Photoinduced Intramolecular Electron Transfer in a Bridged Cc60 (Acceptor)–Aniline (Donor) System. Photophysical Properties of the First “Active” Fulleren Diad

René M. Williams,* Jurriaan M. Zwier, and Jan W. Verhoeven*

Contribution from the Laboratory of Organic Chemistry, University of Amsterdam, Nieuwe Achtergracht 129, 1018 WS Amsterdam, The Netherlands

Received November 7, 1994

Abstract: A covalently functionalized fullerene comprising an electron donating aniline group coupled to the fullerene unit by a saturated heterocyclic bridge is shown to undergo a photoinduced intramolecular electron transfer process that causes quenching of the fluorescence of the adduct and strong decrease of triplet population in polar solvents. VIS-absorption, fluorescence and phosphorescence at 77 K, triplet–triplet absorption, time resolved fluorescence, and redox potentials of the fullerene adduct are presented. Analysis of the solvent dependence of the intramolecular electron transfer is given and is in good agreement with the experimental results.

* Our results regarding fluorescence quantum yields for Cc60 and Cc70 are in excellent agreement with those of Sun et al. Other values have been reported. Average value of the consistent data for the singlet excited state lifetime (τ₁) for Cc60 reported in refs 1d,k–m,s,t; for Cc70 reported in refs 1b,k–m,s,t,2f. The singlet state energy (E0) of Cc60 and Cc70 Palewski et al. reported 1.67 eV for Cc60 d. Triplet yields are reported in refs 1b–h, 2e. The triplet state lifetimes (τ₂) in nondegassed benzene at 295K and in oxygen free matrices have been reported. Taken from ref 1j.

Introduction

The photophysical properties1 of Cc60 and Cc70 and intramolecular electron transfer interactions2 in solution of these remarkable molecules have been the topic of many recent investigations. Relevant photophysical properties are summarized in Table 1.

Besides a triplet yield near unity and a very low fluorescence quantum yield, it has also been shown that, in contrast to some of the earliest reports on their photophysics, both fullerenes of the earliest reports on their photophysics, both fullerenes

charge separation can be feasible even when D and A are spaced up to 15 Å apart. Through bond interaction via the bridge contributes to the electronic coupling between donor and acceptor that is required for electron transfer. However, although the synthesis of several systems of the donor-bridge-fullerene (acceptor) type has been described, no photo-induced intramolecular electron transfer in these covalently functionalized fullerenes has been found until now.

Here we report on the synthesis, characterization, and solvent dependence of the photophysical properties of a new donor-bridge-buckyball compound (1, see Figure 1), that indeed displays photoinduced intramolecular charge separation.

**Experimental Section**

**Syntheses.** The bridged fullerene (acceptor)–aniline(donor) system 1 (see Figure 1) was obtained by a 1,3 dipolar addition to C₆₀ (MER corporation) of the decarboxylated iminium ion from 4-(N,N-dimethylamino)benzaldehyde and N-methyglycine following a procedure slightly modified from that described by Maggini et al.³⁷

³⁷H NMR (400 MHz Bruker ARX 400, CS₂, C₆D₆ (3:1), 308 K) δ (ppm) = 2.63, 3H, s, NCH₃; 2.71, 6H, s, N(CH₃)₂; 4.04, 1H, d, CH (exo), J = 9.24 Hz; 4.71, 1H, s, CH₄; 4.74, 1H, d, CH (endo), J = 9.24 Hz; 6.55, 2H, d, CH (arom), J = 8.91 Hz; 7.51, 2H, d (br), CH (arom), J = 7.43 Hz; ¹³C NMR (400 MHz, CS₂, C₆D₆ (3:1), 300 K, APT) δ (ppm) = 40.75, NCH₃; 40.79, N(CH₃)₂; 59.90, C sp³ C₆H₆; 70.85, CH₂; 78.74 (C sp³ C₆H₆); 84.39, CH; 113.35, CH (arom); 125.05, C (arom); 131.08, CH (arom); 136.73, 136.86, 137.72, 137.75, 140.71, 141.01, 141.12, 141.20, 142.57, 142.68, 142.87, 142.93, 143.02, 143.03, 143.05, 143.12, 143.16, 143.18, 143.30, 143.34, 143.56, 143.58, 143.61, 143.69, 144.03, 144.17, 144.45, 144.54, 144.71, 145.21, 146.22, 146.24, 146.27, 146.39, 146.48, 146.49, 146.55, 146.61, 146.81, 146.91, 147.08, 147.12, 147.15, 147.22, 147.27, 147.58, 147.72, 147.99, 148.23, 148.28, 151.06, 155.07, 155.14, 155.15, 157.64, C₆C₆ and C₆N (arom); IR (KBr, Perkin-Elmer 1310) ν (cm⁻¹) = 2940 (w), 2905 (w), 2830 (w), 2760 (m), 1605 (s), 1515 (s), 1458 (m), 1438 (m), 1422 (m), 1352 (m), 1180 (s), 815 (m); Mass spectra were obtained with a JEOL JMS-SX102A mass spectrometer using field desorption, positive ion. Calculated for C₆₁H₉₂N₂ 896.13134, found 896.1 (and 720 and 176.1).

**Results and Discussion**

Figure 2 shows the fluorescence and the VIS absorption of 1 in methylcyclohexane.

A beautiful symmetry of vibrational progressions is observed, a very minor Stokes shift (51 cm⁻¹) and an λₑₒ of 14 207 cm⁻¹ (704 nm, 1.76 eV). Absorption maxima are observed at (cm⁻¹) 14 225, 14 468, 14 671, 14 952, 15 175, 15 708, 18 416 (sh), 20 886 (sh), 23 256, and 24 765. Fluorescence maxima are observed at (cm⁻¹) 14 615, 14 966, and 14 74. Furthermore a shoulder shows up at 14 440 cm⁻¹ (see Figure 2A) that probably is a “hot band” (it is absent in low temperature emission, see later), and a similar feature can be seen at 13 970 cm⁻¹ in the absorption spectrum.
Figure 2. VIS-absorption and fluorescence of compound 1 in methylcyclohexene at room temperature. The symmetry relation of the emission and absorption is emphasized by the lines in part A.

Vibrational spacings are in reasonable agreement with theoretical and experimental values for native C\textsubscript{60}.\textsuperscript{11} Fluorescence excitation spectra are in excellent agreement with the UV–vis absorption spectra, indicating "normal" photophysical behavior (like C\textsubscript{60} and C\textsubscript{70}, see refs 1n–r and 2f), and the absence of interfering impurities.

Fluorescence quantum yields of 1 in different solvents are given in Table 2. Interestingly the adduct shows a sharp

* Fluorescence quantum yields in dichloromethane and benzonitrile are near detection limit. Triplet yields in chloroform and dichloromethane (denoted with an asterisk) are estimates due to sample decomposition under laser irradiation.

decrease of fluorescence intensity upon going to more polar solvents. A strong indication that the quenching process responsible for this involves the electron donating substituent dimethylaniline is the fact that addition of 10 $\mu$L of trifluoroacetic acid (TFA) to a solution of 1 in dichloromethane (dcm) results in a sharp increase in the fluorescence intensity restoring it to the level in nonpolar solvents (fluorescence yield of $6 \times 10^{-4}$, see Table 2).

Protonation of the nitrogens results in a slight hypsochromic shift of both the emission (713 nm (in for example toluene) to 696 nm (dcm + TFA)) and absorption maxima (704 nm (dcm) to 686 nm (dcm + TFA)). These shifts and the increase in luminescence can be reversed by addition of a few drops of pyridine. The observation that compound 2 does show fluorescence in benzonitrile, dichloromethane, benzene, and methylcyclohexane with a quantum yield of $6 \times 10^{-4}$ indicates that the pyrrolidine “bridge” moiety is not involved in the quenching process in compound 1.

Emission spectra of 2 at 77 K in methylcyclohexane and in a mixture of methylcyclohexane, methylethyltetrahydrofuran, and ethyl iodide (2:1:1) are shown in Figure 3. Whereas in the former matrix fluorescence peaks are sharpened and two new emission maxima are observed at 825 and 880 nm, in the latter all fluorescence is absent, and only the maxima at 825 (1.50 eV) and 880 nm are observed. This is a clear indication that the external heavy atom effect caused by ethyl iodide induces enhanced spin-orbit coupling and only phosphorescence is observed in the mixed matrix.1

The triplet energy ($\Delta E_{00}$) of 1 and 2 is thus determined to be 1.50 eV. Interestingly the singlet–triplet splitting of the $C_{60}$ adducts (i.e., $\Delta(S_1-T_1)$ = 0.26 eV) is smaller than for “native” $C_{60}$ ($\Delta(S_1-T_1)$ = 0.42 eV, see Table 1).

Representative triplet–triplet absorption spectra of 1 and of $C_{60}$ are depicted in Figure 4. Compared to $C_{60}$ the adduct shows a slightly broader transient absorption spectrum with the strongest absorption maximum at a little higher energy and a pronounced $T_1-T_2$ absorption at 800 nm (shoulder) indicating a smaller $T_1-T_2$ energy gap for 1. Interestingly the relative triplet yields of 1 also show a solvent dependence (see Table 2). Whereas the fluorescence of 1 is fully quenched in dichloromethane, the triplet is still populated for ca. 80% in this solvent. In benzonitrile however also the triplet is strongly quenched.

The solvent dependence of the fluorescence and triplet–triplet absorption of 1 indicates that in polar solvents an extra deactivation path of the excited states (S1 or T1) of 1 becomes available. As the population of a charge transfer state is energetically possible in polar solvents (according to the Weller equation, see below) we attribute this quenching path to an intramolecular electron transfer that deactivates the excited state.

We can so far not attribute any transient to the radical cation and anion of the charge separated state, due to the time resolution of our flash photolysis apparatus. This indicates that the charge separated state has a very short (subnanosecond) lifetime. Picosecond resolved transient absorption spectroscopy will be undertaken in the future.

In contrast to adduct 1, the adduct 2 shows strong triplet–
First "Active" Fullerene Diad

triplet absorption (θT ≈ 1) not only in low polarity but also in high polarity solvents (benzonitrile).

The extinction coefficient of the triplet–triplet absorption (ε(T-T)) of 1 at 692 nm is estimated to be 16 700 M⁻¹·cm⁻¹, on the assumption that 1 has a triplet yield near unity in methylcyclohexane. This is obtained by comparison of 1 and C₆₀ under identical experimental conditions and application of

\[ \frac{P_1/A_1(\lambda_{\text{exc}})}{\epsilon_1^{(T-T)}} C_1 \cdot t = \frac{P_2/A_2(\lambda_{\text{exc}})}{\epsilon_2^{(T-T)}} C_2 \cdot t \]

\( P \) = peak intensity, \( A \) = absorbance, \( C \) = concentration, \( t \) = pathlength, subscript 1 refers to adduct 1, and subscript 2 refers to C₆₀. For C₆₀ a ε(λ-) of 14 500 M⁻¹·cm⁻¹, at 750 nm was used.

Fluorescence decays obtained with single photon counting in methylcyclohexane and benzonitrile are represented in Figure 5. Monoexponential deconvolution of the decay in the nonpolar methylcyclohexane (in which electron transfer quenching is not exergonic, see below) gives a fluorescence lifetime of 1280 ± 40 ps (i.e., comparable to native C₆₀). In the polar solvent benzonitrile, in which both luminescence and population of the triplet state are strongly quenched, the fluorescence decay is not monoexponential but displays three components: a long living component with a lifetime of 1750 ps and a very low amplitude (0.008) and two fast components of 481 ps and 78 ps with an equal amplitude of 0.032. Single photon counting thus indicates that the quenching process in benzonitrile takes place with a rate between \( 1.3 \times 10^9 \) and \( 1.2 \times 10^{10} \) s⁻¹ by applying one of the fast components as \( \tau \) and the lifetime of 1 in methylcyclohexane as \( \tau_{\text{ref}} \)

\[ k_{\text{et}} = 1/\tau - 1/\tau_{\text{ref}} \]

The decay in benzonitrile is clearly not monoexponential, which can be attributed to the presence of more conformations of the compound due to ring inversion of the pyrrolidine ring. However, multieponential behavior seems to be a problem often encountered in the determination of the time resolved quenching of local fluorescence by intramolecular electron transfer.

Cyclic voltammetry of the adduct 1 in a toluene–acetonitrile mixture (3:1) using glassy carbon (0 to −2 V vs SCE) shows three reduction waves at −0.76, −1.24, and −1.79 V and two reoxidation waves at −1.30, −0.83, and −0.38 V vs SCE. The first midpoint reduction potential of the fullerene adduct is thus estimated to be ca. −0.57 V vs SCE, i.e., in good agreement with literature reports for other fullerene adducts. A model of the donor (4-(dimethylamino)benzylamine from Aldrich) shows an irreversible oxidation wave of +0.74 V vs SCE in acetonitrile leading to an estimated midpoint potential of +0.71 V vs SCE (i.e., comparable to N,N-dimethylparaloiduline).

The structure of the adduct 1, obtained by minimization with semiempirical AM1 calculations is shown in Figure 6. The aromatic ring of the donor is in an orthogonal relation to the

10 (a) Reasonable triexponential fits (\( \chi^2 < 1.3 \)) of the decay in benzonitrile can also be obtained by keeping \( r_1 \) fixed at 1280 ps (a probable lifetime for an impurity, see ref 10 (d)). (b) Hoffman, B. M.; Ratner, M. A. J. Am. Chem. Soc. 1987, 109, 6237. (c) Harrison, R. J.; Pearce, B.; Beddard, G. S.; Cowan, J. A.; Sanders, J. K. M. Chem. Phys. 1987, 116, 429. (d) Other explanations are possible, such as the presence of impurities or decomposition of the solute. The substance may contain less than 1% monooxide of 1. The existence of a nonexponential electron transfer rate, recently proposed in a theoretical paper, see ref 10e is another possibility. It has to be noted that the fluorescence quantum yield of 1 in benzonitrile is extremely low: ca. 2 × 10⁻⁵, which introduces experimental difficulties. (e) Zabrikov, A. A.; Scherer, P. O. J.; Fischer, S. F. J. Phys. Chem. 1994, 98, 3424.

plane that bisects the two sp$^3$ carbons of the fullerene. Although the center to center distance of the two chromophores is estimated to be ca. 9 Å, the edge to edge distance is only ca. 5 Å.

**Energetic Considerations.** An estimate of the driving force for photoinduced charge separation ($-\Delta G_{0\to e}$) in compound 1 was made using the standard Weller-type approach.$^{13}$ This requires, in addition to the donor and acceptor redox potentials ($+0.71$ V and $-0.57$ V vs SCE, see above) and the singlet or triplet state energy (1$E_{0\to e} = 1.76$ eV and 3$E_{0\to e} = 1.50$ eV, see above), substitution of the center to center distance ($R_c$) and of the effective ionic radii of the donor and acceptor radical cation and anion ($r^+\text{ resp. } r^-$). For $R_c$ a value of 9 Å was estimated.

* Internal reorganization energy (λ) is 0.3 eV.

from our modeling results (Figure 6). The r+ and r− values were calculated from the apparent molar volumes of N,N-dimethylaniline (density 0.956) and of C60 (density 1.65) using a spherical approach.14 This gives r+ = 3.7 Å and r− = 5.6 Å.

Because, even at the relatively small edge-to-edge donor–acceptor distance present in 1, the charge transfer state can only be populated in rather polar solvents, our results also imply that fullerenes are not very well suited for use as electron accepting chromophores for long range electron transfer in bichromophoric donor–bridge–acceptor systems, unless a significantly stronger donor than N,N-dimethylaniline (e.g., N,N,N,N′-tetramethyl-p-phenylenediamine) is used. One of our previous studies on the solvent dependence of intramolecular charge separation has already shown that optimal (in a Marcus sense) electron transfer interactions (at a given distance) can only be accomplished if already in a nonpolar solvent electron transfer is energetically favorable.14 It is also, by applying polar solvents one can gain driving force (and make electron transfer energetically possible) but one will never obtain the highest electron transfer rates. Our results thus suggest that high rate photoinduced intramolecular electron transfer in the systems described in ref 4b, c and 5e will not be possible due to the large separation distance or the small driving force, although the different spatial orientation of the donor and acceptor in these systems may be of influence.

Furthermore our results indicate that functionalization of C60 is accompanied by a decrease of the E00 with ca. 0.23 eV and a shift to a more negative first reduction potential of ca. 0.17 V. Thus, under the same conditions (i.e. donor, distance and solvent), the driving force for charge separation for an adduct of C60, compared to ‘native’ C60, would be ca. 0.40 eV less exergonic. This would mean that C60 adducts are less suited for photoinduced electron transfer systems than ‘native’ C60. It thus would seem preferable to incorporate a C60 unit into an electron transfer system by a supramolecular method, such as complexation by calix[8]arenes16 or γ-cyclodextrins,17 leaving the C60 unit intact.
