Chapter 7

Abstract

Erythrocytes express the Duffy antigen receptor for chemokines. Endotoxin injection into humans induced high levels of interleukin (IL)-8, growth-related oncogene-α and monocyte chemoattractant protein-1 in circulating erythrocytes. IL-8 was also recovered from mononuclear and polymorphonuclear cells. Cell-associated chemokines may more accurately reflect their production than plasma concentrations.
Introduction

Chemokines can be classified into several families which target either granulocytes (CXC-) or mononuclear cells (CC chemokines) (1, 7). The Duffy antigen receptor for chemokines (DARC), present on the surface of erythrocytes, is a promiscuous chemokine receptor binding a number of CXC and CC chemokines (5, 10), and has been proposed to function as a sink receptor for chemokines present in the circulation (3). Indeed, erythrocyte-bound interleukin (IL)-8, the prototypic CXC chemokine, could be detected in humans after administration of IL-1 or IL-2 long after IL-8 had disappeared from plasma (13, 14). Furthermore, patients with sepsis demonstrated high levels of cell-associated IL-8 in their circulation (8, 9), which could be located not only in erythrocytes, but also in mononuclear and polymorphonuclear cell fractions (8). Together these data suggest that besides DARC, surface receptors on leukocytes may contribute to the occurrence of cell-associated chemokines, and that measurement of cell-associated chemokines may provide more accurate information on the extent of chemokine production than plasma concentrations. Knowledge of the in vivo induction of cell-associated chemokines other than IL-8 is highly limited. Like IL-8, growth-related oncogene (GRO)α, a CXC chemokine, and monocyte chemoattractant protein (MCP)-1, a CC chemokine, can bind to DARC (1, 7). In the present study, we sequentially measured the concentrations of IL-8, GROα and MCP-1 in plasma and cell fractions isolated from peripheral blood of healthy humans intravenously injected with lipopolysaccharide (LPS). The induction of these chemokines was compared with the levels of macrophage inflammatory protein (MIP)-1β, a CC chemokine that does not bind to DARC.

Patients and Methods

Eight healthy subjects (mean age ± SE: 24 ± 1 years) were studied after intravenous administration of LPS (lot G from Escherichia coli; the United States Pharmacopeia Convention Inc., Rockville, MD) at a dose of 4 ng/kg of body weight. Written informed consent was obtained from all study participants and the study was approved by the ethics and research committees of the Academic Medical Center. Blood was collected before LPS administration and 0.5, 1, 1.5, 2, 3, 4, 5, 6 and 24 hours thereafter. EDTA plasma was obtained by centrifugation at 1500 g for 20 min. Peripheral
blood mononuclear cells (PBMCs), polymorphonuclear cells (PMNs) and red blood cells (RBCs) were isolated from blood drawn before and 2, 4, 6 and 24 h after LPS injection, as follows. Heparinized blood was layered on an equal volume of Polymorphprep (Nycomed Pharma AS; Oslo, Norway) and centrifuged at 500 g for 30 minutes at 20 °C. The harvested PBMC, PMN and RBC fractions were diluted 1:2 in 0.5 N RPMI 1640 (Bio Wittaker, Verviers, Belgium) in order to restore normal osmolality, and spun at 400 g for 10 minutes at 20 °C. RBCs contaminating PBMC and PMN fractions were lysed using ice-cold isotonic NH₄Cl solution (155 mM NH₄Cl, 10 mM KHCO₃, 0.1 mM EDTA, pH 7.4) for 10 minutes. The cell fractions were spun again at 400 g for 10 minutes at 4 °C and the pellet was resuspended in 1N RPMI containing 5% normal human serum (Bio Wittaker) to the original blood volume. Purity of the cell fractions was checked using a 0.1% eosin stain and was found to be above 99%. All three cell fractions were spun at 400 g for 10 min at 4°C. Next, RBCs were lysed using 30 ml ice-cold isotonic NH₄Cl solution (as described above); PBMC and PMN fractions were lysed by a 15-minute incubation with ice-cold lysis buffer containing 300 mM NaCl, 30 mM Tris, 2 mM MgCl₂, 2 mM CaCl₂, 1% Triton X-100, and Pepstatin A, Leupeptin and Aprotinin (all 20 ng/ml; pH 7.4). Lysed fractions were resuspended in 1 N RPMI. Leukocyte counts and differentials were assessed by a Stekker analyzer (counter STKS, Coulter counter, Bedfordshire, United Kingdom). Chemokine concentrations were measured by ELISA according to the instructions of the manufacturers (IL-8: Central Laboratory of the Netherlands Red Cross Blood Transfusion Service (CLB), Amsterdam, the Netherlands; GROα and MIP-1β: R&D Systems, Abingdon, United Kingdom; MCP-1: PharMingen, San Diego, CA). Detection limits were 1.7 pg/ml (IL-8), 14.3 pg/ml (GROα), 1.1 pg/ml (MCP-1) and 15.6 pg/ml (MIP-1β). In separate experiments we determined that neither of the lysis buffers influenced the ELISA results (data not shown). Values are given as mean ± SEM. Changes of parameters in time were tested using one-way ANOVA followed by Dunnet’s post hoc test. Two sample comparisons were done by paired Student’s t test. α for all tests was set at 0.05.
Results

LPS administration induced profound changes in peripheral blood cell fractions. Table 1 lists blood cell counts at the time points cell fractions were isolated for chemokine measurements. Intravenous injection of LPS was associated with transient increases in the plasma concentrations of all four chemokines measured, peaking after 3 (IL-8: 1.17 ± 0.17 ng/ml; GROα: 0.36 ± 0.04 ng/ml; MIP-1β: 9.18 ± 0.48 ng/ml) or 4 hours (MCP-1: 92.07 ± 28.11 ng/ml) (all P < 0.05) (Figure). LPS further induced a transient increase in IL-8 associated with RBCs, PBMCs and PMNs (Figure and Table 2). At 2 hours after LPS injection, IL-8 mainly was recovered from RBCs. At 4 and 6 hours after LPS administration, when plasma IL-8 concentrations were rapidly decreasing, IL-8 predominantly was associated with PMNs. PBMC and PMN associated IL-8 both peaked at 6 hours post-LPS, at which time point the cell-associated IL-8 concentrations were significantly higher than plasma IL-8 levels (PBMC: 0.59 ± 0.29, PMN: 0.94 ± 0.14, plasma 0.12 ± 0.03 ng/ml; P < 0.005 for the difference between PBMC or PMN, and plasma). In contrast, GROα and MCP-1 virtually exclusively circulated in association with RBCs. Indeed, RBC-associated GROα peaked at 2 hours (1.62 ± 0.16 ng/ml), at which time point plasma GROα levels were 0.33 ± 0.03 ng/ml (P < 0.001 versus RBC).

Data are means ± SEM of eight healthy subjects injected i.v. with LPS at t=0. P values reflect significance for changes in time (ANOVA). Asterisks indicate P < 0.05 versus t=0 by Dunnet's post hoc test. N.S. = non significant.
Figure. Mean ± SE plasma and blood cell–associated IL-8, GROα, MCP-1 and MIP-1β in healthy subjects after administration of endotoxin. RBC - (grey bars), PBMC - (hatched bars) and PMN (white bars) – associated chemokines are plotted against their plasma concentrations (continuous line). All concentrations are given in ng/ml; cell-associated chemokines were measured in lysates of cells that were resuspended to the original blood volume in RPMI after their isolation from peripheral blood. Plasma concentrations were measured prior to endotoxin injection (t=0) and during a follow up of 24 hours. Chemokines associated with blood cells were measured in cell lysates isolated prior to endotoxin injection and 2, 4, 6 and 24 hours thereafter. Asterisks indicate significant difference with t=0. For reasons of clarity, significance for concentrations in plasma at individual time points is not presented. Plasma levels of all 4 chemokines increased significantly (IL-8, MCP-1 and MIP-1β: P < 0.001; GROα: P < 0.05). No MIP-1β was recovered from cell fractions.

The appearance of RBC associated MCP-1 in the circulation followed similar kinetics as the release of MCP-1 in plasma, although RBC MCP-1 tended to be higher than plasma MCP-1 at 2, 4 and 6 hours post-LPS. RBC MCP-1 peaked after 4 hours (127.47 ± 19.69 ng/ml). GROα and MCP-1 remained low and unchanged in PBMC and PMN fractions (virtually all measured values in cell lysates were below the detection limit of the

Discussion

Endotoxemia and gram-negative sepsis are characterized by elevated levels of chemokines in plasma (2, 4, 8, 9, 11, 12). Marie et al. found that in patients with sepsis, IL-8 bound to blood cells exceeds IL-8 concentrations in plasma (8). RBC-bound IL-8 was also found in patients who underwent cardiopulmonary bypass (6), as well as in patients treated with IL-1 and IL-2 (13, 14). We extend these findings by reporting the extent to which other chemokines present in the circulation are associated with different blood cells in the course of experimental endotoxemia. Our study design allowed us to study the kinetics of the appearance of IL-8 in plasma and in RBC, PMN and PBMC fractions. Interestingly, RBC associated IL-8 peaked early and transiently, after 2 hours, while PMN and PBMC associated IL-8 reached a plateau after 4 to 6 hours. We consider it unlikely that RBCs contaminating PMN and PBMC fractions contributed to a significant extent to IL-8 concentrations recovered from PMN and PBMC lysates, since very
few RBCs contaminated leukocytes after separation by Polymorphprep and since MCP-1 could not be recovered in significant concentrations from PMN and PBMC fractions, whereas MCP-1 concentrations in the RBC fraction were more than 100-fold higher than RBC-associated IL-8 levels. Our study does not elucidate the mechanism by which IL-8 appears in the PMN and PBMC fractions. Patients with sepsis had IL-8 mRNA in circulating leukocytes (4), and in preliminary investigations we found IL-8 mRNA expression in PMNs after LPS injection, suggesting that at least some of the IL-8 recovered from PMNs is produced by these cells. Alternatively, IL-8 produced elsewhere could bind to IL-8 receptors present on PMNs and PBMCs, a possibility supported by the finding that recombinant IL-8 added to human whole blood rapidly associated with RBCs, PMNs and PBMCs (8). If this would occur in vivo, the possibility that IL-8 bound by DARC on RBCs can be transferred to PMNs and/or PBMCs warrants further investigation. Our study further shows that during an inflammatory response besides IL-8, also GROα and MCP-1, like IL-8 DARC binding chemokines, circulate in association with RBCs to a significant extent.
Cell-associated chemokines in human endotoxemia
