Supporting Information

ABSTRACT: Multidoped carbons are often used for oxygen activation catalysis, both in heterogeneous catalysis and electrocatalysis. Identifying their catalytic sites is crucial for developing better catalysts. We now report an in-depth study into O₂ activation on an important class of materials: carbons codoped by nitrogen and 10 different metals (V, Cr, Mn, Fe, Co, Ni, Cu, Zn, Mo, and Pb). To identify catalytic sites, we studied their composition and structure (both bulk and surface) by a wide range of techniques, including temperature-programmed reduction, X-ray diffraction, electron microscopy, X-ray photoelectron spectroscopy, and N₂ sorption porosimetry. The O₂ activation step was studied by electrochemical oxygen reduction. To assign active sites, the electrocatalytic activity, selectivity, and stability were correlated to material composition and to known reactivity pathways. Two types of sites for O₂ activation were identified and assigned for each multidoped material: (1) particles of partially reduced metal oxides and (2) metal–nitrogen clusters embedded into the carbon matrix. The detailed assignment correlates to activity in alcohol oxidation through similar volcano plots and leads to practical suggestions for catalyst development.

KEYWORDS: carbon-based catalysts, tandem catalysis, oxygen activation, metal oxides, active site, oxygen reduction reaction, temperature-programmed reduction, cooperative catalysis

INTRODUCTION

Carbons codoped with both metallic and nonmetallic elements are promising heterogeneous catalysts for aerobic oxidation reactions.¹⁻⁶ Nonmetallic elements such as N, P, or B are typically embedded in the graphite surface, while the metal dopants may appear as inorganic particles and/or coordinated to heteroatoms. Such carbons are also used in batteries,⁷⁻¹⁰ in supercapacitors,⁷⁻¹⁰ and as electrocatalysts for the oxygen reduction reaction (ORR) in fuel cells.

Interestingly, both in heterogeneous catalysis and electrocatalysis applications, multidoped carbons are often used to activate molecular oxygen.¹⁻¹⁰ O₂ activation is an important yet challenging reaction: the O=O bond energy is high (498 kJ/mol), and the molecule is kinetically stabilized by its triplet configuration. Activating molecular oxygen depends on understanding what are the catalytic sites and how they operate.

To design multidoped carbons rationally, we must first establish reliable synthesis/structure links. The problem is that many carbons are made by complex pyrolysis reactions of diverse organic matter. Predicting and directing the evolution of their composition (sp²/sp³ ratio and doping) and structure (porosity, crystallinity, and domain sizes) is difficult.¹⁶ Metal ions in the precursors complicate things even further. Iron and nickel, for example, catalyze the growth of carbon nano-

tubes,¹⁷,¹⁸ whereas molybdenum tends to form carbides¹⁹ and alkali-earth metals form carbonates.²⁰,²¹ Doping a carbon also changes its wettability, conductivity, and work function.²²⁻²⁴

The second challenge in using multidoped carbons for oxygen activation lies in understanding the structure–activity correlations. The catalytic sites can range from single-atom sites, such as edge-positioned nitrogen atoms²⁵ or carbon-embedded Fe–N₄ complexes,²⁶ to large inorganic particles.¹⁵ Much research is devoted to determining active site structure and linking it to catalytic activity.

Recently, we reported that carbons codoped by nitrogen and metallic elements can catalyze the oxidation of alcohols¹ and alkenes.² In these catalysts, as well as in others in the literature, the role of each dopant remains unclear.¹⁻³,²⁷⁻²⁹ Does alcohol oxidation happen solely on the metal oxide (MOₓ) particles (Figure 1a), or is this an example of tandem catalysis, with MOₓ particles binding the substrate and surface-embedded M–Nₓ clusters activating the oxygen (Figure 1b)?

Here we identify the catalytic sites for O₂ activation on these multidoped carbons. Starting with N-doped carbon as our active support, we dope it with 10 metals (V, Cr, Mn, Fe, Co,
Ni, Cu, Zn, Mo, and Pb). We then examine the composition, structure, and bonding in these catalysts, using both bulk and surface techniques. To understand the O₂ activation step in catalytic oxidations, we study the electrocatalytic oxygen reduction reaction (ORR). The active sites for O₂ activation in catalytic and electrocatalytic reactions are similar, sharing peroxide and hydroxide surface-localized intermediates. Thus, the electrocatalytic activity, selectivity, and stability of the M–N–C materials help us to identify the oxygen activation sites.

**EXPERIMENTAL SECTION**

**Synthesis of Multidoped Carbons.** Magnesium nitrolotriacetate (MgNH(CH₂COO)₃(H₂O)₆) was prepared from a solution of basic magnesium carbonate and nitrolotriacetate acid at 85 °C, precipitated by ethanol, and dried. The powder was pyrolyzed in quartz boats under argon flow (900 °C/1 h, ramp rate 10 °C/min), yielding a nitrogen-doped carbon loaded with MgO nanoparticles. The MgO was washed out by overnight stirring in 1 M HCl, followed by washing with 5 L of deionized (DI) water, overnight drying at 70 °C, and a final annealing in argon (1000 °C/1 h, ramp rate 5 °C/min). The resulting N-doped, hierarchically porous carbon (100 mg) was impregnated with metal salts (0.2 mL, 0.66 M). The salts included NH₄VO₃ (with 2 equiv of oxalic acid for dissolution), Cr(NO₃)₃·9H₂O, Mn(NO₃)₃·4H₂O, Fe(NO₃)₃·9H₂O, Co(NO₃)₃·6H₂O, Ni(NO₃)₂·6H₂O, Cu(NO₃)₂·3H₂O, Zn(NO₃)₂·6H₂O, (NH₄)₂MoO₄·4H₂O, and Pb(NO₃)₂. The powder was then dried at 75 °C overnight and annealed in argon (300 °C/1 h), to yield the final M–N–C material. Chemicals were obtained from commercial sources (>99% pure) and used as received.

**Material Characterization.** Scanning electron microscopy (SEM) was done on a Zeiss EVO50 microscope operated at 15 kV. Temperature-programmed reduction was performed by placing 25 mg of sample sandwiched between two quartz wool plugs in a quartz tube reactor (4 mm inner diameter), purging with N₂, and applying a flow of 5% H₂/N₂. The system was allowed to equilibrate and then heated at 5 °C/min to 800 °C (no hold time). X-ray diffraction (XRD) patterns were obtained with a MiniFlex II diffractometer using Ni-filtered Cu Kα radiation, at 30 kV and 15 mA. X-ray photoelectron spectroscopy (XPS) measurements were carried out using a PHI VersaProbe II scanning XPS microscope (Physical Instruments AG, Germany), using a monochromatic Al Kα X-ray source of 24.8 W power with a beam size of 100 μm. The spherical capacitor analyzer was set at a 45° takeoff angle with respect to the sample surface. The pass energy was 46.95 eV, yielding a full width at half-maximum of 0.91 eV for the Ag 3d₅/₂ peak. Peaks were calibrated using the C 1s position.

**Curve fitting was done using XPSpeak 4.1. N₂ adsorption–desorption isotherms were measured on a Thermo Scientific Surfer instrument at 77 K, using vacuum-dried samples (200 °C/3 h). Isotherms were analyzed by the ThermoFischer Advanced Data Processing 6.0 software, using the two-parameter Brunauer—Emmett—Teller (BET2) model for specific surface area.

**Electrochemistry.** Inks of the catalytic powders were prepared according to the following proportions: 0.80 mL of DI water, 0.20 mL of ethanol, 10 μL of Nafion (5 wt % in water/isopropanol), and 1 mg of M–N–C powder. Inks were sonicated, stirred, and dropcast on a glassy carbon working electrode (φ = 5 mm, A = 0.196 cm²) to give a total catalyst loading of 30 μg, or 153 μg/cm². Electrochemical experiments were performed in a three-electrode homemade glass cell, filled with KOH (0.1 M, 150 mL), and stabilized at 25.0 ± 0.1 °C. A Gamry Reference 600 potentiostat was employed, together with a Gamry RDE710 rotating electrode setup. A saturated calomel electrode (SCE) separated from the solution by a 10 cm bridge was used as a reference electrode, and a graphite rod was used as a counter electrode. Potentials were reported vs reversible hydrogen electrode (RHE) by adding 1.011 for pH 13. Nitrogen (99.999%) or oxygen (99.999%) were bubbled for 30 min to saturate the solution and were flowed above the solution during the experiments. Cyclic voltammetry experiments were performed in O₂-saturated 0.1 M KOH solution and corrected for background currents in a N₂-saturated solution (Figure 7a). The number of electrons transferred per O₂ molecule (n) was calculated by Koutecký–Levich analysis from linear sweep voltammetry curves performed on a rotating disk at rotation speeds of 400–2400 rpm. To compare stability, chronoamperometry experiments recorded the decay of the ORR activity under continuous operation (E = 0.41 V vs RHE), while bubbling oxygen and stirring.

**RESULTS AND DISCUSSION**

We prepared the carbon support following published procedures, based on pyrolysis of a Mg-based metal–organic framework. These carbons have a high surface area (1570 m²/g) and high nitrogen content (5.9 at % by XPS). They feature interconnected micro-, meso-, and macropores, assisting mass transport. A percolating network of graphitic shells boosts the electrical conductivity of the matrix and charge transfer between redox sites. The carbons were loaded with 1.3 mmol/g of metal solutions by incipient wetness vacuum impregnation. A reductive heat treatment (300 °C/1 h) under argon yielded the final M–N–C materials, containing 0.8–2.3 at % of metals (Table 1). Unlike copyrolysis, this strategy fixes the carbon matrix, allowing for a fair comparison between the metals.

**Scanning Electron Microscopy.** Scanning electron microscopy (SEM, Figure 2) reveals highly similar MOx particles for all metals, as expected from incipient wetness impregnation. The particles are spherical or near-spherical, between 100–400 nm in diameter. Further analysis of the subsurface by backscattered electrons (see Figure S1 in the Supporting Information) reveals many more particles under the carbon surface, suggesting a firm embedding in the carbon support. Thus, combining incipient wetness impregnation with mild reduction yields structurally similar materials, allowing us to focus on the finer distinctions between the metals.

**Temperature-Programmed Reduction.** Temperature-programmed reduction (TPR) in a flow of 5% H₂ in N₂ was
Moreover, extrinsic factors such as metal loading, particle size, or heating rates may also shift the reduction temperatures. In our case, the homogeneity of the MO particles suppresses the effects of particle size and loading, facilitating comparison by TPR.

All TPR traces show a support gasification reaction above 600 °C (Figure 3, denoted by “X”). This is the metal-catalyzed carbon methanation reaction (C + H₂ → CH₄). The Cr–N–C trace is typical for mixed Cr(III)–Cr(VI) oxides. The main peak at 450 °C (2) corresponds to the reduction of Cr(VI) to Cr(III). Cr(VI) chromates with different degrees of oligomerization are found on large Cr₂O₃ particles. The TPR shoulder at 380 °C (1) is attributed to support interactions and/or crystallization of such surface Cr(VI) species. Peak 3 corresponds to further reduction of the Cr₂O₃ particles to CrO. The Mn–N–C trace exhibits multiple peaks, typically assigned to oxides such as MnO₂ and MnO₃, and possibly MnO and Mn₂O₃. The lower-temperature peaks (250–400 °C, peaks 1 and 2) may reflect the reduction of Mn(IV), Mn(IV/III), and possibly Mn(III). Peak 3 corresponds to reduction of either Mn(III) or carbon-stabilized MnOx species. Higher-temperature peaks (4 and 5) may be assigned to the reduction of Mn(II/III), Mn(IV), Mn(IV/III), and possibly Mn(III). Finally, MnO₃ catalyzes methanation, lowering its temperature by ~100 °C relative to free-standing activated carbon. The Fe–N–C trace shows Fe₂O₃ reduced to Fe₂O₄ (350 °C, 1), then to FeO (450 °C, 2), and finally to Fe (610 °C, 3). The low-temperature shoulder in peak 1 reveals some Fe₃O₄ in the starting sample. Peak 4 may be assigned to reduction of micropore-confined Fe₂O₄ particles or to support gasification. The broadening of peaks 2 and 3 may indicate particle–support interactions. Similarly, CoO is first reduced to CoO (360 °C, 1) and then to metallic cobalt (460 °C, 2). The high intensity of the second peak suggests that both are present in the sample. Reductions above 400 °C reflect carbon methanation combined with particle–support interactions. For Ni–N–C, we see two types of NiO: large particles with little support interaction (400 °C, 1) and smaller, harder-to-reduce particles (520 °C, 2). Peak 2 is assigned to pore-constrained or support-stabilized NiO. A shoulder below 350 °C suggests a higher oxidation state, either Ni₂O₃ or NiOOH. In the Cu–N–C trace, CuO is reduced to Cu₂O (280 °C, 1) and then to metallic copper (380 °C, 2). The splitting in peak 1 indicates weakly and strongly interacting CuO particles. The Zn–N–C trace identifies only well-dispersed ZnO (reduction at 400 °C). For Mo–N–C, the first two peaks correspond to the reduction of MoO₂ to MoO₃. The difference is attributed to octahedral/tetrahedral Mo(VI) species and/or to support interactions of the MoO₃. Peak 3 (650 °C) is assigned to Mo(IV) → Mo(II) reduction, with the latter either an oxide or a carbide. Finally, the H₂-TPR traces of Pb–N–C and V–N–C are harder to assign. In both, the typical oxides (PbO and V₂O₅, respectively) are reduced above 600 °C when present as bulk powder, and support interactions lower reduction temperatures to 400 °C. Peak 1 in the VOₓ trace probably belongs to V₂O₅ with strong interactions to the support. In the PbO trace, the early peaks (1 and 2) relate to support interactions or to unreacted Pb(NO₃)₂.

Overall, the H₂-TPR describes several oxides (mostly partially reduced), with significant particle–support interactions. The reducing species may be the carbon itself or volatile gases.
species released from it during the annealing step. Indeed, the annealing temperature (300 °C) is close to the temperature at which carbon methanation may begin, especially when catalyzed by metals. The “support-interacting” species could be particles, clusters, or even strongly bound metal atoms.

**X-ray Diffraction.** X-ray diffraction (XRD) showed that most MO₅ₓ particles are amorphous (Figure S2). Only the Mn-, Cu-, and Zn–N–C samples displayed additional diffraction peaks (Figure 4), corresponding to Mn₃O₄, CuO, and ZnO (JCPDS cards 01-080-0382, 48-1548, and 89-1397, respectively). Importantly, the presence of crystalline phases does not rule out additional, amorphous phases in the catalysts—for example, the lower reduction states of Mn that were suggested by TPR.

**X-ray Photoelectron Spectroscopy.** X-ray photoelectron spectroscopy (XPS) was used to describe composition and bonding on the surface of both MO₅ₓ particles and the N:C support (Figures 5 and S3; see Supporting Information for deconvolution method). The pristine N-doped carbon contains pyridinic (398.3 eV), pyrrolic (399.5 eV), graphitic (400.9 eV), and oxidized (402.9 eV) nitrogen atoms. Pyridinic nitrogens are suitable for metal coordination, and 300 °C is sufficient temperature for forming metal–nitrogen bonds. XPS in the N 1s region is more useful for detecting metal–nitrogen bonding than metal XPS, which often has low sensitivity due to symmetry breaking and charge redistribution related to the binding. Indeed, the spectra reveal that metal codoping shifts the N 1s binding energies. Introducing the metal leads to a peak in the intermediate region (398.5–400 eV) in most materials, suggesting the formation of new metal–nitrogen bonds. Other possible assignments for this new peak could be pyrrolic or pyrimidonic nitrogen. These moieties, however, are unlikely to form as a result of an impregnation with metal and mild heat treatment. The new M–N bonds vary in intensity between the cations and are most obvious for Cr-, Fe-, Co-, Ni-, and Cu-based carbons (Figure 5). The M–Nₓ clusters are dispersed on the carbon surface, in addition to the MO₅ₓ particles. Alternative methods were considered to confirm metal–nitrogen binding, namely, Fe–Mössbauer and X-ray absorption spectroscopies. These methods, however, are unsuitable in the current composites, due to the small percentage of metals in M–Nₓ clusters (most of it is in the oxides) and the similarity in X-ray absorption between M–N and M–O bonds.

In the metal regions of the XPS (Figure 6), most spectra are too complex for reliable mathematical deconvolution, especially when the signal-to-noise ratio is low and varies between samples. Nevertheless, “shape fitting” (overlaying the spectra with literature spectra) helped identify oxidation states.
and binding modes on the surfaces of MO\textsubscript{x} particles. This method helps avoid overfitting of broad peaks and focuses on peak positions and relative magnitudes. The V 2p XPS is characteristic to V\textsubscript{2}O\textsubscript{5}, based on the high-energy binding energy of the 2p\textsubscript{3/2} peak (517.2 eV).\textsuperscript{81,82} Shape fitting shows that there might also be traces of VO\textsubscript{2}, indicating partial reduction of V(V) to V(IV).\textsuperscript{81} In the Cr 2p XPS, two doublets (2p\textsubscript{3/2} peaks at 576.6 and 579.2 eV) indicate the presence of Cr(III), either as Cr\textsubscript{2}O\textsubscript{3} particles or as Cr\textsuperscript{−}\textsubscript{N}\textsubscript{4} sites. Both have typical binding energies of 576.5–576.7 eV.\textsuperscript{43,83–85} In addition, Cr(VI) is present, probably as a CrO\textsubscript{3} layer on the surface of Cr\textsubscript{2}O\textsubscript{3} particles.\textsuperscript{43,83} Shape and position comparison of the Mn 2p XPS reveals Mn(III) and Mn(IV) oxidation states.\textsuperscript{86–88} These probably correspond to the Mn\textsubscript{2}O\textsubscript{3} and MnO\textsubscript{2} phases detected earlier by TPR, rather than to Mn–N centers (which are scarce, according to N 1s XPS). In the Fe XPS spectrum, a typical 2p\textsubscript{3/2} peak of Fe(III) appears at 710.4 eV,\textsuperscript{83} with some contribution from Fe(II). These oxidation states may be related to Fe\textsubscript{2}O\textsubscript{3} with some residual FeO and/or to Fe\textsuperscript{III}\textsubscript{−}\textsubscript{N}\textsubscript{4} clusters embedded into and interacting with the carbon sheets.\textsuperscript{89} The Co 2p XPS signals indicate a mixture of Co(II) and Co(III) states.\textsuperscript{90–92} These ions could be located in

![Figure 5. XPS in the N 1s region of the metal-free N-doped carbon (black trace) and the corresponding M–N–C composites (red traces).](image)

![Figure 6. XPS of the M–N–C samples in the metal regions.](image)
the CoO₃ particles detected by TPR, to partially reduced (CoO) or oxidized (Co₂O₃) oxides, or to Co−Nₓ centers. Similarly, the Ni 2p XPS shows signals from both Ni(II) and Ni(III), possibly as NiOOH surface layers on the NiO particles or as Ni−Nₓ sites. Shape fitting of the Cu 2p XPS also reveals two reduction states (Figure S4), Cu(II) and Cu(I)/Cu(0). The first (2p₃/2 line at 932.4 eV) could correspond to CuO or to CuII−Nₓ, and the second (934.1 eV) corresponds to Cu₂O or to CuI−Nₓ. Even if metallic copper exists (it is indistinguishable from Cu(I) by XPS), it is not expected to contribute to any catalytic activity, as it would not survive long in an oxygenated environment. The Zn 2p spectrum represents only Zn(II) species (2p line at 1022.1 eV). This ion probably corresponds to ZnO rather than to a Zn−Nₓ cluster, which is rare according to the N 1s XPS (Figure S3). The Mo 3d spectrum reveals pure Mo(VI), without any lower oxidation states (e.g., no carbides). The broad peak at 232.5 eV could correspond to amorphous MoO₃ or to MoV−Nₓ clusters. Finally, the Pb 4f spectrum shows peaks typical to PbO, albeit shifted 0.5 eV to higher energies. This shift (see Figure S4) is assigned to unreacted Pb(NO₃)₂, which dissolves during catalysis.

Overall, XPS in the metal region suggests that the surface chemistry of the MOₓ particles generally matches their bulk composition. Most surfaces are partially reduced, with the exception of MoO₃, V₂O₅, and ZnO where the metals are fully oxidized.

**ORR Electro catalysis.** ORR electrocatalysis was used to understand how the M−N−C materials activate oxygen. We studied three aspects: activity (determined by cyclic voltammetry), selectivity for the 2e⁻ vs the 4e⁻ reduction (determined by Koutecký−Levich analysis), and stability (determined by chronoamperometry). All the M−N−C materials were active in ORR electrocatalysis, within a narrow range of overpotentials (Figure 7 and Table 2). In all cases, the pristine N-doped carbon was slightly better, with the E₁/₂ within 50 mV. The MOₓ particles may be blocking micropores (hindering access to surface sites) and slowing down mass transfer. Both effects may lead to lower currents and hence to lower observed onset potentials.

To quantify the blocking, we focused on Pb−N−C. Neither PbO nor Pb−Nₓ clusters have any ORR activity, here or in the literature. Thus, doping by Pb has a purely blocking effect on
O₂ activating sites. The specific surface area of Pb–N–C, measured by N₂ sorption and analyzed by BET, decreases from 1570 m²/g in the pristine carbon to 520 m²/g in Pb–N–C. This drop corresponds to surface blocking by PbO particles. It should be similar in magnitude for all similarly sized MOₙ particles (cf. Figure 2), with the catalytic activity of each metal offsetting this blocking.

Chronoamperometry reveals 19–45% drops in activity after 8 h of oxygen reduction (Figure 7b and Table 2). The pristine N-doped carbon decays to a stable current, due to its gradual oxygenation. All M–N–C catalysts also decay over time, sometimes after an initial rise (e.g., Ni, Cr, and Cu). This decay can be related to leaching out of M–Nₙ centers and/or the dissolution of MOₙ particles. In describing MOₙ dissolution, solubility constants fall short, because the particles’ composition is mostly mixed. Instead, we use Pourbaix diagrams to identify thermodynamically stable phases for a given element at a range of pH values and applied potentials. Here, the Pourbaix diagrams describe narrow belts at the base of the MOₙ particles, because these are the regions both exposed to solution and electrically wired to the external circuit. These regions, responsible for the ORR activity, experience an applied potential of −0.36 V vs normal hydrogen electrode (NHE), and an effective pH of 13 to ∼14–15 (because alkaline ORR generates hydroxides locally).

The more insulated regions at the top of the particles are harder to describe by this approach, because their potential is ill-defined. Pourbaix diagrams (Figure S5) predict that all metals dissolve under these conditions, yielding oxo or hydroxy(oxo) anions, namely, HV₂O₇⁻, CrO₂⁻, HMnO₄⁻, HFeO₂⁻, HCoO₂⁻, HNiO₂⁻, HCuO₂⁻, HZnO₂⁻, MoO₄²⁻, and HPbO₂⁻. This dissolution cannot be correlated to the ORR activity, because it may simultaneously (1) clear blocked sites, (2) destroy catalytic surface layers, or, conversely, (3) expose better catalytic layers.

The most active codopants in this study are based on Fe and Co. Both the oxide particles (Fe₂O₃, Fe₃O₄, CoO, and Co₃O₄) and the surface-embedded Fe–Nₙ and Co–Nₙ clusters can contribute to ORR electrocatalysis. However, the ORR peak is sharper for Co–N–C than for Fe–N–C, suggesting a narrower distribution of active sites. The Co–N–C also decays faster in activity than Fe–N–C, possibly reflecting their difference in selectivity, as observed both here and elsewhere. M–N–C catalysts can reduce O₂ by either 2e⁻ (yielding HO₂⁻) or 4e⁻ (to OH⁻). The number of electrons transferred per O₂ molecule (n) is 2.7 for Co–N–C and 3.2 for Fe–N–C. Thus, the products of ORR contain a higher HO₂⁻/OH⁻ ratio for Co–N–C than for Fe–N–C. Peroxides can corrode metal-doped carbons, destroying their ORR activity. Both Mn–Nₙ clusters and MnO₄ particles are known ORR electrocatalysts, yet XPS shows little Mn–N binding, suggesting that MnO₄ phases (MnO₄²⁻, Mn₂O₆³⁻, Mn₃O₈⁵⁻, or MnO₄⁴⁻) contribute more to O₂ activation in the Mn–N–C catalyst.

The Cu–N–C catalyst is highly active, closely following the first metals. In nature, the tricopper center in the lacasse enzyme has excellent ORR performance. Many synthetic complexes and particles of copper show ORR activity. Copper is exceptionally active toward alcohol oxidation (Figure 8), suggesting that the reaction is not limited by the O₂ activation rates. The copper in the Cu–N–C sample starts as a mixture of CuO, Cu₂O, and/or Cu(0). According to the Pourbaix diagram, CuO first dissolves to HCuO₂⁻ and is then reduced to Cu₂O (reduction to Cu(0) is unlikely in an oxygenated solution). Interestingly, the stepwise changes in the chronoamperogram may reflect these reductions (Figure 7b). If we think of the first 2 h of ORR as a “pretreatment” step, then the Cu(1)–N–C catalyst has the highest stability by far. The catalytic site could be either Cu₂O or Cu⁺–Nₙ, because both are active toward the ORR.

The high ORR activity of the Ni–N–C and V–N–C catalysts is surprising. Neither NiO, NiOOH, or Ni–Nₙ macrocycles are good ORR electrocatalysts. NiO, NiOOH, or Ni–Nₙ particles typically reduce O₂ only by 2e⁻, whereas we see n = 3.16 e⁻/O₂. Thus, the Ni–Nₙ sites in the Ni–N–C catalysts contribute more to the ORR than the NiO and/or NiOOH particles. Similarly, V₂O₅ particles are unlikely to be good ORR catalysts, suggesting that it is the V(IV) surface layer, detected by XPS and TPR, that drives the catalysis.

Little is known about V–Nₙ centers for alkaline ORR catalysis; such activity was only observed for homogeneous vanadium complexes in acidic media.

Cr–N–C has mediocre ORR activity, like other Cr₂O₃/carbon composites and Cr–Nₙ macrocycles. Typically, Cr₂O₃ particles prefer the 4e⁻ reduction, while Cr–Nₙ clusters are selective toward the 2e⁻ reduction. Our Cr–N–C catalyst shows n = 3.1, suggesting that the Cr₂O₃ particles are more significant for ORR electrocatalysis. Moreover, the rise in ORR activity after ∼5 h (Figure 7b) suggests that initial dissolution of the Cr₂O₃ surface layer (detected by TPR) improves activity.

The ORR activity of the Mo–N–C catalyst approaches that of Cr–N–C. Because MoO₃ is inactive in ORR, the activity is assigned to the prominent Mo–Nₙ sites. In the Zn–N–C material, conversely, Zn–N binding is weak, suggesting that ZnO contributes to the meager ORR activity observed.

In future studies, we hope to refine the active site assignment by using selective leaching or selective reduction of MOₙ particles, or the selective blocking of M–Nₙ sites, in order to decouple the interactions in their activities. This should lead to better control materials, which are otherwise hard to produce.

**O₂ Activation—From ORR to Alcohol Oxidation.** The ORR activity follows a “volcano”-type trend with respect to the number of d-electrons (Figure 8). The volcano peak is on Fe–N–C. This behavior matches most systematic comparisons of
third-row transition metals as electrocatalysts for alkaline ORR. This alignment with the literature further supports the hypothesis that the drop in ORR activity (relative to the pristine N-doped carbon) that was observed for all metal dopants is indeed a systematic effect—despite the small differences in electrocatalytic activity ($E^{1/2}$ spreads over 50 mV). Interestingly, vanadium outperforms the trend, calling for additional studies of this novel V–N–C catalyst.

Similarly, the catalytic activity of the M–N–C materials toward cinnamyl alcohol oxidation is volcano-shaped. The peak is centered on Co or Cu, with one outlier (Cu or Co, respectively). This similarity between the volcanoes suggests that O$_2$ activation is the reaction bottleneck. The outlier must respect the volcano-shaped trend, calling for additional studies of this novel V–N–C catalyst.

In catalysts where O$_2$ activation is done primarily on Co, Cu, Fe, Ni, V, Mn, Mo, Zn, and Cr, the oxide particles block some of the surface sites. The oxide particles block some of the surface sites. Furthermore, carbon graphitization (and hence conductivity) is more important in tandem catalysts, as it boosts conductivity and stability. Carbon optimization efforts should then focus on pore design (for easier flow) and promoting graphitization (to boost conductivity and stability). Conversely, if O$_2$ is activated at the surface-embedded M–N$_x$ clusters, then the M–N–C material is a tandem catalyst. During catalytic alcohol oxidation, sites such as V$^{IV}$/O$_2$–, Fe$^{IV}$–, Co$^{IV}$–, Ni$^{IV}$–, Cu$^{IV}$–, and Mo$^{VI}$–N$_x$ activate O$_2$ while the MOX particles bind and oxidize the alcohol. We have recently analyzed this situation in depth, focusing on the interaction between the two types of active sites. This interaction can be chemical (exchange of intermediates) or electronic (charge transfer). Its efficiency determines the dimensions of the so-called “active doughnut”, the toroidal volume at the base of the particles, where the reaction occurs during the exchange step. In these tandem catalysts, the loading of oxide particles cannot be maximized or they will block M–N$_x$ sites. Rather, the particle dispersion needs to be carefully tuned, aiming at (1) maximum exposure of both types of sites and (2) interparticle distances optimized to the lifetimes and diffusivities of reaction intermediates. Furthermore, carbon graphitization (and hence conductivity) is more important in tandem catalysts, as it determines the rate of charge transfer between reux sites.

**CONCLUSIONS**

We studied the structure and catalytic activity of 10 carbon materials, codoped by nitrogen and transition metals. These materials are promising catalysts for heterogeneous oxidations with molecular oxygen. To identify the active sites for O$_2$ activation, we separated the two doping processes by loading with molecular oxygen. To identify the active sites for O$_2$ activation, we separated the two doping processes by loading with molecular oxygen. To identify the active sites for O$_2$ activation, we separated the two doping processes by loading with molecular oxygen. To identify the active sites for O$_2$ activation, we separated the two doping processes by loading with molecular oxygen. To identify the active sites for O$_2$ activation, we separated the two doping processes by loading with molecular oxygen.
