Since the discovery of iron-sulphur clusters in mitochondrial Complex I by Beinert and Sands in 1960 \cite{1} quite some research groups have been studying this most complicated enzyme. At present at least four different Fe-S clusters have been detected with EPR, but their precise function in the energy-linked electron transfer catalyzed by the enzyme is not really understood. The analysis of Weidner et al. \cite{2} of the operon encoding Complex I in \textit{Escherichia coli} indicates that only 14 of the 41 polypeptides of the bovine-mitochondrial enzyme \cite{3} are essential for coupled electron transfer. Five polypeptides show conservative Cys patterns that might accommodate Fe-S clusters. Four of these are quite likely inherited from hydrogenases [see e.g. 4]. The remaining polypeptide, the TYKY subunit \cite{3}, contains a Cys pattern typical for two classical cubane clusters. With this information a monomeric model, rather than a dimeric one \cite{5} can be constructed, explaining most physico-chemical and kinetic properties of the enzyme (see figure). All Fe-S clusters of Complex I are fully reduced within 5 ms, when SMP are mixed with NADH. Within 40 ms the $g_z$ line of the EPR signal of the clusters 2, but not the $g_{xy}$ line, disappears in coupled particles. This effect is sensitive to uncouplers. It is also reversed upon anaerobiosis. It is concluded that we have detected an 'energized' form of Complex I in which the protein structure around the clusters 2 has changed. It is proposed here that the TYKY subunit holds the Fe-S clusters 2 and renders the enzyme the ability to perform coupled electron transfer.
