CHAPTER 6

PREFRONTAL CHANGES IN THE GLUTAMATE-GLUTAMINE CYCLE AND NEURONAL/GLIAL GLUTAMATE TRANSPORTERS IN DEPRESSION WITH AND WITHOUT SUICIDE

ABSTRACT

Background: There are indications for changes in glutamate metabolism in relation to depression or suicide. The glutamate-glutamine cycle and neuronal glutamate transporters mediate the uptake of the glutamate and glutamine.

Materials and Methods: The expression of various components of the glutamate-glutamine cycle and the neuronal glutamate transporters was determined by Q-PCR in postmortem prefrontal cortex. The anterior cingulate cortex (ACC) and the dorsolateral prefrontal cortex (DLPFC) were selected from young MDD patients who had committed suicide (MDD-S; N = 17), from MDD patients who died of non-suicide related causes (MDD-NS; N = 7) and from matched control subjects (N = 12). We also compared elderly depressed patients who had not committed suicide (N = 14) with matched control subjects (N = 22).

Results: We found that neuronally located components (EAAT3, EAAT4, ASCT1, SNAT1, SNAT2) of the glutamate-glutamine cycle were increased in the ACC while the astroglia located components (EAAT1, EAAT2, GLUL) were decreased in the DLPFC of MDD-S patients. In contrast, most of the components in the cycle were increased in the DLPFC of MDD-NS patients.

Conclusions: The glutamate-glutamine cycle - and thus glutamine transmission - is differentially affected in suicide patients and depressed patients in an area specific way.
INTRODUCTION

Suicide is an important public health problem that has a strong association with psychopathology, in particular with mood disorders (Hawton and van Heeringen, 2009). A large body of evidence suggests that neurobiological factors play an important role in the predisposition to suicide (Ernst et al., 2009b; Mann and Currier, 2012). Although there is some overlap, this neurobiological predisposition appears to differ considerably from the predisposition to mood disorders per se, especially in the case of major depressive disorder (MDD) (Egeland and Sussex, 1985; Mann and Currier, 2010; Turecki, 2014).

The prefrontal cortex (PFC) is one of the major brain structures to modulate the stress response. It can be stimulatory or inhibitory, depending on specific sub-regions or stressor types (Dedovic, 2009). The PFC has also been implicated in mood disorders and there is a negative correlation between the severity of post-stroke depression and the distance between the brain injury site and the frontal pole (Narushima et al., 2003). Furthermore, a dysfunctioning anterior cingulate cortex (ACC) and dorsolateral PFC (DLPFC) were shown by functional and structural imaging in MDD (Drevets, 2000; Drevets et al., 2008) as well as an altered glucose metabolism and blood flow (Drevets, 1999; Mayberg, 2003; Seminowicz et al., 2004). Also, postmortem data support PFC involvement in MDD: e.g. reduced glial cell density and neuronal size were observed in the ACC and DLPFC (Cotter et al., 2002; Cotter et al., 2001; Rajkowska and Miguel-Hidalgo, 2007; Rajkowska et al., 1999).

Recent large-scale gene array studies in post-mortem subjects have provided strong support for alterations in GABAergic and glutamatergic neurotransmission in the PFC of depression (Bernard et al., 2011; Choudary et al., 2005; Duric et al., 2013). However, these postmortem studies consisted largely of psychiatric patients who had committed suicide, whereas none of the subjects in the control group had a psychiatric disease during their lifetime or committed suicide. Therefore, it remains unclear whether these changes in the PFC were related to depression or to suicide per se.

In a recent study, we found that only few GABA and glutamate-related genes were different in the ACC of elderly depressed patients who had not committed suicide (Zhao et al., 2012), while there were obvious changes in depressed patients who had committed suicide (Zhao et al., 2015). The present study therefore studied whether changes in the ACC and DLPFC occur in terms of the glutamate-
glutamine cycle and glutamate transporters, in relation to depression with and without suicide.

Glutamate is synthesized from glutamine by glutaminase in neurons. After glutamate is released from the synaptic terminal, it is taken up by astrocytes through high affinity sodium-dependent neuronal glutamate transporters, such as the excitatory amino acid transporter (EAAT) 1 and EAAT2 (Bar-Peled et al., 1997; Chaudhry et al., 1995; Kugler and Schmitt, 2003; Milton et al., 1997), where it is converted back into glutamine by glutamine synthetase (Martinez-Hernandez et al., 1977). Glutamine is then transported back to the neurons by the neutral amino acid transporter (SNAT) 1 and SNAT2, ready for reuse (Melone et al., 2004). Interestingly, brain-derived neurotrophic factor (BDNF)-induced increases in SNAT1 expression are required for the regulation of dendritic length and neuronal complexity during development (Burkhalter et al., 2007), but BDNF is also clearly linked to depression and suicide (Dwivedi et al., 2003; Ernst et al., 2009b; Grah et al., 2014; Qi et al., 2013). This suggests that the glutamate-glutamine cycle is not only an important constituent of the glutamatergic neurotransmission system in physiology, but may also be a vulnerable pathway in psychiatric disorders due to its linkage with both BDNF and glutamate and GABA neurotransmission. Intrasynaptic glutamate can also be taken up by EAAT3 and EAAT4, which are located on neurons (Danbolt, 2001; Rothstein et al., 1994; Yamada et al., 1997). The EAAT family of glutamate transporters shows homology to the neutral amino acid transporters (ASCT) 1 and ASCT2 (Arriza et al., 1993; Utsunomiya-Tate et al., 1996). Studies showed that ASCT1 in glutamate transmission mediates the efflux of glutamate from the neuron into the synaptic junction via calcium-dependent release, and that ASCT2 activity plays an important role in the glutamine-glutamate cycle between neurons and glia by facilitating the efflux of glutamine from glial cells (Broer et al., 1999).

In the present study, we hypothesized that the glutamate-glutamine cycle is impaired in the brains of depressed individuals who committed suicide and that the neuronal glutamate transporters associated with this cycle are dysregulated. Thus, we used real-time quantitative PCR (Q-PCR) to compare the gene expression patterns in the PFC of the astrocytic glutamate-glutamine cycle and neuronal/glial glutamate transporters in depressed patients in relation to suicide.
EXPERIMENTAL PROCEDURES

Subjects from the Stanley Medical Research Institute (SMRI)
Brain material was obtained from the SMRI, after obtaining permission for a brain autopsy and for the use of the brain material and clinical data for research purposes. Diagnostic and Statistical Manual of Mental Disorders (DSM)-IV diagnoses of MDD were made independently by two senior psychiatrists based on the medical records and, when necessary, telephone interviews with family members. This systematized procedure was carried out as described before (Torrey et al., 2000). The demographic information and medical data, including a life-long use of psychotropic medication and a history of drug abuse provided by SMRI, is shown in Supplementary S-Table 1 in Chapter 5.

The SMRI frozen brain samples contained ACC (Brodmann area 24) and DLPFC (Brodmann area 46) and were obtained from MDD patients who died of suicide (MDD-S; N = 17), MDD patients who died from other causes than suicide (MDD-NS; N = 7), and matched control subjects without a history of suicidal behaviour or any other psychiatric or neurological diagnosis (N = 12). These three groups were matched for race, age, gender, brain weight, postmortem delay (PMD), brain pH and hemispheric side (see Table 1A) as much as possible. All analyses were performed by investigators blind to the diagnosis.

Subjects from the Netherlands Brain Bank (NBB)
Frozen ACC (Brodmann area 24) and DLPFC (Brodmann area 9) brain material was obtained from the NBB and consisted of elderly depressed patients who died from non-suicidal causes MDD, N = 5; bipolar disorder (BD), N = 10; and matched controls who did not have a psychiatric or neurological disease (N = 22). The MDD versus BD subgroup and the combined depression group (DEP) versus the control group were well matched for age, gender, brain weight, clock time and month of death, PMD and brain pH. Demographic information and P-value of parameter matches are given in Table 1B, further clinico-pathological information has been described in a previous study (Zhao et al., 2012) and is provided in Supplementary S-Table 2 in Chapter 5.

Quantitative Real-time PCR (Q-PCR)
RNA isolation, cDNA synthesis and Q-PCR reactions were performed as described before (Wang et al., 2008; Zhao et al., 2012). The genes detected were Excitatory Amino Acid Transporter (glial high affinity glutamate transporter): EAAT1, 2; Excitatory Amino Acid Transporter (neuronal high affinity glutamate transporter): EAAT3, 4; Sodium-coupled neutral amino acid transporter: SNAT1, 2; Glutamine synthase: GLUL; Solute Carrier Family 1 (Glutamate/Neutral Amino Acid Transporter), member 4 (SLC1A4) and member 5 (SLC1A5): ASCT1 and ASCT2. Additional information on all tested genes and the sequences for each primer pair are shown in Supplementary S-Table 3.

Normalization strategy
To remove sampling-related differences (RNA quantity), a normalization strategy was used (Vandesompele et al., 2002). The expression of target genes was normalized using the sets of stable reference genes mentioned below. The information of reference genes is as follows: Glyceraldehyde-3-phosphate dehydrogenase (GAPDH), actin-beta (ACTß), tubulin-alpha (TUBα), tubulin-beta 4 (TUBß4), hydroxymethylbilane synthase (HMBS), ubiquitin C (UBC) for the SMRI-ACC/DLPFC study, GAPDH, ACTß, HPRT1 (hypoxanthine phosphoribosyltransferase 1), UBC (ubiquitin C), TUBα, TUBß4, HMBS for the NBB-ACC/DLPFC study.

Statistical analysis

For the demographic data analyses (age, brain weight, PMD, brain pH) we used the Mann-Whitney test for 2 sample situations and the Kruskal-Wallis test with multiple comparisons for 3 sample situations. Gender and race differences were determined using the Chi-square test (For more details, see Table 1A and 1B). For the statistical analyses of gene expression data TIBCO S+ software (version 8.2.0, TIBCO, Seattle, WA, USA) was used. Before processing, the expression data from target and reference genes were $^{10}$log-transformed. The statistics used to describe data obtained from studies using precious human brain material (with limited availability and consequently small samples) may not conform to the approximate theoretical distributions (e.g. Student-t) usually assumed in hypothesis testing. The stability of $P$-values obtained with parametric statistical tests may, therefore, be insufficient to provide reliable conclusions about the differences of gene expression in different psychiatric patient groups or about the correlations between genes within a patient group. Resample procedures (without replacement) may help to shed light on this problem. To keep the resample procedures simple and easy to interpret we resorted to two-group comparisons (like in t-tests) and correlations per patient group. We used 999 replicates of permuted gene expression data to generate permutation NULL distributions of the appropriate test statistics that correspond to NULL hypotheses implying that the mean differences between 2 groups or the mean correlation coefficients between 2 genes within a group are zero (Davison and Hinkley, 1997). For the difference between groups we used:

$$T = \frac{(\text{mean}(x_2) - \text{mean}(x_1))}{\sqrt{\text{sd} \cdot (\text{df})^{-1/2}}}$$

Here, sd is the pooled standard deviation and df denotes the Welch modified degrees-of-freedom. For normally distributed data with unknown, unequal variances, $T$ is approximately distributed as a t-distribution with df degrees-of-freedom. The simulated $T$'s are called permutation t-values and the $T$ corresponding to the observed difference of expression is called the observed t-value. The following statistic

$$\text{cor} = \frac{\text{sum} [(x_1 - \text{mean}(x_1)) \cdot (x_2 - \text{mean}(x_2))]}{\sqrt{\text{sum} (x_1 - \text{mean}(x_1)) \cdot \text{sum} (x_2 - \text{mean}(x_2))}}$$

150
was calculated for correlation problems. For pairs of normally distributed data
this statistic has an approximate t-distribution with \( n - 2 \) degrees-of-freedom
(N = number of observations). The observed test statistic and permutation test
statistics are called observed and permutation cor-values, respectively. In each
procedure the observed test statistic was combined with the permutation test
statistics and ordered. Subsequently, the number of statistics equal to or smaller
than and the number of statistics equal to or larger than the observed value were
counted. These numbers were divided by 1000 (999+1) to yield the left (p-left)
and right (p-right) probabilities. Two-sided permutation P-values were calculated
as 2 times the minimum of p-left and p-right. All presented tests for the gene
expression data are 2-sided and p-values were corrected for multiple testing using
the Benjamini-Hochberg criterion (Benjamini and Hochberg, 1985) and were
considered statistically significant if their value was less than 0.05.

RESULTS

Changes in glutamate-glutamine cycle gene expression are related to
suicide, not to depression

Brain material obtained from the SMRI was analyzed for changes in the genes
involved in the glutamate-glutamine cycle and neuronal/glial glutamate
transporters. We determined the RNA integrity value (RIN) to assess whether the
quality of the human post-mortem tissue RNA isolated from the ACC or DLPFC
did not differ between patient groups (Stan et al., 2006). The RIN did not show any
significant differences between the diagnostic groups in the SMRI material (RIN
value of the ACC from MDD-S patients: 7.69 ± 0.66; MDD-NS patients: 7.49 ±
0.56 and the control group: 7.73 ± 0.95, mean ± SEM; RIN value of the DLPFC
from MDD-S: 7.69 ± 0.66, MDD-NS patients: 7.49 ± 0.56 and the control group:
7.73 ± 0.95, mean ± SEM).

In ACC, the expression of neuronal glutamate transporters ASCT1, EAAT3
and EAAT4 were significantly increased in MDD-S compared with MDD-NS
patients \( (P = 0.024, P = 0.008 \) and \( P = 0.008 \) respectively) or with the controls
(ASCT1: \( P = 0.015 \), Figure 1A; EAAT3: \( P = 0.028 \), Figure 1C; EAAT4: \( P = 0.008 \),
Figure 1D). In addition, neuronal located glutamine transporter SNAT1 and
SNAT2 transcription levels were elevated in MDD-S patients compared with
MDD-NS patients \( (P = 0.008 \) and \( P = 0.020 \) respectively) or with control subjects
(P = 0.028, Figure 1E; and P = 0.028, Figure 1F; respectively). ASCT2 transcript level was also increased in the MDD-S patients compared to MDD-NS patients (P = 0.008, Figure 1B). However, none of these genes showed difference between MDD-NS and control subjects. In contrast, we found that ASCT1 and glial related genes (EAAT1, EAAT2 and GLUL) were decreased in the MDD-S compared with MDD-NS patients in DLPFC (P = 0.042, Figure 1G; P = 0.038, Figure 1H; P = 0.038, Figure 1I; P = 0.038, Figure 1K; respectively). Furthermore, the transcript levels of these genes, and of EAAT3 (P = 0.038, Figure 1J) SNAT1 (P = 0.038, Figure 1L) and SNAT2 (P = 0.041, Figure 1M) were increased in the MDD-NS patients compared with control subjects (Table 2).

To explore what aspects of suicide may cause gene transcription alterations in the MDD patients, the SMRI MDD-S group was divided into two subgroups: violent suicide method (hanging, jumping, shooting and stabbing, N = 12) and non-violent method (overdose, N = 5). However, we did not find any significant difference in the expression of the genes studied in either ACC (P > 0.58) or DLPFC (P > 0.28).

**Changes in glutamate-glutamine cycle gene expression are not related to suicide ideation**

We then examined ACC and DLPFC samples from the NBB (RIN value of the ACC from the elderly depressed patients: 7.29 ± 0.55 and the control group: 7.24 ±1.15, mean ± SEM; RIN value of the DLPFC from the elderly depressed patients: 7.51 ± 0.66 and the control group: 7.66 ± 0.88, mean ± SEM).

None of the depressed patients from the NBB had committed suicide. Consistent with our results from the SMRI subjects, we did not observe significant changes in the ACC of depressed patients and controls. Based on their clinical records, we divided the DEP group into subgroups of patients that either did or did not have a record of suicidal thoughts and ideation. To assess whether suicidal ideation contributes to gene transcription in this area, the same set of markers related to glutamate-glutamine cycle and neuronal glutamate transporters were tested. We did not find any significant differences in the ACC (P > 0.95) nor in the DLPFC (P > 0.16) with respect to suicide ideation, either for neuronal located genes (ACC: P > 0.95; DLPFC: P > 0.45) or astrocytic genes (ACC: P > 0.95; DLPFC: P > 0.16). These findings suggest that suicide itself, but not mere suicide ideation, may cause changes in the expression of genes involved in the glutamate-glutamine cycle.

The differences among MDD-S, MDD-NS and Ctr in the SMRI, Dep-NS and Ctr in the NBB were tested with permutation tests respectively. The permutation P-values were corrected for multiple testing using the false discovery rate. P < 0.05 were considered significant and marked as bold Italic style, * indicates P < 0.05, ** indicates P < 0.001. Fold changes were calculated using the mean gene expression values.

Abbreviations: ACC, anterior cingulate cortex; Ctr, control; DLPFC, dorsolateral prefrontal cortex; MDD-S, major depressed patients who committed suicide; MDD-NS, major depressed patients who died from causes other than suicide. For abbreviations of genes see S-Table 3.
Correlation with BDNF/TrkB
As both the SMRI and NBB patient cohorts of the present study had also been investigated in our previous studies on the expression of BDNF/TrkB-related genes (Qi et al., 2013; Zhao et al., 2015), we investigated the putative relationship between truncated receptor of BDNF (TrkB.T1) and BDNF with the present target genes here. There appeared to be a positive correlation between the TrkB.T1 and astrocytic genes (EAAT1, EAAT2, GLUL), and also neuronal located genes (EAAT3, SNAT1, SNAT2, ASCT1) in the MDD-S individuals (For more details of $P$-values, see Table 3). TrkB.T1 only correlated with astrocytic genes in the MDD-NS group, while there was no such correlation in the control group in the ACC. We found that TrkB.T1 was correlated with both astrocytic genes (EAAT2, GLUL) and neuronal located genes (EAAT3, SNAT1, SNAT2, ASCT1) in the MDD-S patients, but not in the MDD-NS nor control subjects in the DLPFC (For more details of $P$-values, see Table 3). BDNF is correlated with EAAT3 and SNAT1 in the ACC of MDD-NS patient group, while there was no correlation in either MDD-S or control subjects. In addition, we did not find any correlation in the DLPFC (For more details of $P$-values, see Table 3).

Possible Confounding factors
The possible confounders in our study, such as age, gender, brain pH, brain weight, PMD, hemisphere side, ethnicity, history of substance abuse, severity of substance abuse and psychotic feature, did not differ between the groups (Table 1A and 1B), implying that they will not have affected our conclusions. Concerning the possible differences between MDD and BD in the NBB cohort, calculation for all the target genes proved that there was no significance difference between these two subgroups (ACC: $P > 0.30$; DLPFC: $P > 0.05$). Furthermore, we have shown earlier that there is no significant difference between MDD and BD patients on the GABA/glutamate related genes in the PFC in our previous study (Zhao et al., 2012). Thus, there is no indication that pooled MDD-BD in the NBB cohort would affect our conclusion. Since psychosis was present in some of the subjects in the SMRI patient cohort, all differentially expressed genes were compared for the presence or absence of psychosis. None of the comparisons were found to be significant in ACC ($P > 0.94$). In the DLPFC, there is a significantly lower EAAT3 expression in non-psychotic MDD patients ($P = 0.036$), the expression of the other genes is not different between psychotic and non-psychotic patients ($P > 0.11$). A potentially contributing confounding factor in all postmortem studies

Permutation P-values of the correlations of BDNF and TrkB with the target genes. The P-values were corrected for multiple testing. P < 0.05 were considered significant and marked as bold Italic style. * indicates P < 0.05.

Abbreviations: ACC, anterior cingulate cortex; Ctr, control; DLPFC, dorsolateral prefrontal cortex; MDD-S, major depressive disorder who committed suicide; MDD-NS, major depressive disorder who died of non-suicidal cause; SMRI, Stanley Medical Research Institute. For abbreviations of genes see S-Table 3.
is medication. However, this does not seem to be a confounder for our data, as medication (SSRI, SARI, TCA) did not affect any of the gene expression in ACC ($P > 0.48$) or in DLPFC ($P > 0.51$). SNRI could not be tested because one group only had 2 observations.

**DISCUSSION**

In the present study, we found in the SMRI cohort that ASCT2 and neuronal located molecule transcript levels were significantly higher in the ACC of MDD-S patients than in the MDD-NS patients or the control subjects. In contrast, decreased ASCT1 and astroglia located molecule transcript level were found in the DLPFC of MDD-S patients compared to MDD-NS patients. Furthermore, most of the target genes were increased when comparing MDD-NS with control subjects in the same brain area. We did not find any difference in expression level in the NBB cohort. Our results suggest that the changes in ACC synaptic glutamate cycle are rather related to suicide than to depression per se, and that they are neuronal located. For DLPFC, suicide related changes are more astroglia located and the depression related changes are from both neuronal and astroglia. In both brain areas, the molecular changes in suicide and depression seem to go into an opposite direction.

Glutamine serves as a substrate in both glutamatergic and GABAergic neurons (Gao and Bao, 2011). The uptake of glutamine into neurons is facilitated by system A amino-acid transporters (Mackenzie and Erickson, 2004; Ogura et al., 2006) and these transporters can thus alter both GABA and glutamate functioning. SNAT1 (also termed SLC38A1) is a system A transporter localized in neurons. It shows a high affinity for glutamine released by astroglia (Broer, 2014; Schioth et al., 2013) and is present at the start of the glutamate-glutamine cycle in neurons. Although the 11 human transmembrane domains of SNAT1 show a high homology with the murine ortholog of this protein (Wang et al., 2000), their functional and kinetic properties in humans are still poorly understood (Pochini et al., 2014). Like SNAT1, SNAT2 (also termed SLC38A2) is also expressed in neurons, and acts as a system A transporter (Sundberg et al., 2008; Varoqui et al., 2000; Yao et al., 2000). One of the differences between these two transporters is that SNAT1 prefers glutamine (Varoqui et al., 2000), while SNAT2 carries several neutral amino acids, including glutamine and alanine, with alanine transport being approximately four times as
efficient as glutamine transporter (Yao et al., 2000). Alanine can be converted into glutamate later. Glutamine is a precursor of glutamate, which is further converted into GABA by glutamate decarboxylase (GAD), which is present in GABAergic neurons. The increased SNAT1 and SNAT2 in our study may thus cause more glutamine influx into neurons and over-activate GABA synthesis. This is in line with our previous study, which showed increased GAD levels in the ACC of MDD-S patients (Chapter 4). Furthermore, animal experiments have shown that SNAT1 is significantly up-regulated by diazepam (a GABA-A receptor agonist) treatment (Sundberg et al., 2008), and the transcript levels of both GABA-A and GABA-B receptor transcript were up-regulated in the MDD-S patients (Chapter 4), suggesting that increases in SNAT1 might be involved in the dysfunction of GABA receptors in the ACC of MDD patients who committed suicide. Five depressed patients in the NBB cohort were treated with benzodiazepine (BDZ) during the last 3 months of their life, but we did not find significant differences in SNAT1 mRNA between the BDZ treated and non-BDZ treated depressed patients. No such comparison could be performed in the SMRI cohort, as there was insufficient information on their BDZ use. Another animal study showed that SNAT1 and/or SNAT2 are altered in a post-traumatic epilepsy model. Moreover, exogenous glutamine enhanced the abnormal evoked and spontaneous activity characteristic of the injured neocortex. This effect could be blocked by inhibition of SNAT1 and SNAT2 in the post-traumatic epilepsy model (Tani et al., 2007), suggesting that the increased SNAT1 and SNAT2 in the MDD-S patients (ACC) and in the MDD-NS patients (DLPFC) are promising novel pharmaceutical target for suicide and depression treatment.

The main candidates to mediate glutamate efflux from neurons are EAAT3, EAAT4 and ASCT1 which are significantly increased in the ACC of MDD-S individuals. In contrast, we found that ASCT1 mRNA expression is decreased in the DLPFC, while also the expression level of EAAT3 and EAAT4 were decreased although they did not reach significance. This shows that impaired glutamate transport in suicide shows opposite changes in ACC and DLPFC. Furthermore, when comparing MDD-NS to control subjects, most of the target genes are increased, which strongly indicates that suicide and depression also show opposite changing patterns in the DLPFC. This pattern was supported by our observations in ACC. We found that all the suicide related changes were upregulated, while the depression related changes were decreased according to the fold changes, although they did not reach significance. Although the mechanism by which EAAT3,
EAAT4 and ASCT1 expression is altered in the different brain areas is unknown, as functional consequence, extracellular and synaptic glutamate levels could be elevated in the ACC and decreased in the DLPFC in MDD-S patients. In clinical investigations, NMDA-antagonists, such as ketamine, turned out to be potent and rapid acting antidepressant agents and also to be effective in suppressing suicide ideations (Ballard et al., 2014; Chen and Lipton, 2006; Zarate et al., 2006) while they also modify glutamate signaling via AMPA-receptors (Maeng and Zarate, 2007), a possibility supported by our previous study (Chapter 4).

We did not find any similar changes in the NBB cohort, which is in line with our finding from SMRI cohort that the changes in ACC synaptic glutamate cycle are rather related to suicide than to depression per se in ACC. For DLPFC, it seems there is a discrepancy between SMRI and NBB results. Since the age difference between SMRI cohort (average: 43.72 years old) and NBB cohort (average: 75.42 years old), also the PMD difference (SMRI: 28.19 hours and NBB: 7.55 hours), we performed further calculation and found that all adjusted permutation P-values of the correlation between target gene expression and age are > 0.05, and > 0.98 for PMD in DLPFC of SMRI cohort. This suggests that age and PMD did not affect our result and did not contributed to the discrepancy. It has also to be noted that the DLPFC in the SMRI and NBB cohorts represented different Brodmann areas (i.e. BA 46 or BA 9 respectively). This may explain why DLPFC-SMRI showed numbers of changes while DLPFC-NBB did not show any significant change.

The BDNF/TrkB system has been linked to depression and suicide (Dwivedi et al., 2003; Ernst et al., 2009b; Qi et al., 2013). BDNF regulates dendritic length and neuronal complexity during development, which requires BDNF-induced increases in SNAT1 expression (Burkhalter et al., 2007). Interestingly, in a previous genetic study an association was observed between altered expression P-values of the correlation between target gene expression and age are > 0.05, and > 0.98 for PMD in DLPFC of SMRI cohort. This suggests that age and PMD did not affect our result and did not contributed to the discrepancy. It has also to be noted that the DLPFC in the SMRI and NBB cohorts represented different Brodmann areas (i.e. BA 46 or BA 9 respectively). This may explain why DLPFC-SMRI showed numbers of changes while DLPFC-NBB did not show any significant change.
astroglia related.

In conclusion, we observed that the neuronal located components of the glutamate-glutamine cycle were increased in the ACC while the astroglia located components were decreased in the DLPFC of MDD-S patients. In contrast, most of the components were increased in the DLPFC of MDD-NS patients. These data suggest that glutamine transmission in the glutamate-glutamine cycle is affected differentially in suicide patients and depressed patients in an area specific way.

ACKNOWLEDGEMENTS

Postmortem brain tissue was donated by The Stanley Medical Research Institute Brain Collection and by the Netherlands Brain Bank. We are indebted to them for providing us with the brain material and patient information. We thank U. Unmehopa for her technical help. W. Verweij and Prof. H. Kessels for critical reading of the manuscript.
