illustrated in Scheme 2 for the reaction with CpMn(CO)$_3$. In this hypothetical scheme, the reaction at the metal centre is assumed to involve a $\eta^5$ to $\eta^3$ change in the bonding of the C$_5$H$_5$ ligand prior to attack at the manganese atom [29], whereas the reaction at the Cp ligand is presumed to occur from the exo-side of the ring as suggested for the comparable reaction of O$^-$ with the CpCo(CO)$_2$ compound [10]. The mechanistic proposals in Schemes 1 and 2 lead to the prediction that the $^{18}$O atom is retained in the product ions generated by the loss of two carbon monoxide molecules irrespective of the initial site of attack (vide infra). In other words, the insight into the regioselectivity may be obtained more readily by considering the extent to which the label is incorporated in the product ions resulting from the loss of three carbon monoxide molecules.

As indicated in Scheme 1, initial attack on a CO ligand and the loss of two CO molecules can lead to ion 2, which may expel CO and C$^{18}$O with equal probability. In contrast, initial attack on the metal or the organic ligand is anticipated to lead to complete incorporation of the label in the ions formed by loss of three carbon monoxide molecules as shown in Scheme 2. In the reactions of $^{18}$O$^-$ with the CpMn(CO)$_3$ compound, the C$_5$H$_5$Mn$^{18}$O$^-$ and C$_5$H$_5$MnO$^-$ ions are generated in an abundance ratio of 55:45 (Eq. (4)). Based on the proposal in Scheme 1, initial CO attack can account for the generation of $45\%$ C$_6$H$_7$Mn$^{18}$O$^-$ and $45\%$ C$_6$H$_5$MnO$^-$ ions, whereas the remaining $10\%$ C$_5$H$_5$Mn$^{18}$O$^-$ ions are liable to be formed as a result of attack on the Cp ligand and/or the metal centre in CpMn(CO)$_3$. Similar considerations apply to the results of the reactions between the $^{18}$O$^-$ ion and CH$_3$CpMn(CO)$_3$. Loss of three carbon monoxide molecules from the collision complex yields for this substrate $\approx 70\%$ C$_6$H$_7$Mn$^{18}$O$^-$ and $\approx 30\%$ C$_6$H$_5$MnO$^-$ ions (Eq. (5)). This leads to the suggestion that initial attack on a CO ligand by $^{18}$O$^-$ is responsible for the formation of $30\%$ C$_6$H$_7$MnO$^-$ and $30\%$ C$_6$H$_5$Mn$^{18}$O$^-$ ions, whereas the remaining $40\%$ C$_6$H$_7$Mn$^{18}$O$^-$ ions are likely to be generated by other routes (vide infra).

5.2. Structures and formation of the C$_5$H$_5$MnO$^-$ and C$_6$H$_7$MnO$^-$ ions

A detailed and unambiguous analysis of the structure(s) of the ions generated by attack of O$^-$ on the manganese compounds is restricted owing to the presently limited knowledge of the gas-phase ion chemistry of organometallic negative ions. On the basis of the results of the bimolecular chemistry of the C$_5$H$_5$MnO$^-$
and C₆H₇MnO⁻ ions some insight into the possible structures of these species can be obtained. In particular, the predominant reaction of the C₅H₅MnO⁻ ions with SO₂ involves the loss of a neutral species with the elemental composition of C₅H₄O (Eq. (11) and Table 2). This elemental composition may represent a single neutral species or, for example, a CO and a C₄H₄ molecule. However, loss of CO from the collision complex in the reaction with SO₂ is not observed and, in addition, no reaction occurs with NO even though this neutral species is known to be able to displace a CO ligand in organometallic negative ions [10,30,31]. The loss of C₅H₄O leads, therefore, to the suggestion that C₅H₅MnO⁻ ions with a cyclopentadienone and a hydride ligand are formed; that is, ion 8 is generated in the reaction of O⁻⁻ with CpMn(CO)₃ [32].

The formation of ion 8 is also supported by the observation that one of the hydrogen atoms of the reactant ions is incorporated in the hydrogen molecule expelled in the reactions with water (Eq. (8)) and aliphatic alcohols (Eq. (9)). The reaction with the aliphatic alcohols can be formulated as insertion into the O-H bond followed by reductive elimination of a hydrogen molecule as shown in Scheme 3 [1].

The main fraction of the C₅H₅MnO⁻ ions (≈80%) reacts with the alcohols by reductive elimination of a hydrogen molecule, whereas the remaining ions are unreactive. Moreover, in the reactions with SO₂, ≈70% of the product ions arises by loss of C₅H₄O from the collision complex. These results indicate that 8 is the main species formed in the reaction with the O⁻⁻ ion. In combination with the results of the experiments with ¹⁸O⁻⁻, which indicates that nearly all of the ions (≤90%) are generated following attack on a CO ligand, we are forced to conclude that 8 is formed by initial reaction at a CO ligand in contrast to what could be anticipated on the basis of Scheme 2 (vide supra). In Scheme 4 attack on a CO ligand is suggested to be followed by loss of two CO molecules and intramolecular attack of either of the two oxygen atoms of the -C(O⁻⁻)O⁻ group in 1' on the Cp ligand. This yields intermediate 11 in which one of the carbon atoms of the ring carries an oxygen atom at the endo-side and a hydrogen atom at the exo-side. Subsequently, a CO molecule may be expelled concurrent with structural reorganization leading to 8. Based on the present results it is not possible to reach a conclusion as to the precise nature and sequence of the chemical events leading to
Scheme 4. Proposed mechanism for the formation of (cyclopentadienone)MnH$^-$ ions following initial attack of the O$^-$ ion on a CO ligand in CpMn(CO)$_3$.

$\text{8 from 11.}$ It is evident, however, that one of the hydrogen atoms of the original Cp ligand migrates to the metal centre at some stage during the process yielding 8.

A further uncertainty relates to whether two CO molecules are expelled prior to the migration of an oxygen atom to the organic ligand. The proposal shown in Scheme 1 is based upon the expectation that two CO molecules are expelled before an oxygen atom migrates to the remaining part of the ion. Based on this suggestion, initial attack of the $^{18}\text{O}^-$ ion on a CO ligand is predicted to lead to complete retention of the label in the product ions generated by the loss of two CO molecules. In the performed experiments with the $^{18}\text{O}^-$ ion, $\approx 85\%$ of the ions generated by loss of two carbon monoxide molecules retains the label in the reaction with CpMn(CO)$_3$ (Eq. (2)), whereas $\approx 95\%$ of the product ions of this process incorporates the label if CH$_3$CpMn(CO)$_3$ is the substrate (Eq. (3)). These findings indicate that an oxygen atom in intermediates 1 (Scheme 1) and 1$'$ (Scheme 4)—or the comparable species formed in the reaction with CH$_3$CpMn(CO)$_3$—can migrate before two carbon monoxide molecules are expelled. Insight into the relative importance of this migration prior to the loss of two carbon monoxide molecules is not readily achieved, however, from the extent of the incorporation of the label in the product ions of this process. Nevertheless, the probability for migration of the $^{18}\text{O}$ atom will be the same for 1 and 2 in Scheme 1. This means that the predicted extent of incorporation of the label in the product ions formed by loss of three carbon monoxide molecules is the same regardless of whether an oxygen atom migrates prior to or following the expulsion of two carbon monoxide molecules.

In the reaction of O$^-$ with CpCo(CO)$_2$, ions with a (cyclopentadienone)CoH$^-$ structure were concluded to arise as a result of initial attack on the Cp ligand [10]. In the present study of the reaction with the related manganese compounds, it is clear that agreement between the different observations can be achieved by postulating the formation of ion 8 following initial attack on a CO ligand. The mechanistic details of the process leading to the formation of these ions are unknown and at present we are unable to explain the different behaviour observed for the cobalt and the manganese compounds. Another uncertainty relates to the non-reactive C$_3$H$_5$MnO$^-$ ions. In the experiments with $^{18}\text{O}^-$, it is observed that the C$_3$H$_5$MnO$^-$ ions react completely with N$_2$O and the parent organometallic compound (see Eqs. (6) and (7), respectively), whereas some of the C$_3$H$_5$Mn$^{18}$O$^-$ ions appear unreactive towards these substrates. In other words, the non-reactive ions contain the $^{18}\text{O}$ atom suggesting that these species are formed by initial attack on the metal and/or the Cp ligand (see also Scheme 2). From the present results it is not possible to conclude whether, for example, CpMnO$^-$ ions are formed as a result of attack on the metal centre as suggested in Scheme 2. However, the CpMnO$^-$ ion is a 15-electron species and one may expect such an ion to be able to react with aliphatic alcohols on the basis of the reported occurrence of dehydrogenation in the reaction.
between the comparable 17-electron ion, \( \text{CpCoO}^- \), and methanol in the gas phase [33]. Irrespective of the structure(s) of the unreactive ions, we notice that they represent a minor fraction of all the \( \text{C}_6\text{H}_7\text{MnO}^- \) ions generated by loss of three carbon monoxide molecules from the collision complex in the reaction with \( \text{CpMn(CO)}_3 \).

The main part of the \( \text{C}_6\text{H}_7\text{MnO}^- \) ions react with water and aliphatic alcohols by loss of a hydrogen molecule from the collision complex (Eqs. (13), (14) and (17)) and in the reaction with \( \text{SO}_2 \), about 55% of the ions expels a neutral species with the elemental composition of \( \text{C}_6\text{H}_6\text{O} \) (Table 2). These results suggest that the main part of the \( \text{C}_6\text{H}_7\text{MnO}^- \) has a structure, which is similar to the one proposed for the ions generated in the reaction with \( \text{CpMn(CO)}_3 \), that is, ion 12 arises following attack of \( \text{O}^- \) on \( \text{CH}_3\text{CpMn(CO)}_3 \). In view of the conclusion that initial attack on a CO ligand is responsible for 60% of all the ions formed by the loss of three carbon monoxide molecules, we suggest that 12 is formed as shown for 8 in Scheme 4:

\[
\begin{align*}
\text{CH}_3 & \quad \text{Mn}^- \\
\text{O} & \\
\text{H} & \quad 12
\end{align*}
\]

The formation of 12 following attack on a CO ligand implies that all the 30% \( \text{C}_6\text{H}_7\text{MnO}^- \) ions generated in the reaction with \( \text{H}^{18}\text{O}^- \) has this structure. A different situation arises for part of the 70% \( \text{C}_6\text{H}_7\text{Mn}^{18}\text{O}^- \) ions, which are liable to have a distinct structure. This is supported by the occurrence of water loss in the reaction of the \( \text{C}_6\text{H}_7\text{MnO}^- \) ions with alcohols and methanethiol (Eqs. (18) and (20)). Furthermore, 25–30% of the \( \text{C}_6\text{H}_7\text{MnO}^- \) ions reacts with \( \text{SO}_2 \) to expel \( \text{C}_6\text{H}_6 \) (Table 2) and a minor fraction of the ions react with \( \text{D}_2\text{O} \) by hydrogen–deuterium exchange (Eq. (16) and Fig. 1). The loss of a water molecule in the reaction with methanethiol indicates that a hydroxy ligand is present, whereas the loss of \( \text{C}_6\text{H}_6 \) in the reaction with \( \text{SO}_2 \) points toward the formation of \( \text{C}_6\text{H}_7\text{MnO}^- \) ions containing a ligand with this elemental composition. These findings suggest the formation of a (fulvene)-\( \text{Mn(OH)}^- \) ion [34]; that is, ion 13 may be formed in addition to 12.

\[
\begin{align*}
\text{C} & \quad \text{Mn}\quad \text{OH} \\
\text{H} & \quad 13
\end{align*}
\]

A possible mechanism for the formation of 13 involves initial hydrogen atom abstraction by the oxygen radical anion from the methyl group of the substrate molecule to give species 14 in Scheme 5. The hydroxide ion in 14 can attack a CO ligand to generate 15 prior to migration of the hydroxy group to the metal centre and the loss of three carbon monoxide molecules. A similar mechanism has been proposed for the reaction of the hydroxide ion with \( \text{CpCo(CO)}_2 \), which yields a \( \text{CpCo(OH)}^- \) ion after the loss of two carbon monoxide molecules [10]. In the reaction of the \( \text{H}^{18}\text{O}^- \) ion with \( \text{CpCo(CO)}_2 \), the label was incorporated almost completely in the product ions resulting from the loss of two carbon monoxide molecules. In the present context, it may be expected, therefore, that 1,3-H shifts between the oxygen atoms in 15 are not occurring. This leads to the prediction that all the product ions of the pathway involved retain the label if \( \text{H}^{18}\text{O}^- \) is the reactant ion. Formation of 13 by a pathway involving intermediate 14 is thus in agreement with the conclusion that all the \( \text{C}_6\text{H}_7\text{MnO}^- \) ions formed in the reactions with the \( \text{H}^{18}\text{O}^- \) ion have structure 12 (vide supra). An alternative mechanism
for the generation of 13 could involve initial attack on a CO ligand to give 16 which then rearranges to 15 by an intramolecular H-shift (Scheme 5). However, if $^{18}\text{O}^-$ is the reactant ion, such a mechanism would lead to incorporation of the label in 50% of the product ions of the process in conflict with the proposal that none of the C$_6$H$_7$MnO$^-$ ions formed in the reaction with $^{18}\text{O}^-$ (Eq. (5)) has structure 13.

Ion 13 may be responsible for the exchange of three hydrogen atoms for deuterium atoms in the presence of D$_2$O (Eq. (16) and Fig. 1). The exchange of only three hydrogen atoms could imply that this process involves the hydrogen atom of the hydroxy ligand and the two hydrogen atoms of the methylene group of the fulvene ligand. A possible mechanism for the exchange involves insertion into an O–D bond with formation of

Scheme 6. Possible mechanism for the hydrogen–deuterium exchange in the reactions of the (fulvene)Mn(OH)$^-$ ions with D$_2$O.

17a in Scheme 6. This step may be followed by reductive elimination of HDO or a shift of the deuterium atom bonded to the manganese atom to the methylene group can occur thus forming 18. Transfer of a hydrogen atom from the generated CH$_2$D group in 18 leads to 17b, which then expels H$_2$O to give an ion containing two deuterium atoms (see Scheme 6). The process can be repeated until three of the hydrogen atoms have been exchanged for deuterium atoms as observed experimentally (Fig. 1).

Based largely upon the reactions with SO$_2$ (Table 2), we conclude that 25–30% of the ions are formed with structure 13, whereas 55–60% of the ions have structure 12. The remaining 10–20% of the ions
represent the unreactive fraction of the \( \text{C}_6\text{H}_7\text{MnO}^- \) ions and from the present results we are unable to reach a conclusion as to the structure(s) of these \( \text{C}_6\text{H}_7\text{MnO}^- \) ions.

5.3. Formation and structure of the \( \text{C}_5\text{H}_5\text{MnO}_2^- \) and \( \text{C}_6\text{H}_7\text{MnO}_2^- \) ions

In the reactions of the \( \text{C}_5\text{H}_5\text{MnO}^- \) ions with \( \text{N}_2\text{O} \), roughly 85\% of the ions reacts by oxygen atom abstraction to form \( \text{C}_5\text{H}_5\text{MnO}_2^- \) ions \cite{27} in line with the relative yield of the ion 8. Similarly, the percentage (\( \approx 70\% \)) of the \( \text{C}_6\text{H}_7\text{MnO}^- \) ions which reacts with \( \text{N}_2\text{O} \) by oxygen atom transfer is close to the relative yield of 12 (\( \approx 60\% \)). The reaction with \( \text{N}_2\text{O} \) is likely, therefore, to involve 8 and 12, respectively, indicating that the \( \text{C}_5\text{H}_5\text{MnO}_2^- \) ions may contain a cyclopentadienone ligand and the \( \text{C}_6\text{H}_7\text{MnO}_2^- \) ions a methylcyclopentadienone ligand. In addition, the loss of a water molecule in the reactions of either dioxide ion with aliphatic alcohols, methanethiol and \( \text{SO}_2 \) indicates the presence of a hydroxy ligand. This implies that oxygen atom transfer leads to 19 and 20:

The presence of structurally distinguishable oxygen atoms in the \( \text{C}_5\text{H}_5\text{MnO}_2^- \) ions is indicated also by the result that only one oxygen atom is exchanged for an \( ^{18}\text{O} \) atom in the presence of \( \text{H}_2^{18}\text{O} \) (Eq. (21)). For the \( \text{C}_6\text{H}_7\text{MnO}_2^- \) ions, the presence of the methylcyclopentadienone ligand is supported by the occurrence of loss of \( \text{C}_6\text{H}_6\text{O} \) in the reactions with \( \text{SO}_2 \).

The reactivity of the \( \text{C}_5\text{H}_5\text{MnO}_2^- \) and \( \text{C}_6\text{H}_7\text{MnO}_2^- \) ions generated in the reactions with water is similar to the reactivity of the ions formed with \( \text{N}_2\text{O} \) as the substrate. The ions 19 and 20 are suggested, therefore, to arise in the reactions with water as well as with \( \text{N}_2\text{O} \) (Scheme 7). With \( \text{N}_2\text{O} \) as the substrate \cite{27}, bond formation between the manganese atom and the oxygen atom of the substrate molecule is suggested to precede the expulsion of \( \text{N}_2 \) with formation of 22 in Scheme 7. Subsequently, ion 22 can rearrange to 19. In the reaction with water, insertion into an \( \text{O}-\text{H} \) bond is proposed to be followed by reductive elimination of \( \text{H}_2 \), thus forming 19 directly.

6. Conclusions

The present results for the reactions of the atomic oxygen radical anion with \( \text{CpMn(CO)}_3 \) and \( \text{CH}_3\text{CpMn(CO)}_3 \) indicate
that initial attack occurs mainly on a CO ligand and only to minor extent on the Cp/CH₃Cp ligand and/or the metal centre. Reaction at a CO ligand and the loss of three carbon monoxide molecules in the reaction with CpMn(CO)₃ is proposed to yield a (cyclopentadienone)MnH⁻ ion. Similarly, initial attack on a CO ligand in CH₃CpMn(CO)₃ is suggested to yield a (methylcyclopentadienone)MnH⁻ ion. The conversion of the Cp and CH₃Cp ligands into cyclopentadienone and methylcyclopentadienone ligands, respectively, is formulated as an intramolecular oxygen atom transfer accompanied by a shift of a hydrogen atom from the original organic ligand to the metal centre. In addition to a (methylcyclopentadienone)MnH⁻ ion, the reaction of O⁻ with CH₃CpMn(CO)₃ leads to a (fulvene)-Mn(OH)⁻ species by a process, which is suggested to involve initial hydrogen atom abstraction from the methyl group in the substrate molecule followed by attack of the HO⁻ ion on a CO ligand in the generated (fulvene)Mn(CO)₃ species.

The relatively limited insight into the chemistry of organometallic negative ions in the gas phase prevents firm conclusions with regard to the precise structures of the product ions and the mechanisms of the processes leading to their formation. The results of the experiments with the ¹⁸O⁻ ion in combination with the observed bimolecular chemistry of the C₅H₅MnO⁻ and C₆H₇MnO⁻ product ions illustrate, however, that the O⁻ ion can react with organometallic species in the gas phase with formation of new organometallic negative ions, whose chemistry may be of general interest.

8. References

Several of the ions examined in the present study react predominantly with a substrate molecule to form stable adduct ions with an unknown structure. This holds for the C5H4MnO2R- ions generated by the loss of H2 from the collision complex in the primary reaction of the C5H5MnO- ions with an aliphatic alcohol (Eq. (10)). These C5H4MnO2R- ions react further quite readily with an alcohol molecule to generate adduct ions and a similar situation applies to the C6H6MnO2R- ions derived from the C6H7MnO- ions as indicated in Eq. (17). Adduct formation is observed also for the reactions of the C5H5MnO$ and C6H7MnO2 ions with water, alcohols, methanethiol and SO2 (see Eq. (23)). In addition, stable adducts have been reported to be formed as terminal ionic products in the reactions of the MnO3 ion with aliphatic alcohols [35].

Prevalent formation of adduct ions is often reported for reactions occurring in flowing afterglow (FA) or selected ion flow tube instruments (SIFT) [36]. For example, adduct ions are reported to be formed in the reactions of carbanions and alkoxide ions with CpMn(CO)3 in a FA instrument [5]. The formation of adducts in these instruments is ascribed normally to the occurrence of third body collisions between the reactant species and the helium carrier gas present at a pressure of ≈ 70 Pa [36]. These collisions can remove part of the excess energy with the result that the internal energy is decreased and dissociation either to the reactant species

In addition, stable adducts have been reported to be formed as terminal ionic products in the reactions of the MnO3 ion with aliphatic alcohols [35].

Prevalent formation of adduct ions is often reported for reactions occurring in flowing afterglow (FA) or selected ion flow tube instruments (SIFT) [36]. For example, adduct ions are reported to be formed in the reactions of carbanions and alkoxide ions with CpMn(CO)3 in a FA instrument [5]. The formation of adducts in these instruments is ascribed normally to the occurrence of third body collisions between the reactant species and the helium carrier gas present at a pressure of ≈ 70 Pa [36]. These collisions can remove part of the excess energy with the result that the internal energy is decreased and dissociation either to the reactant species
or the formation of separated product ions of a reaction is no longer possible. In a typical FT-ICR experiment the pressure is too low ($\leq 10^{-4}$ Pa) for the occurrence of third body collisions. Nevertheless, the formation of stable adduct ions under FT-ICR conditions has been reported in some instances [35,37–43]. The reported examples include the formation of proton bound adducts by association of an alkoxide ion to an alcohol molecule [39] or a carboxylate anion to a molecule of the conjugate acid [43]. The formation of stable adducts at low pressures is commonly ascribed to the emission of IR photons, thus lowering the internal energy below the threshold for dissociation. In the present cases, radiative stabilization may be held responsible for the formation of adducts in the reactions of the $\text{C}_5\text{H}_4\text{MnO}_2\text{R}^-$, $\text{C}_6\text{H}_6\text{MnO}_2\text{R}^-$, $\text{C}_5\text{H}_3\text{MnO}_2^-$ and $\text{C}_6\text{H}_7\text{MnO}_2^-$ ions. We note that these ions are relatively large implying that the number of degrees of freedom over which the energy may be distributed is relatively large for the adducts formed with an aliphatic alcohol molecule. This may decrease the rate of a possible reaction with the result that the lifetime of the excited adduct is enhanced. An increased lifetime enhances also the probability for photon emission and the formation of an adduct with an internal energy below the threshold for dissociation. The structures of the present adducts are not known and it is uncertain whether insertion of the metal centre into a bond of the substrate has occurred. In this respect we note that adduct formation competes with loss of water in the reactions of the $\text{C}_5\text{H}_5\text{MnO}_2^-$ and $\text{C}_6\text{H}_7\text{MnO}_2^-$ ions with aliphatic alcohols, methanethiol and SO$_2$. The loss of water is observed to become more important if the kinetic energy of the reactant $\text{C}_5\text{H}_5\text{MnO}_2^-$ or $\text{C}_6\text{H}_7\text{MnO}_2^-$ ion is increased by applying a suitable r.f. pulse to the excitation plates of the FT-ICR cell [12]. This is in keeping with the formation of adducts with a relatively high internal energy and an associated increase in the rate of the reaction leading to water loss. Furthermore, the average lifetime of the adducts generated in the reactions of ions with excess kinetic energy may be relatively short with the result that photon emission competes less effectively with product ion formation.
