Abstract

Objective—To examine the relation between trends over time in mortality and hospital morbidity caused by various cardiovascular diseases in the Netherlands.

Design—Trend analysis by Poisson regression of national data on mortality and hospital admissions from 1975 to 1995.

Subjects—The Dutch population.

Results—All cardiovascular diseases combined were responsible for 39% of all deaths and 16% of all hospital admissions in 1995. From 1975 to 1995, age adjusted cardiovascular mortality declined by an annual change of −2.0% (95% confidence intervals (CI) −2.1% to −1.9%), while in the same period age adjusted discharge rates increased annually by 1.3% (95% CI 1.1% to 1.5%). Around 60% of the gain in life expectancy in this period was related to lower cardiovascular mortality. For mortality, major reductions were seen in coronary heart disease (annual change −2.9%) and in stroke (−2.1%), whereas the increase in hospital admissions was mainly caused by chronic manifestations of coronary heart disease (5.1%), heart failure (2.1%), and diseases of the arteries (1.8%). In recent years, the gap between men and women at risk of dying from coronary heart disease became smaller for those aged <65 years.

Conclusions—Our findings of a decrease in cardiovascular mortality and an increase in admission rates for chronic conditions such as heart failure, chronic coronary syndromes, and diseases of the arteries, support the hypothesis that the longer survival of many patients with heart diseases is leading to a growing pool of patients at increased risk for subsequent cardiovascular complications in Western countries.

Methods

Data on the number of deaths in the Netherlands from 1975 to 1995 inclusive were obtained from Statistics Netherlands in Voorburg. Mortality data were grouped by five year age categories, sex, and primary cause of death. The eighth version of the International Classification of Diseases (ICD) was used for the years 1975 to 1978 and the ninth version thereafter. The total group of CVD consisted of all codes from group VII of the ICD classification (diseases of the circulatory system), together with ICD codes identifying congenital anomalies of the circulatory system (in ICD-8 codes 746 and 747; in ICD-9 codes 745–747). The following diseases were analysed separately: coronary heart disease (a combination of ICD codes 410–414), stroke (codes 430–438), and diseases of the arteries (codes 440–448).

The number of hospital admissions for CVD was derived from the central database of hospital admissions in the Netherlands called the National Medical Register. This database is maintained by SIG Health Care Information. In 1975, 83% of all hospital admissions in the Netherlands was recorded in this database. Cover had grown to 95% in 1980, and was complete from 1986 onwards. These percent-

Results

ALL CVD COMBINED: PRESENT BURDEN AND TRENDS

The total group of CVD was responsible for the deaths of 52 329 men and women in 1995, which is equivalent to 39% of all deaths in the Netherlands (table 1). All cancers combined caused 36 489 deaths in 1995, corresponding to 27% of all deaths. Proportionate mortality by age for the main causes of death is shown in fig 1. Figure 1 can be divided into four main segments, each linked with a predominant cause of death: from birth to 5 years, perinatal conditions and congenital diseases; from 5 to 34 years, injuries and suicide; from 35 to 64 years, cancer and to a lesser degree CVD; and 65 years and older, CVD and to a lesser degree cancer.

Age adjusted mortality from all CVD in the Netherlands decreased steadily from 419 per 100 000 in 1975 to 283 per 100 000 in 1995. In the same period, all cause mortality dropped from 934 per 100 000 to 760 per 100 000. As a result, life expectancy at birth for men in this period rose by 3.1 years to 74.6 years in 1995, and for women by 2.7 years to 80.5 years. Fifty four per cent of the gain in life expectancy for men and 63% for women could be explained by the lower mortality from CVD.

In contrast to the decline in mortality with an annual change of −2.0% (95% confidence interval (CI) −2.1% to −1.9%), there was a constant increase in age adjusted discharge rates for CVD with an annual growth of 1.3% (95% CI 1.1% to 1.5%). The absolute number of hospital admissions for CVD nearly doubled from 142 522 in 1975 (10% of all hospital admissions) to 248 308 in 1995 (16% of all hospital admissions).

TIME TRENDS FOR DIFFERENT CVD

Figure 2 combines the trends in age adjusted mortality and discharge rates for several CVD. For mortality, major reductions were seen for coronary heart disease (annual change of −2.9%; 95% CI −3.0% to −2.8%) and stroke (−2.1%; 95% CI −2.3% to −2.0%), whereas mortality from arterial diseases remained more or less stable (0.3%; 95% CI 0.0% to 0.6%). Although the relative decline in mortality from coronary heart disease and stroke over the whole study period was similar in magnitude, trends over time were different. During the first half of the study period (1975 to 1985), the rate of decline was faster for stroke (annual change of −3.0%; 95% CI −3.3% to −2.8%) than for coronary heart disease (−2.3%; 95% CI −2.4% to −2.1%). During the second half of the study period, coronary heart disease mortality continued to decline at an even higher rate of −3.7% (95% CI −3.9% to −3.4%), whereas
mortality from stroke slowed down with an annual relative change of −0.6% (95% CI −0.7% to −0.6%).

For hospital admissions, striking increases were seen in admissions for coronary heart disease (annual growth of 2.0% to 2.8%) with a remarkable difference between acute syndromes (0.3% to 0.6%) and chronic manifestations (2.6% to 2.8%) for heart failure (2.1% to 2.3%) and for arterial diseases (1.6% to 2.0%). Age adjusted hospital case fatality improved for all major CVD: hospital case fatality for coronary heart disease declined from 12.7% in 1975 to 4.2% in 1995, for stroke from 28.6% to 17.0%, and for arterial diseases from 9.4% to 5.4%.

Discussion

Our analysis showed that CVD are still the leading cause of death in the Netherlands, despite a 30% decline in age adjusted mortality during the past 20 years. Based on the death rates observed in 1995, the lifetime probability of dying from CVD is 40% for both men and women, although the mean age at which they die is very different. Of all 40,761 women that would die from CVD, the mean age at death would be 82.3 years, with 82% of these women dying after age 75. For men the mean age at death would be 76.4 years, with 61% dying after age 75.

The rate of decline in mortality from CVD varied among different age groups. In general, the rate of decline was faster in younger age groups. For instance, the relative decline in CVD mortality for those younger than 75 years was −2.4% (95% CI −2.5% to −2.3%) compared with −1.8% (95% CI −1.9% to −1.6%) for those 75 years and older. The annual increase in discharge rates was in general more pronounced in older age groups. The annual growth in the age groups above 75 years was 2.0% (95% CI 1.9% to 2.1%) compared with 1.1% annual growth (95% CI 0.9% to 1.4%) in the age groups younger than 75 years.

Generally, trends in mortality from different CVD showed similar patterns among men and women. Only for mortality from diseases of the arteries were trends in the opposite direction observed, with men having an annual increase of 1.3% (95% CI 1.0% to 1.6%) and women an annual decline of 1.0% (95% CI −1.3% to −0.6%). In recent years, different trends by sex and age were observed for coronary heart disease mortality. Figure 3 presents the age specific sex ratios for coronary heart disease mortality. The following observations can be made. Firstly, in all age groups sex ratios were above 1, indicating that men had a higher rate of mortality than women. Secondly, sex ratios became smaller with increasing age. Thirdly, sex differences in the age groups below 65 years of age were severely reduced in recent years, whereas sex differences in the older age groups remained more or less stable.

CHRONIC CONDITIONS
LONGER SURVIVAL BUT MORE PATIENTS WITH
CHRONIC CONDITIONS
It has been hypothesised that the longer
survival of patients with coronary heart disease
will lead to a growing group of patients at high
risk from subsequent vascular events, causing
an increase in the prevalence of chronic
conditions.8–11 The remarkable growth in the
number of hospital admissions for CVD and
the type of diseases responsible for this increase
are in line with this hypothesis. Major increases
were seen for congestive heart failure, chronic
coronary syndromes, and arterial diseases (fig
2). In the interpretation of the increase in hos-
pital admissions it is important to recognise
that multiple admissions of the same patient
cannot be determined. In the case of chronic
conditions like heart failure and arterial
diseases, readmissions might be frequent. What
proportion of the increase in hospital admis-
sions is related to readmissions and how much
to "new" patients remains unclear. We have
already demonstrated that in heart failure
patients multiple readmissions within a short
period of time are common.21 An additional
factor in the rise of the number of admissions
for coronary heart disease is the intensive use of
diagnostic and therapeutic procedures in pa-
tients with coronary syndromes.

DIFFERENCES IN TIME TRENDS FOR MORTALITY
FROM CORONARY HEART DISEASE BETWEEN MEN
AND WOMEN
A significant finding of this study is that the gap
between men and women at risk of dying from
coronary heart disease has become smaller in
recent years for those aged 65 years and
younger (fig 3). The reasons for this are not
clear, but might be related to men having more
benefit from recent advances in medical care or
women adopting more unfavourable lifestyles.
Several studies have demonstrated that women
with coronary heart disease are treated dif-
dently from men.22–25 These differences include
a lower use of invasive diagnostic testing in
women, lower rates of revascularisation in
women, and less likelihood of women being
discharged with aspirin and β blocking agents.
The fact that women with myocardial infarc-
tion are in general older and have more
traditional risk factors such as hypertension,
diabetes mellitus, and congestive heart failure
than men at the time of admission, could not
fully explain the lower use of thrombolysis in
women.20

STRENGTHS AND LIMITATIONS OF THE STUDY
This was a descriptive study, analysing only
temporal relations in data from two national
registries. The validity of this study depends
strongly on the accuracy of the primary cause
of death or the primary diagnosis at discharge.
For mortality, discrepancies have been found
between the judgment of physicians and subse-
quent findings at necropsy, and between physi-
cians coding identical cases for research
purposes.27–30 The use of broad categories of
diseases, as has been done in this study, is
known to lead to fewer discrepancies than ana-
lysing single disorders.29 30

The use of hospital statistics data is limited
by the inability to identify multiple admissions
of the same patient. Furthermore, the number
of hospital admissions is affected by changes in
admission policy and by improvements in
diagnostic capabilities. The significance of
these factors will vary with the disease under
study. They will be of minor importance for
diseases like acute myocardial infarction, in
which nearly all patients are hospitalised, but
become more important for diseases like stroke
(introduction of computed tomography) and
heart failure (coding problems and admission
policy). The lower hospital case fatality could
have been influenced by more admissions for
milder forms, by more frequent readmissions,
and by more admissions for diagnostic pur-
poses.
This study underlines the dynamic and complex interactions that exist between morbidity and mortality caused by different CVD. Studies with a limited time of follow up or trials dealing with selected patients will reveal only part of the total picture important from a public health point of view. More attention needs to be given to the exact benefits, both short and long term, of new additions to the treatment of heart patients and to differences in medical care and outcomes between men and women. The shift from acute and fatal to more chronic conditions should lead to more attention being focused on the reasons for and prevention of readmissions in patients with chronic disorders.

To summarise, CVD are still the leading cause of death among men and women in the Netherlands, despite a major decline in age adjusted mortality of more than 30% in both men and women. This decline was the major reason behind the gain in life expectancy. In the same period that mortality declined, the number of hospital admissions for CVD rose steadily. This increase was mainly caused by diseases related to non-acute syndromes of coronary heart disease, heart failure, and arterial diseases. These findings support the hypothesis that improvements in medical care have resulted in a longer survival of many heart disease patients, and led to a growing prevalence of patients with chronic cardiovascular conditions. These growing numbers of patients, coupled with the increased aging of many European populations, will increase the strain on forthcoming health care budgets even further. The reduced difference in mortality from coronary heart disease between men and women aged 65 years and younger might suggest that men have had more benefit from the recent improvements in medical care than women.
