Chapter 3

Photochemical conversion of tin-oxo cage compounds studied using hard x-ray photoelectron spectroscopy*

Molecular inorganic materials are currently considered as photoresists for extreme ultraviolet lithography (EUVL). Their high EUV absorption cross section and small building block size potentially render high sensitivity and resolution as well as low line-edge roughness. The photochemical reaction mechanisms that allow these kinds of materials to function as photoresists, however, are still poorly understood. We discuss photochemical reactions upon deep UV (DUV) irradiation of a model negative-tone EUV photoresist material, namely the well-defined molecular tin-oxo cage compound [(SnBu)$_{12}$O$_{14}$(OH)$_6$(OH)$_2$, which is spin-coated to thin layers of 20 nm. The core electronic structures (Sn 3d, O 1s and C 1s) of unexposed and DUV exposed films were then investigated using synchrotron radiation-based hard X-ray photoelectron spectroscopy. Different chemical oxidation states and concentrations of atoms and atom types in the unexposed and exposed films were found. We observed that the exposure in a nitrogen atmosphere prevented oxidation but still led to carbon loss, albeit with a smaller conversion. Finally, a mechanistic hypothesis for the basic DUV photoreactions in molecular tin-oxo cages is proposed.

3.1 Introduction

Metal-containing hybrid inorganic materials are considered promising candidates as photoresists in high volume semiconductor manufacturing using extreme ultraviolet lithography (EUVL), ever since these materials were introduced in the past years.\textsuperscript{1-5} Photoresists based on HfO\textsubscript{2} and ZrO\textsubscript{2} nanoparticles were synthesized and shown to form patterns in EUVL by Ober’s group.\textsuperscript{1-3} Tin-oxo cages,\textsuperscript{6} palladium complexes,\textsuperscript{7} organotin compounds,\textsuperscript{8} and other molecular compounds have further been explored as EUV photoresist by Brainard’s group. Recently, Inpria introduced Sn-based hybrid photoresists.\textsuperscript{5} Compared with traditional organic chemically amplified photoresists (CARs), some of these inorganic photoresists show higher sensitivity,\textsuperscript{2,4,9,10} can be employed as thinner layers due to their higher EUV absorptivity, have higher etching resistance,\textsuperscript{9} and potentially yield both lower line-edge roughness and higher resolution due to their smaller building blocks.\textsuperscript{11-13} Such findings have shown the great potential for inorganic materials to be used as EUV photoresist. CARs have now been used and optimized for many years, first for deep UV (DUV) and more recently for EUV, and their critical photochemical reactions are generally well understood.\textsuperscript{14} In contrast, the photoreaction mechanisms in the inorganic photoresist have not been thoroughly investigated yet. To further improve the performance of the inorganic photoresists, systematic studies of the key photoreaction mechanisms in the photoresist are necessary.

In this contribution, we study the structure and photochemistry in spin-coated layers of the tin-oxo cage compound [(SnBu)\textsubscript{12}O\textsubscript{14}(OH)\textsubscript{8}](OH)\textsubscript{2}, which can be seen as an ideal model system of inorganic nanoscale photoresists, given its well-defined metal-oxo core structure with surrounding n-butyl organic ligands and hydroxide counterions; see Fig. 3.1. To synthesize the compound, we followed the route in Ref. 15. The molecule contains Sn atoms with high EUV photon absorption,\textsuperscript{10,16,17} and it has been demonstrated to work as an EUV photoresist.\textsuperscript{6,8} Despite the relatively simple structure of this molecular system, few spectroscopic methods are suitable to study the details of the photochemical reactions occurring in thin films, both due to limited sensitivity and limited chemical contrast. For example, UV-absorption spectra contain little structural information, while vibrational spectra (Raman or IR absorption) of thin films are close to their sensitivity limits, and in the case of the tin cages, give limited information due to the absence of characteristic vibrational marker bands. Here, we apply hard X-ray photoelectron spectroscopy (HAXPES) with tunable high photon energies from synchrotron sources, typically ranging from 1.7 keV to 10 keV. The detection limit is extremely low, and core-level photoemission naturally gives rise to elemental sensitivity because each element emits electrons from core levels in completely separated and well-defined energy ranges. The known relative emission efficiencies for different core levels
allow quantitative analysis of chemical composition. The chemical shifts in the binding energies of atoms in chemically different bonding environments make the method sensitive to chemical structure.\(^\text{18}\)

Finally, the high photon energy in HAXPES gives the photoemitted electrons high kinetic energy and thus long inelastic mean free paths that allow the probing of molecular layers far below the surface. Thus, the bulk properties of the spin-coated photoresist layer can be accessed before and after exposure.\(^\text{19}\)

### 3.2 Materials

#### 3.2.1 Materials

The tin-oxo cage with tosylates as counterions (TinS) was synthesized from butylstannoic acid hydrate and \(p\)-toluene sulfonic acid monohydrate.\(^\text{15}\) Tin-oxo cages with hydroxide as counterions (TinOH) were obtained by mixing a solution of aqueous tetramethylammonium hydroxide (TMAH) with a solution of TinS in isopropanol. TinOH precipitated, and the product was filtered directly. Results of a more extensive series of tin cage compounds will be published elsewhere. Glass coverslips were purchased from Menzel Gläser and cut into \(1 \times 1 \text{ cm}^2\).

#### 3.2.2 Photoresists film preparation

For photoelectron spectroscopy experiments, it is essential that the substrates are conducting. These were prepared by coating piranha base-cleaned glass coverslips with 2 nm Cr and 18 nm Au layers using a sputter coater (Leica EM ACE 600 Double sputter coater). The tin oxo-cage material was dissolved in toluene to a concentration of 7.5 mg mL\(^{-1}\). Solutions were filtered through a 0.25 \(\mu\)m PTFE filter right before spin coating. Thin layers \([\sim 20 \text{ nm}],\) determined by atomic force microscopy (AFM)] were obtained by spin coating under 2000 rpm for 45 s with a
speed of 750 rpm s⁻¹ on the Cr/Au coated glass coverslips. The samples were subjected to post-application bake at 90 °C for 1 min.

3.2.3 Photoresists exposure
A YAG-pumped OPA laser (Ekspla NT342B), delivering nanosecond pulses at 225 nm at 10 Hz (2.5 mJ pulse⁻¹) was used as the irradiation source. Some samples were exposed under ambient conditions with a dose of 1.3 J cm⁻². The dose was chosen to ensure a substantial chemical conversion in this first study of product formation. The other samples were exposed in an enclosed sample chamber, containing dry N₂, to the same dose (i.e. the exposure time was corrected for the losses due to window reflectivity).

3.2.4 Characterization
All samples were characterized using HAXPES at the HIKE end station. The photon energy used for measurement was 2005 eV. The total energy resolution of the experiment was estimated to approx. 250 meV. Two types of spectra were recorded; (i) overview spectra taken from 0-800 eV binding energy (BE) in which all relevant lines were included, and (ii) detailed core-level spectra of the Sn 3d, C 1s and O 1s regions. The overview spectra were used to extract atomic number ratios, whereas the detailed spectra were used to resolve the chemical shifts in the respective elemental region. The X-ray power was ~10 µW cm⁻², which allowed the recording of a spectrum in a few minutes. Radiation damage to the materials was apparent only after ca. 2 hours.

3.3 Result and Discussion

3.3.1 Atomic concentration of different samples
Overview HAXPES spectra of unexposed TinOH thin films, as well as samples exposed to DUV in air and in N₂, are shown in Fig. 3.2. All the peaks are marked with the electronic state from which the electrons originate. Au 4f peaks, originating from the layer underneath the tin cage layer, are present in the spectra and were used for binding energy calibration; the Au 4f7/2 binding energy was set to 84.00 eV. The tin cage gives rise to clear Sn 3d peaks at ~487 and ~498 eV (5/2 and 3/2 spin-orbit components, respectively), an O 1s peak at ~531 eV, and a C 1s peak at ~285 eV. The peak positions correspond well with those in the literature.

The atomic ratios of Sn, O and C atoms inside the three samples are proportional to the area ratios of the peaks in the spectrum, and can be extracted with knowledge of the photoionization cross sections. For the unexposed sample, the extracted atomic ratios correspond well within the error bar to the expected chemical composition. For the exposed samples, since the number of Sn atoms is unlikely to change due to
exposure, the O1s and C1s peak areas are normalized to the Sn peak area, and the atom ratios for these samples are given in Table 3.1.

Table 3.1. Atomic ratios of TinOH unexposed sample, TinOH DUV-exposed in air, and TinOH DUV-exposed in N₂.

As can be seen from Table 3.1, after the TinOH sample was exposed to DUV in air, the oxygen content was significantly increased while the carbon content was drastically decreased. This suggests that oxidation happens during the exposure, together with Sn-C bond or C-C bond cleavage, causing a loss of volatile carbon-containing species. When the sample was exposed in dry N₂, however, the O content stayed the same; this is because when no oxygen-containing gas-phase species is present, no further oxidation is possible and the photo-induced outgassing apparently does not cause any further loss of oxygen either. Compared with the carbon loss when TinOH was exposed in air, less C was lost under the same DUV dose.
For the TinOH sample exposed to DUV in air, we can make a crude estimate of the average photochemical quantum yield for breaking of Sn-C bonds based on the loss of carbon of ~63%. Using the measured UV absorbance of the thin film at 225 nm we find that the absorbed dose is ~0.40 J cm\(^{-2}\). This corresponds to \(4.5 \times 10^{17}\) photons cm\(^{-2}\). These lead to the breaking of \(6.7 \times 10^{15}\) Sn-C bonds per cm\(^{-2}\). The average quantum yield for loss of a butyl group is thus ~1.5 %. More accurate quantitative characterization of the photochemical process is needed, but we can already conclude that the carbon loss reaction is not very efficient.

### 3.3.2 Analysis of Sn, O and C chemical shifts

The high-resolution Sn 3d\(_{5/2}\) photoelectron spectra of the samples are shown in Fig. 3.3(a). Small, well-reproducible shifts can be clearly observed, which we interpret as a result of a change of the Sn oxidation state. The dependency of the Sn 3d binding energy on the Sn oxidation state has been well established in the literature.\(^{19}\) The center of the Sn 3d\(_{5/2}\) peak after DUV exposure in air is shifted to higher binding energy, indicating that the oxidation state of the Sn atoms has increased. In contrast, the center energy position after DUV exposure in N\(_2\) is shifted to a lower binding energy, indicating a net reduction of Sn atoms.

![Figure 3.3](image)

**Figure 3.3.** Sn 3d\(_{5/2}\) core-level spectra for TinOH unexposed sample, TinOH DUV-exposed in air, and TinOH DUV-exposed in N\(_2\). (a) Core-level spectra sharing the same scale on the ordinate axis, (b)-(d) Fits for each sample using the two-component model described in the text.
In Fig. 3.3(b)-(d), we show least squares fits to the data using two Voigt line-shapes, i.e. each component is a Gaussian convoluted with a Lorentzian function (10%) that accounts for the finite lifetime of the core ionized state. Because there are two kinds of Sn atoms inside the tin oxo cages (5-coordinated Sn atoms in the center part of the molecule, 6-coordinated Sn atoms in the side parts of the molecule facing the counter-ion), two sub-peaks were used to model the spectrum of the unexposed sample. Although the photolysis products are probably more complex, we take these peaks to be representative for tin in lower and higher oxidation states, respectively, and use the same peak positions and bandwidths to model the Sn peaks in the exposed samples – leaving only the amplitude as the free parameters. Under these constraints, the spectra in Fig. 3.3(b)-(d) were simultaneously fitted for the best global fit describing the full data set.

The results are presented as solid lines in Figs. 3.3(b)-(d), together with the data as circles. The peak at 486.7 eV (green) corresponds to the 5-coordinated Sn (low oxidation state, low BE) and the peak at 487.3 eV (purple) to the 6-coordinated Sn (higher oxidation state, high BE). In Fig. 3.3(b), the intensity of the two peaks is constrained to the 1:1 ratio corresponding to the equal abundance of the two types of tin. After DUV exposure in air, the intensity of the component corresponding to the low oxidation state decreases and the intensity is transferred to the peak of the more highly oxidized Sn component. In contrast, the fitting results from the sample exposed in N$_2$ indicated that some of the higher oxidation state Sn atoms were converted to a lower oxidation state. The FWHM of the three spectra were 1.58 eV, 1.22 eV and 1.27 eV, respectively; see Fig. 3.3(a). The peaks became narrower after exposure because one type of Sn atom became more dominant, but the FWHM values of the underlying components were constant at 1.17 eV.

The O 1s photoelectron spectra are shown in Fig. 3.4. O 1s peaks from all samples were normalized based on the O atoms ratio obtained from the overview spectra. Similar to the Sn 3d data, Fig. 3.4(a) shows the O 1s spectra with a common scale on the ordinate axis, whereas Fig. 3.4(b)-(d) show least squares fits to the data. As seen in Fig. 3.4(a), after DUV exposure in air, the O 1s peak shifted to higher binding energy and a considerably higher intensity, whereas the O 1s peak of the sample exposed under N$_2$ atmosphere shifted slightly to lower binding energies without change of the intensity.²²

There are three kinds of O atoms in the TinOH cage, as can be seen in Fig. 3.1. Three Voigt peaks are assumed in the modeling of the unexposed sample, each shown in Fig. 3.4(b). We assign the low-BE peak (red) to the oxygen atoms bridging three Sn atoms, the intermediate one (dark blue) to the oxygen in the OH groups bridging two Sn atoms, and the high-BE (light blue) to the O in the OH\textsuperscript{−} counterions. Similar to the Sn 3d\textsubscript{5/2} fitting, we assume that the underlying spectral features in the spectra of the DUV-exposed samples are the same, i.e. their binding energy positions and linewidth parameters, whereas the intensities might be altered
due to chemical conversion. Under these assumptions, the three spectra were fitted simultaneously to get a global optimum fit. The result is shown in Fig. 3.4(b)-(d).

After the sample was exposed to DUV in air, the peaks of all three kinds of O increased in intensity. Because extensive oxidation has obviously taken place here, most probably resulting in a mixture of oxidation products, the simple approximation with three types of O is probably not fully valid, but again they do likely represent chemical environments close to those of the unexposed material. It is also possible that $O_2^-$, $O^-$, $O_2^{2-}$ would be chemisorbed on top of the photoresist. For the sample exposed to DUV in N$_2$, on the other hand, no oxidation can take place, and the intensity of the three components almost stayed the same. The intensities of the peaks were converted into the number of oxygen atoms per molecule in the corresponding chemical state; the values are listed in Table 3.2, along with the extracted binding energy of the respective peak.

The C 1s photoelectron spectra were analyzed in the same way as their Sn 3d and O 1s counterparts. Figure 3.5(a) shows the data, normalized by the calculation from the overview spectra of the three samples. There is no clear energy shift observed in the main low-BE peak of the spectra after exposure, but the intensities and peak shape change significantly. In the unexposed sample, only two kinds of C atoms inside the tin-oxo cage can be distinguished from the spectra, attributed to Sn-C and C-C bonding configurations. After exposure, however, there is a shoulder observed near 286.1 eV and a new feature around 289.2 eV. These features likely arise from C 1s electron emission from C atoms with C-O and C=O bonds, respectively, as the increased BE indicates higher oxidation of some of the C atoms. Thus, four Voigt peaks are used to describe the spectra of the DUV-exposed samples, the results of which are shown in Fig. 3.5(c)-(d). The extracted concentration of the respective atomic type per molecule and the corresponding binding energies are listed in Table 3.3. The unexposed sample gives the ratio expected from the chemical structure. Furthermore, the C atom number in the in C-C and Sn-C configurations from both samples exposed to DUV was decreased. At the same time C in C-O and C=O binding motifs were increased slightly, which further demonstrated the oxidation during the DUV exposure. For the sample exposed in air, the C-O and C=O can be taken as a sign of oxidation on the carbon chain part, in agreement with the increasing of the O content. However, as we concluded from the overview spectra and Sn 3d, and O 1s spectra, there was no oxidation or O gain in the sample exposed to DUV in N$_2$. The increase of the C=O feature at 289.2 eV from the sample exposed in N$_2$ must, therefore, be because of a light-induced rearrangement within the tin-oxo cages. Although there is no extra O gained, the carbon chain might be cleaved at the Sn-C bond or C-C bond after which the product could further react with an oxygen atom in the cage to form C-O or C=O bonds.
Based on the analysis of the HAXPES data presented above, we propose reaction pathways of the DUV induced reaction, schematically shown in Fig. 3.6. According to quantum-chemical calculations using density functional theory (DFT), the lowest electronically excited triplet state is of a $\sigma \rightarrow d$ type. In this state, the Sn-C bond is easily broken to form two radicals. If present, oxygen and H$_2$O can directly react with the Sn radicals and increase the oxidation states of Sn atoms, which corresponds to the results shown in Fig. 3.3. The butyl radical could further donate a hydrogen atom or abstract one from neighbor cages to form butene or butane, volatile stable molecules that are readily released into vacuum. A hydrogen atom could be abstracted from a butyl group and form a C-centered radical, which could further react and form side chain oxygenation products that may account for the 289.2 eV band in Fig. 3.5. For the sample exposed in N$_2$, the chance for the radicals to recombine is greater after the Sn-C bond cleavage occurs, since there is no active molecule like O$_2$ or H$_2$O. That would explain why more C is lost in the sample exposed in air than in the sample exposed in N$_2$. The cleaved butyl radical could also react with the O inside the cage forming a C-O bond, corresponding to the C-O peaks in Fig. 3.5(c) and (d). Another possible reaction is the transfer of a hydrogen atom from the butyl radical to the Sn radical to form butene and a tin hydride. The formation of such an oxidation-sensitive but otherwise stable reaction product could be the explanation of our finding that the formation of insoluble material after exposure to EUV is enhanced by post-exposure baking.

Figure 3.6. Proposed photochemical reactions for TinOH exposed to DUV in air and N₂.

3.4 Conclusion

HAXPES is demonstrated to be a powerful tool for analyzing the chemical changes upon DUV exposure in air and under N₂ in thin films of tin-oxo cages. Based on the detailed analysis of the presented HAXPES spectra, a mechanism of the photoreactions of TinOH films exposed to DUV in air or under N₂ could be proposed.
While the exposure conditions are very different from those in an EUV lithography tool, the present study highlights the relevance of gas-phase/film interactions for the final photochemical product formation. In ongoing experiments, we further compare these results with the changes induced in solution-phase photochemistry of the tin cages, in which products can be isolated and subjected to a wide range of chemical analysis techniques and with the results of EUV exposures of thin films at 13.5 nm.
