Synthesis, electronic structure and redox properties of the diruthenium sandwich complexes \([\text{Cp}^*\text{Ru}(\mu-\text{C}_{10}\text{H}_8)\text{RuCp}^*]^x\) 
\((x = 0, 1+; \text{Cp}^* = \text{C}_5\text{Me}_5; \text{C}_{10}\text{H}_8 = \text{naphthalene})\)

Dirk Herrmann, a Christian Rödl, a Bas de Bruin, b,c František Hartl, b,d and Robert Wolf b,e,a

The dinuclear ruthenium complex \([\text{Cp}^*\text{Ru}(\mu-\text{C}_{10}\text{H}_8)\text{RuCp}^*]\) \(1\; \text{Cp}^* = \eta^5-\text{C}_5\text{Me}_5\) was prepared by reduction of the cationic precursor \([\text{Cp}^*\text{Ru}(\eta^6-\text{C}_{10}\text{H}_8)]\text{PF}_6\) with \(\text{KC}_8\). Diamagnetic \(1\) has a symmetric molecular structure with an anti-facial configuration of the \(\text{Cp}^*\text{Ru}\) moieties coordinating to naphthalene. Density Functional Theory (DFT) studies showed an electronic structure similar to that of the analogous diiron complex \([\text{Cp}^*\text{Fe}(\mu-\text{C}_{10}\text{H}_8)\text{FeCp}^*]\). Cyclic voltammetry and UV-vis spectroelectrochemistry showed that \(1\) can be reversibly oxidized to \(1^+\) and \(1^{2+}\). Chemical oxidation with \([\text{Cp}^*\text{Fe(BAr}_7^*)\text{L}^\text{a}]\) afforded the paramagnetic compound \([1]B\text{Ar}_7^\text{a}\), which was investigated by EPR, single-crystal X-ray diffraction and DFT calculations. Reaction of \(1\) with Brookhart’s acid gave the hydride complex \([1]B\text{Ar}_7^\text{a}\), which was characterized spectroscopically and crystallographically. Cyclic voltammetry showed that \([3]^+\) is converted back to \(1\) upon reduction and oxidation.

**Introduction**

Hydrocarbon-bridged complexes are of potential interest as model compounds to study the electronic communication between two metal centers, which is relevant for the design of potential electronic devices.\(^1\) In this regard, considerable attention has been directed toward the use of polyaromatic bridging ligands, which may provide a varying degree of electronic coupling between the coordinated metal atoms through their conjugated \(\pi\) system.\(^2\) The two simplest polyarenes, naphthalene and anthracene, should enable a particularly strong electronic conjugation between the metal atoms, yet the number of known bimetallic naphthalene and anthracene complexes is still surprisingly small. Compounds A–E (Fig. 1) containing vanadium, chromium and manganese are early examples.\(^3\) A related diiron complex, \([\text{CpFe}(\mu-\text{C}_{14}\text{H}_{10})(\text{FeCp})]^\text{2+}\) \((\text{F}^+, \text{C}_{14}\text{H}_{10} = \text{anthracene})\), was prepared by Hendrickson and co-workers.\(^4\) The group of Jonas later extended this family by synthesising \([\text{CpFe}(\mu-\text{C}_{10}\text{H}_8)\text{FeCp}]\) \((\text{H})\) and \([\text{Cp}^*\text{Fe}(\mu-\text{C}_{10}\text{H}_8)\text{FeCp}^*]\) \((\text{J})\). A single-crystal X-ray structure analysis of \(J\) confirmed the anti-facial arrangement of the \(\text{FeCp}\) moieties.

Polyarene-bridged complexes are also known for ruthenium and rhodium (Fig. 2).\(^6,8\) Diruthenium cations \(\text{anti-}[\text{Cp}^*\text{Ru}(\mu-\eta^6:\eta^5:6-L)\text{RuCp}^*]^\text{2+}\) \((L=O, x = 1 \text{ or } 2+; L = \text{anthracene} [L], \text{phenanthrene} [M], \text{pyrene} [N] \text{ and chrysene} [O])\) were reported by the groups of Kölle and Román.\(^7>\)\(^9\) A single crystal X-ray diffraction study of the chrysene complex revealed the anti-facial configuration of the metal centers.\(^7\)\(^d\) The \(\mu-\eta^6:\eta^6:6\)-naphthalene diiruthenium complex \([\eta^4\text{cod}]\text{Ru}(\mu-\eta^6:\eta^5-\text{C}_{10}\text{H}_8)\text{Ru}(\eta^4\text{cod})[\text{L}]\) \((\text{P}, \text{cod} = 1,5\text{-cyclooctadiene}, L = \text{PMe}_3, \text{PET}_{3}, \text{and P(OMe)}_3)\) reported by Bennett and co-workers also displays an anti-facial structure,\(^9\) while Chin and co-workers recently described the \(\text{syn-facial naphthalene and anthracene-bridged complexes} \text{Q} \text{and R}^\text{2+}\) (Fig. 2). The \(\text{syn-facial} \) arrangement is due to the presence of a doubly-bridged dicyclopentadienyl ligand connecting the ruthenium atoms.\(^7\)\(^d\)

During our investigations of synthetic applications of low-valent polyarene transition metalates,\(^10\) we became interested in the chemistry of bimetallic polyarene iron and ruthenium complexes. We discovered a new route to the previously reported diiron complex \(J\) (Fig. 1), and synthesized and characterized the closely related diiron complex \(K\) (Fig. 2) and the iron-ruthenium complexes \(S\) and \(T\).\(^11\) In an independent study, Ohki, Tatsumi and co-workers prepared \(\text{Cp}^*\)-substituted

Monocationic oxidation products \([\text{Cp}^\prime\text{Fe}(\mu\text{-C}_{10}H_8)\text{FeCp}^*]\text{BArF}_4\) (\(\text{Cp}^\prime = \text{C}_5\text{H}_2-1,2,4\text{-tBu}_3\)) and \([\text{J}]\text{BArF}_4\) were isolated by oxidizing the neutral precursors with \([\text{Cp}_2\text{Fe}]\text{PF}_6\) and subsequent anion exchange with \(\text{NaBArF}_4\).\(^{12}\) We similarly obtained the monocationic diiron and iron–ruthenium complexes \([\text{Cp}^\prime\text{Fe}(\mu\text{-C}_{10}H_8)\text{FeCp}^*]\text{PF}_6\) (\([\text{K}]\text{PF}_6\)) and \([\text{Cp}^\prime\text{Fe}(\mu\text{-C}_{10}H_8)\text{RuCp}^*]\text{PF}_6\) (\([\text{T}]\text{PF}_6\)) by oxidizing neutral \(\text{K}\) and \(\text{T}\) with \([\text{Cp}_2\text{Fe}]\text{PF}_6\).\(^{11}\) Combined spectroscopic, electrochemical and quantum chemical studies showed that the electronic structures of such diiron and iron–ruthenium complexes are only marginally influenced by different substitution patterns on the Cp ligand (\(\text{Cp}^*\) vs. \(\text{Cp}^\prime\)).\(^{11}\) Interestingly, substituting one of the iron centers by ruthenium in the heterometallic complexes \(\text{S–T}\) had a modest effect as well.\(^{11c}\) This observation was explained by the similar composition of the frontier molecular orbitals in the diiron and iron–ruthenium complexes, which are dominated by contributions from iron and ligand-based atomic orbitals, whereas the ruthenium-based orbitals appear to be less relevant.\(^{11c}\)

In extension of these previous studies, we next sought to prepare the corresponding diruthenium complexes. Here, we report the synthesis, structural, and spectroscopic characterisation of the new naphthalene-bridged complexes \(\text{anti-}[\text{Cp}^*\text{Ru(\mu-C}_{10}H_8)\text{RuCp}^*]\) (1, Fig. 3) and \(\text{anti-}[\text{Cp}^*\text{Ru(\mu-C}_{10}H_8)\text{RuCp}^*]\) \(\text{BArF}_4\) (\([1]\text{BArF}_4\)). By comparing the structural and spectroscopic characteristics with data from DFT calculations, we now arrive at a comprehensive picture of the electronic structures of the naphthalene-bridged diiron, iron–ruthenium, and diruthenium compounds.
Results and discussion

Two previous studies have described reductions of the cation [Cp*Ru(η₆-C₁₀H₈)]⁺ (2⁺). In their electrochemical investigation of 2⁺ and related ruthenium–arene complexes, Kölle and co-workers observed a reduction of 2⁺ in CH₂Cl₂ at −1.96 V. This redox event was reversible only at very high scan rates. They concluded that “short-lived neutral Cp*Ru[η₆-arene] complexes undergo decomplexation rather than dimerization or hydrogen abstraction”. In a subsequent study, Gusev and co-workers observed a reversible reduction of 2⁺ in acetonitrile at −2.10 V and a second, irreversible reduction at −3.16 V. The mononuclear benzocyclohexadienyl complex [Cp*Ru(C₁₀H₉)] (U) was identified as the major product of the chemical reduction of 2⁺ with an excess of Na/Hg in THF (Scheme 1a). We recorded a cyclic voltammogram of [2]PF₆ in THF. In contrast to the previous studies in CH₂Cl₂ and acetonitrile, we observed two overlapping reduction processes at −1.99 and −2.10 V (Fig. 4), which are chemically reversible on the CV time scale. The reason for the observed splitting is not entirely clear, but a plausible explanation might be that there is an interaction between 2⁺ and 2 as a first step to trigger the formation of dinuclear complex 1 (vide infra).

Chemical reduction of [2]PF₆ with potassium graphite in 1,2-dimethoxethane (Scheme 1b) yielded the dinuclear complex [Cp*Ru(µ-C₁₀H₈)RuCp*] (1) rather than mononuclear 2. Dichroic red-green crystals of 1 were isolated in 28% yield after work-up. Compound U was detected as a by-product by ¹H NMR spectroscopy of the crude reaction mixture.

X-ray structural analysis

Complex 1 crystallizes from n-hexane (space group P2₁/n with two molecules in the unit cell). The solid-state molecular structure is centrosymmetric and reveals an anti-facial configuration of the two Cp*Ru moieties that bind to opposite faces of the bridging naphthalene ligand (Fig. 5). The naphthalene ligand is η⁴-coordinated to both Cp*Ru units with Ru–C distances from 2.158(1) to 2.230(1) Å (Table 1), while the distances to the bridgehead carbons C15 and C15’ (av. 2.589(1) Å) are substantially longer. In accord with this, the coordinated arene rings are folded by 14.6°. The C11–C12, C12–C13, and C13–C14 bond lengths (see Table 1 and Fig. 6) are very similar due to the back-bonding from the low-valent ruthenium centers to the ligand. The structural data of 1 are comparable to those of the analogous diiron and iron–ruthenium complexes (F–K, S and T, Fig. 1 and 3), which display similar centrosymmetric structures with an anti-facial configuration of the metal centers and essentially η⁴-coordinated aromatic rings. It is also noteworthy that the molecular structure of 1 differs from the closely related syn-facial complex Q (Fig. 2), which features an asymmetric η⁴:η⁶ coordination of the naphthalene ligand distinct from the symmetric structure of 1 (Ru1–C 2.180(2) to

† All redox potentials given in this manuscript refer to the Cp₂Fe/Cp₂Fe⁺ couple.
DFT calculations performed by Chin and co-workers gave an indication of the mixed-valent RuIIRu0 electronic structure with disfavored C_{2v} symmetric structure akin to 1 and the C_{s} symmetric ground state.\textsuperscript{7d}

**NMR spectroscopic characterization**

In accord with the symmetric structure observed for 1 in the solid state, the \(^{1}H\) NMR spectrum in C6D_{6} shows a single Cp\(^{+}\) resonance at 1.84 ppm and two multiplets at 4.89 and 2.17 ppm, which are assigned to the hydrogen atoms of the naphthalene ligand. The naphthalene signals are notably shifted to lower frequency relative to free naphthalene. An even more pronounced chemical shift difference is observed for the related Cp\(^{+}\)-substituted diiron and iron- ruthenium complexes J and T (Table 2), which display strongly shielded 1,4-hydrogen signals (1.11 ppm for J, 1.31 ppm for T).\textsuperscript{11,12} The diruthenium complex 1 shows a less pronounced low frequency shift for the 1,4-hydrogen atoms (H11 and H14) than J and T, but the 2,3-hydrogen atoms (H12 and H13) are some-

| bond lengths (Å) and angles (°) of complexes 1, J, T, and Q determined by X-ray crystallography and DFT (DFT values given in italics). Numbering according to Fig. 6 |

**Fig. 6** Numbering scheme for naphthalene-bridged complexes.
what more shielded. The same trend is observed in the $^{13}$C($^1$H) NMR spectra of 1, J and T. In all cases, the 1,4-carbon signals are shifted to higher field, as are the 2,3-carbon signals. While the difference to the spectrum of free naphthalene is striking, the $^{13}$C($^1$H) NMR spectra of 1, J and T show only marginally different chemical shifts for the naphthalene carbon atoms.

It is interesting to compare the $^1$H NMR data of 1 with those of the related syn-facial complex Q. In $^{13}$CD$_2$O, Q is fluxional and thus gives a symmetric $^1$H NMR spectrum. Resonances for the naphthalene ligand of Q were observed at 3.71 and 4.88 ppm.\textsuperscript{7d}

### Cyclic voltammetry and UV-vis spectroelectrochemistry

In order to gain insight into the redox properties of 1, we recorded a cyclic voltammogram in THF/TBAH (Fig. 7). The reduction potentials and peak-to-peak separations are summarized in Table 3 along with data for some related complexes. The CV of 1 shows two well-separated oxidation processes $1 \rightarrow 1^+ (−1.47 \text{ V vs. } \text{Fc/Fc}^+) \text{ and } 1^+ \rightarrow 1^{2+} (−1.25 \text{ V vs. } \text{Fc/Fc}^+)$, which are fully reversible under the experimental conditions. The cyclic voltammograms of the analogous diiron and iron-ruthenium complexes J and T and the syn-facial dicyclopentadiene complex Q are qualitatively similar.\textsuperscript{7d,11,12}

Notably, the separation of the half-wave potentials $\Delta E_{1/2} = 220 \text{ mV}$ is similar for Q (180 mV), but substantially larger for J (660 mV) and T (590 mV). While J and T show a quasi-reversible reduction around $−3.0 \text{ to } −3.1 \text{ V}$\textsuperscript{11} no such reduction wave was observed for 1. The anthracene-bridged complex F\textsuperscript{2+} (Fig. 1) displays two reductions at $E_{1/2} = −0.78 \text{ and } 1.47 \text{ V}$ with a separation of 690 mV, while related complexes [Cp*Ru(µ-L)-RuCp\*]\textsuperscript{2+} (L\textsuperscript{2−}-O\textsuperscript{2−}) with non-linear polyarenes (phenanthrene, pyrene and chrysene) feature two reduction processes at substantially more negative potentials than 1 ($\Delta E_{1/2} = 130 \text{ to } 690 \text{ mV}$). From these data, it appears that the nature of the bridging ligand has a more profound influence on the redox potential than the metal atom or the cyclopentadienyl ligand.

The changes in the electronic transitions upon oxidation of 1\textsuperscript{0} to 1\textsuperscript{+} and 1\textsuperscript{2+} were monitored by UV-vis spectroelectrochemistry using an OTTLE cell.\textsuperscript{15} While both oxidation steps were found to be fully reversible at a scan rate of $v = 100 \text{ mV s}^{-1}$, \textit{i.e.}, on a time scale of 20 s, the neutral species 1\textsuperscript{0} could be only partially recovered after a CV measurement at $v = 2 \text{ mV s}^{-1}$ (74% of original amount). When performing the oxidation and back-reduction in rapid potential steps rather than a slow CV, 85% of the starting material was recovered.

The UV-vis spectrum of 1 shows a band in the visible region at 492 nm and UV bands at 309, 274, 240 and a shoulder at 370 nm. Upon oxidation to 1\textsuperscript{+} (Fig. 8, top), these bands disappear and a new band of the dication close to that of 1\textsuperscript{+} appears at 240 nm along with new, very broad and weak bands at 385, 260, 220 and 185 nm. In all four complexes, oxidation to the mixed-valence species leads to the appearance of a new, very broad and weak band at lower energy (around 900 nm for J, 796 nm for T, 854 nm for Q\textsuperscript{+}, 609 nm and 680sh for 1\textsuperscript{+}). In J\textsuperscript{+}, T\textsuperscript{+} and 1\textsuperscript{+}, another band appears at slightly higher energy relative to the visible absorption of the neutral complex (633 nm for J, 591 nm for T and 467 nm for 1\textsuperscript{+}). The oxidation to the dications J\textsuperscript{2+}, T\textsuperscript{2+} and 1\textsuperscript{2+} leads to the disappearance of all bands in the visible region.

### Quantum chemical calculations

In order to study the electronic structure of 1, we performed DFT calculations at the BP86/def2-TZVP level of theory.\textsuperscript{16,17} A geometry optimization without symmetry constraints gave a nearly C\textsubscript{2h}, symmetrical structure in close agreement with the

\textsuperscript{a} Ref. 7a. \textsuperscript{b} Ref. 7b. \textsuperscript{c} $E_{pc}$ values instead of $E_{1/2}$. \textsuperscript{d} Values from ref. 7d. Measured in acetonitrile/NBu4PF6; $\Delta E_P$ not available.
structure determined by X-ray crystallography (Table 1), with the difference in bond lengths remaining below 0.07 Å. An analysis of the frontier molecular orbitals (Fig. 9) shows that the HOMO is largely metal-centered with smaller contributions from the naphthalene and Cp* ligands, while the lower-lying orbitals (HOMO−1 and HOMO−2) are essentially composed of d orbitals of the two ruthenium centers. HOMO−3 and HOMO−4 are largely associated with one metal center each with small ligand contributions. By contrast, the LUMO displays larger contributions from the naphthalene ligand, as do the higher-lying orbitals LUMO+1, LUMO+3 and LUMO+4. The LUMO+2 shows interactions of metal d orbitals and the Cp* ligands with only minor contributions from the naphthalene ligand. Comparison with the diiron complex J and the iron-ruthenium complex T shows that the composition of the molecular orbitals is largely identical in the three complexes.

The experimental UV-vis spectrum of 1 is reproduced well by TD-DFT calculations at the B3LYP/def2-TZVP level (see the ESI† for details). The only band in the visible region at 492 nm is composed of transitions from the HOMO−2 to the LUMO and the Cp* ligands with only minor contributions from the naphthalene ligand. Comparison with the diiron complex J and the iron-ruthenium complex T shows that the composition of the molecular orbitals is largely identical in the three complexes.

**Chemical oxidation of [Cp*Ru(µ-C10H8)RuCp*] (1)**

**Generation of hydride complexes.** Since the electrochemical measurements indicated that the monocationic species 1+ is stable, we attempted to synthesize it on a preparative scale. However, attempted oxidations of 1 with ferrocenium hexafluorophosphate in THF did not yield 1+. Instead, the cationic hydride complex [3]PF6 was identified as one of the products by 1H NMR spectroscopy and X-ray crystallography, presumably due to traces of residual moisture. This is in contrast to reactions of J and T, which cleanly afforded the one-electron oxidation products J+ and T+.

Single crystals of [3]PF6 suitable for X-ray diffraction were grown by layering a THF solution of the compound with n-hexane and storage at −30 °C. [3]PF6 crystallizes in the triclinic space group P1 with two molecules and one equivalent...
of THF in the unit cell. The molecular structure of [3]⁺ (Fig. 10) features two distinct Ru centers. While one ruthenium atom is coordinated by the naphthalene ligand in an η⁶ fashion, the other ruthenium center is η⁴-coordinated by naphthalene and bound by the hydride ligand, resulting in a 36-e complex with both Ru centers in a formal oxidation state of +II. The asymmetric coordination of the naphthalene results in a significant folding along the C15/18 vector by 36.5°, which is in line with analogous η⁴-naphthalene complexes (vide supra).

To investigate [3]⁺ in more detail, we developed a rational synthesis by protonation of 1 with Brookhart’s acid, [H(OEt₂)₂]BARF₄, in diethyl ether (Scheme 2). After layering a concentrated diethyl ether solution with n-hexane, [3]BARF₄ was obtained as a colourless crystalline solid in 56% yield. The diamagnetic complex gives rise to sharp signals in the 1H NMR spectrum (recorded in C₆D₆). As observed for 1, the naphthalene ligand signals shifted to higher field with respect to free naphthalene to 2.82, 3.78, 4.86 and 4.14 ppm. The hydride signal is found at −2.95 ppm. The two Cp* rings give rise to signals at 1.41 and 1.17 ppm, while the BARF₄⁻ protons resonate at 8.42 and 7.72 ppm. It is noteworthy that a second set of signals can be observed when recording the spectrum immediately after adding [H(OEt₂)₂]BARF₄ to 1 in THF-d₈. The 1H NMR resonances of this second species are shifted slightly upfield relative to the major product with a hydride resonance at −3.09 ppm and signals for the naphthalene ligand at 2.68, 3.75, 4.04 and 4.69 ppm, respectively. Only the major product is observed after storing the NMR sample overnight. Presumably, the minor species is an isomer of [3]BARF₄ where the hydride atom points away from the naphthalene ligand (“exo-hydride”, Scheme 2).

Our DFT calculations have revealed that the main isomer (“endo-hydride” endo-[3]BARF₄) is stabilised by 39.5 kJ mol⁻¹ with respect to the exo-isomer exo-[3]BARF₄ at the BP86/def2-TZVP level. Since the attack of the proton should proceed from the sterically least hindered position, the exo-hydride is assumed to be the kinetically favoured species which slowly converts to the thermodynamically more stable endo-hydride complex.

The electrochemical analysis of [3]BARF₄ showed an irreversible oxidation at E_{pa} = −0.13 V as well as a strong, quasireversible reduction at −2.36 V (Fig. 11). Notably, complex 1 is reformed upon both of these irreversible processes along with a minor amount of the mononuclear cation 2⁺. The absence of redox waves corresponding to 1 at the start of the measurement confirms that 1 (or 1²⁺) is only formed upon electrochemical reduction or oxidation, respectively.

Preparation of [Cp*Ru(µ-C₅H₅)RuCp*]⁺ (1⁺). The desired monooxidation product 1⁺ can be obtained using [Cp₂Fe]BARF₄.
instead of [CpFe]PF$_6$ as the oxidizing agent and diethyl ether rather than THF as the solvent. After removing the by-product ferrocene and recrystallizing from diethyl ether, [1]Bar$_4^P$ was obtained in excellent yield as an olive-green crystalline solid. X-ray quality crystals were grown by slow evaporation of the solvent from a concentrated diethyl ether solution of [1]Bar$_4^P$. The molecular structure of [1]Bar$_4^P$ (Fig. 12), which crystallizes in the triclinic space group P1, shows contracted Ru1–C15 and Ru1–C15’ distances relative to those in complex 1 by 0.17 Å, which indicate that the hapticity of the naphthalene is between η$^4$ and η$^6$ in this case. This change and the smaller fold angle of 7.9° are consistent with less electron-rich metal centers and a smaller degree of back-bonding. Structural parameters obtained by DFT calculations at the BP86/def2-TZVP level of theory are in very good agreement with the values from X-ray crystallography. A list of relevant structural parameters is given in Table 4.

Due to the paramagnetic nature of 1+, no signals were observed in the $^1$H NMR spectrum. The magnetic moment was determined by the Evans method. The observed value of $\mu_{\text{eff}} = 1.3(1)\mu_B$ is lower than the expected spin-only value of 1.73 $\mu_B$ for a complex featuring one unpaired electron. The EPR spectrum of [1]Bar$_4^P$ reveals the presence of two species (Fig. 13).

The main species, representing ~97% of the total signal intensity, apparently corresponds to 1+. The species reveals a rhombic spectrum with (poorly resolved) Ru hyperfine interactions (HFIs) along the $g_e$ value (Fig. 13, Table 5). The HFI seem to stem from a single ruthenium nucleus (coupling to 99Ru and 101Ru, ~40 MHz, $I = 5/2$, 30% natural abundance). The minor species, representing only 3% of the total signal intensity, reveals an isotropic signal with $g$-values around 2.008. While the nearly isotropic nature of the signal may suggest the presence of an organic radical, the $g$-value perhaps deviates a bit too much from $g_e$ to correspond to a pure organic radical like the naphthalene radical anion. As such, this minor signal probably stems from a second metal complex of unknown structure. Repeated experiments of several different samples of [1]Bar$_4^P$ in all cases revealed the presence of both components in similar ratios.

The UV-vis spectrum of [1]Bar$_4^P$ (recorded in diethyl ether) is identical with the spectrum recorded by UV-vis spectroelectrochemistry (vide supra), showing a relatively strong band at 469 nm and a weaker absorption at 609 nm with a shoulder at 680 nm. The degree of electronic interaction between the two metal centers in a dinuclear complex can be estimated utilizing the theories of Hush, Brunswig, Creutz and Sutin, by analyzing the ratio of the theoretical half-height width of the intervalence transition band with the observed line width.$^{19}$ Unfortunately, a reliable analysis using Hush theory was not possible for [1]Bar$_4^P$ due to the severe overlap of the absorption bands at 609 and 680sh nm. Therefore, we investigated the electronic structure of 1+ (the cation in [1]Bar$_4^P$) by DFT calculations. The def2-TZVP basis set and various pure and hybrid functionals were used (BP86, B3LYP, CAM-B3LYP and BLYP35).$^{20}$ The frontier molecular orbitals are qualitatively similar to 1 with these functionals (see Fig. S8 in the ESI†).

### Table 4: Structural parameters of 1+, J+, S+ and T+ obtained by X-ray crystallography and DFT calculations. DFT values given in italics. Numbering according to Fig. 6

a X-ray and DFT values taken from ref. 12. b DFT values taken from ref. 11c. $^c$ X-ray and DFT values taken from ref. 11c. $^d$ Dihedral angle C11–C12–C13–C14–C14’–C20–C19–C11. $^e$ Dihedral angle C15–C16–C17–C18/C18–C19–C20–C15.
The SOMO shows a high degree of symmetry with equal contributions from both metal centers. The spin density (Fig. 14) is largely centered on the metal centers with minor contributions from the naphthalene and Cp* ligands. The contribution of both Ru centers is the same. These calculations support the assignment of $1^+$ as a fully charge-delocalized class III species. However, it should be noted that making a distinction between class III and borderline class II species is intricate even when several complementary spectroscopic techniques are applied.

Conclusions

We report a series of new diruthenium compounds $[\text{Cp}^*\text{Ru}(\mu-C_{10}H_8)\text{RuCp}^*]$ ($1$), $[\text{Cp}^*\text{Ru}(\mu-C_{10}H_8)\text{RuCp}^*]\text{BARF}_4$ ($1\text{BARF}_4$) and $[\text{Cp}^*\text{Ru}(\mu-\eta^6-n^4C_{10}H_8)\text{Ru(H)Cp}^*]\text{BARF}_4$ ($3\text{BARF}_4$), which complement the existing literature on related diiron, iron–ruthenium and diruthenium complexes. Diruthenium complex $1$ is readily prepared by the reduction of the well-known ruthenium(II) precursor $[\text{Cp}^*\text{Ru}(C_{10}H_8)]\text{PF}_6$ ($2\text{PF}_6$) with KC$_8$, while $1\text{BARF}_4$ and $3\text{BARF}_4$ are accessible from $1$ by oxidation and protonation, respectively. All three complexes were isolated in moderate yields and were fully characterized by X-ray crystallography, spectroscopic techniques, cyclic voltammetry and UV-vis spectrroelectrochemistry and DFT calculations. The structures are similar to recently reported complexes $[\text{Cp}^n\text{Fe}(\mu-C_{10}H_8)\text{MCp}^*]$ ($\text{C}^n = \text{C}_5\text{Me}_5, 1,2,4-\text{C}_5\text{H}_2\text{tBu}_3; M = \text{Fe (H–K), Ru (S–T)})$. However, related diruthenium complexes are still scarce. The few known examples (Fig. 2) were only partially characterized or display different structural arrangements due to the presence of dicyclopentadienyl ligands. The complexes presented herein thus provide valuable new data on this class of compounds. In particular, the tendency of the naphthalene bridge to mediate strong electronic coupling between the metal centers is striking. An extension to a wider range of polyarene ligands seems warranted to study this phenomenon in more detail. In addition, the reactivity of hydride complex $3\text{BARF}_4$ toward oxidation and reduction should also be the subject of future studies.

Experimental details

General considerations

All reactions were carried out under an inert atmosphere of purified argon, using standard Schlenk and glovebox techniques. Solvents were dried by distillation over sodium/benzophenone (DME) or using an MBraun SPS-800 solvent purification system (toluene, n-hexane, THF). $C_5\text{Me}_5\text{H}$ and KC$_8$ were prepared following standard procedures. Naphthalene was obtained commercially and used as received.
NMR spectra were recorded with a Bruker Avance 300 spectrometer (300.13 and 75.47 MHz, respectively). ¹H and ¹³C{¹H} NMR signals were referenced internally to residual solvent signals. UV-vis spectra were recorded with a Varian Cary 50 spectrometer. Elemental analyses were determined by the analytical department at the University of Regensburg.

**Synthesis**

[Cp*Ru(C₁₀H₈)]PF₆ ([2]PF₆). [2]PF₆ was synthesized following a modified procedure by Williams and co-workers.²⁴ A solution of RuCl₃·3H₂O (1.500 g, 5.640 mmol, 1.0 equiv.) in 50 mL degassed ethanol was slowly added to a solution of naphthalene (3.589 g, 28.00 mmol, 5.0 equiv.) and C₅Me₅H (3.814 g, 28.00 mmol, 5.0 equiv.) in 50 mL ethanol via a dropping funnel. The mixture was refluxed overnight, yielding a dark orange solution. After having removed the solvent in vacuo, the residue was extracted with 150 mL H₂O and 150 mL diethyl ether. The aqueous phase was washed with 3 × 50 mL diethyl ether. A saturated solution of NH₄PF₆ was added to the aqueous phase to precipitate the complex as an orange solid, which was separated by filtration and washed with diethyl ether. The crude product was dissolved in acetonitrile, filtered over a short alumina column, and subsequently recrystallized from acetonitrile/ethyl acetate, yielding a light yellow crystalline powder. Yields: 1.251 mg (28%). ¹H NMR (300.13 MHz, CDCl₃): δ (ppm) 1.64 (s, 15H, Cp*), 5.92 (m, 2H), 6.38 (m, 2H), 7.49 (m, 2H), 7.68 (m, 2H) ppm. ¹³C{¹H} NMR (75.47 MHz, CDCl₃): δ (ppm) 11.6 (CH₃ of Cp*), 60.9 (C₁₁/C₁₄ of coordinated naphthalene), 72.5 (C₁₂/C₁₃ of coordinated naphthalene), 85.8 (C₁₅ of coordinated naphthalene).

[Cp*Ru(μ-C₅H₅)RuH(C₁₀H₈)]PF₆ ([1]PF₆). [1]PF₆ was prepared from [2]PF₆ (1.500 g, 2.944 mmol) and 5.0 equiv. of BArF₄. Yield: 45.9 mg (94%). ¹H NMR (300.13 MHz, CDCl₃): δ (ppm) 1.85 (s, 30H, Cp*), 2.17 (m, 4H), 4.89 (m, 4H). ¹³C{¹H} NMR (75.47 MHz, CDCl₃): δ (ppm) 11.6 (CH₃ of Cp*), 60.9 (C₁₁/C₁₄ of coordinated naphthalene), 72.5 (C₁₂/C₁₃ of coordinated naphthalene), 85.8 (C₁₅ of coordinated naphthalene).

**X-ray Crystallography**

The crystallographic data for 1, [1]BarF₄ and [3]PF₆ were collected with an Agilent Technologies SuperNova and an Agilent Technologies Gemini Ultra diffractometer, respectively. The structural data are summarised in Table 4 and crystal data are given in the ESI. The structures were solved with SHELXT and least-square refinements on F² were carried out with SHELXL.²³ The dataset of the major isomer was solved using PLATON/TwinRotmat.²⁶ Only the data for the minor component were weak. Details are given in the corresponding CIF files. CCDC 1842108–1842110 contain the supplementary crystallographic data.

**Cyclic voltammetry**

The cyclic voltammogram of 1 was recorded in dry THF in a single-compartment cell connected to a Metrohm Autolab PGSTAT101 potentiostat. The cell was equipped with a Pt microdisc working electrode polished with 0.25 μm diamond paste, a Pt coil auxiliary electrode and an Ag wire pseudoreference electrode. Predried tetrabutylammonium hexafluorophosphate (TBAH) was used as a supporting electrolyte. All redox potentials are reported against the ferrocene/ferrocenium (Fc/Fc⁺) redox couple used as an internal standard.
Spectroelectrochemistry

Controlled-potential electrolysis of compound 1 was carried out within an optically transparent thin-layer electrochemical (OTTLE) cell equipped with a Pt minigrid as the working electrode, a Pt coil as the auxiliary electrode and an Ag wire as the pseudoreference electrode, all connected to a Metrohm Autolab PGSTAT302N potentiostat. The UV-vis absorption spectra were recorded using an Agilent Technologies 8453 diode array spectrophotometer. The different redox steps were identified with the aid of the contemporarily recorded thin-layer cyclic voltammogram.

Computational methods

The calculations on 1, 1’ and 3 were performed using the Gaussian09 program package (Revision E.01). The BP86 density functional and the Ahlrichs def2-TZVP basis set were employed for all atoms. Atom-pairwise dispersion corrections were included using the self-consistent reaction field (SCRF), as implemented in Gaussian. Molecular orbitals and spin density plots were visualized with GaussView. The isosurface value is set to 0.05 for all figures.

Conflicts of interest

The authors declare no conflict of interest.

Acknowledgements

The authors thank Dr M. Bodensteiner (University of Regensburg) for expert crystallographic assistance and Johnson–Matthey for a generous loan of ruthenium trichloride.
