Prevalence of depression in patients with chronic obstructive pulmonary disease: a systematic review

L van Ede, C J Yzermans, H J Brouwer

Abstract

Background—Patients with chronic obstructive pulmonary disease (COPD) have repeatedly been characterised as a population of chronically ill patients with a higher than normal prevalence of depression. Susceptibility for depression has been noted in patients with certain other chronic conditions. This systematic review was conducted to achieve a more definite answer to the question: do patients with COPD show a higher than normal prevalence of depression?

Methods—Studies in English language journals were retrieved by an electronic search over the period from 1966 to December 1997 and by an extended search of reference lists, and were included or excluded according to a system of diagnostic and methodological criteria.

Results—Ten studies were included, of which only four had a case-control design. Three of the case-control studies reported an increased prevalence of depression among patients with COPD which was statistically significant in only one. The fourth controlled study found a significantly increased depression score among COPD patients. Of the remaining six uncontrolled studies three found a high baseline prevalence of depression among their study group.

Conclusions—An association between COPD and depression was found in the four controlled studies. The two methodologically best conducted studies that did not detect a statistically significant higher prevalence lacked power. The two studies that did find a significant association used a questionable depression measure. The prevalence of depression was high compared with general population figures in three of six non-controlled studies. The empirical evidence for a significant risk of depression in patients with COPD remains inconclusive, due to the poor methodological quality of most of the published studies, the lack of studies with an adequate sample size, and variability in instruments and cut off scores used to measure depression.

Keywords: chronic obstructive pulmonary disease; depression; review

Patients with chronic airway problems form an important population in primary care. Chronic obstructive pulmonary disease (COPD) is a term for a group of chronic lung disorders, especially chronic obstructive bronchitis and emphysema, mostly characterised by a slowly progressive irreversible bronchial obstruction (expressed in a progressive limitation of the forced expiratory volume in one second (FEV₁)) and a fluctuating symptom complex of recurrent productive cough and dyspnoea. Eighty percent of the medical care for these patients in the Netherlands is provided by the general practitioner. Caring for the chronically ill in primary care is a challenging task for the general practitioner; the most important task is not cure but optimising the quality of life of the individual patient.

How likely is the development of depression in patients with COPD? Several non-systematic overviews of the literature on this subject have been published, in all of which a high prevalence of depression has been described. The present review was conducted to answer the following question: do patients with COPD show a higher prevalence of depression than those who do not suffer from COPD?

Methods

ASSESSMENT OF COPD AND DEPRESSION

There is still a lack of uniformity on the objective characteristics and test results of COPD. A clinical diagnosis and the FEV₁ value are the minimum requirements for a study to be considered valid. The FEV₁ is an indicator of the severity of bronchial obstruction; the best way to present and interpret this value is as a percentage of the optimal value calculated for the individual's age, height, sex, and race.

Caution is needed with the interpretation of spirometric values because the results are influenced by the patient’s cooperation. In patients with COPD the FEV1 is <75% of the predicted value; an FEV1 of 60–70% of the predicted value is indicative of moderate bronchial obstruction and an FEV1 of <50% of the predicted value or <1.5 l/s indicates severe bronchial obstruction.12

In this review the term “depression” is used to indicate a significant depressive disorder and not a temporarily depressed mood. In research depression is usually detected by using one of three types of measures: self-report questionnaires, checklist based structured interviews, and clinical assessment by a psychiatrist. The latter, based on DSM-III-R standards, is often used as the golden standard in validation studies of the first two measures. The self-report instruments are most often used because they are quick and inexpensive. The cut off values of the rating scales are usually calculated to detect a depressive disorder. When structured interviews or clinical assessments are used, DSM criteria are usually applied to identify a depressive disorder.

SELECTION OF STUDIES
All relevant studies published since 1966 (the starting year for Medline) were retrieved from the literature data bases as well as from the reference lists of the resulting articles. The electronic search was undertaken with the OVID search program using the following terms: “Exp Lung diseases, obstructive” or “COPD.tw” and “Exp Depressive disorder” or “Depression.tw” or “Exp affective disorder”. The period 1966–1997 was covered by Medline, 1988–1997 was covered by Embase, and 1982–1997 was covered by CINAHL. All studies dealing with depression in patients with COPD were selected for further evaluation.

Overall, 393 abstracts were read. Excluded were studies on patients with bronchial asthma (n = 128), clinical trials of antidepressive medication (where patients were included because of a depressive disorder), studies on the prevalence of anxiety disorders (n = 89), animal experiments (n = 7), and studies published in a language other than English (n = 48). Furthermore, 56 reviews, case descriptions, and letters to the editor without original research results were excluded from our review. A further 16 studies were identified from the reference lists of the selected publications, four of which were also included in the review.

The remaining 69 studies were rated by the three authors on three sets of criteria chosen in several sessions: the assessment of COPD, the method used to detect depression, and the methodology applied. The first two sets (on COPD and depression) were applied as entry criteria; studies that failed to meet one of these were excluded. The COPD criteria were checked by an expert opinion (senior pulmonologist): a clinical diagnosis in combination with the mean value of the FEV1, preferably expressed as a percentage of the predicted value. The severity of the disease in the sample can be estimated from the mean FEV1 (table 1).

To detect depression most of the retrieved studies used a self-rating measuring instrument and some used a clinical interview. A clinical interview by a psychiatrist based on DSM-III (or later versions) was considered an acceptable method.13 Self-rating instruments were considered acceptable if they had been validated in earlier studies. Bowling’s book14 on measuring instruments was used as a guide to check this; the instruments used in the studies finally selected have all been validated in earlier studies (table 2).15-19 From the 69 studies thus judged, 35 failed to meet the criteria on COPD or depression and were excluded.

The methodology of the 34 remaining studies was assessed using a scoring system. Five methodological criteria were considered important: a case-control design with controls matched for age and sex, preferably random selection of patients in both groups, the exclusion of important physical co-morbidity, the prevalences were applied as entry criteria; studies that failed to meet one of these were excluded. The COPD criteria were checked by an expert opinion (senior pulmonologist): a clinical diagnosis in combination with the mean value of the FEV1, preferably expressed as a percentage of the predicted value. The severity of the disease in the sample can be estimated from the mean FEV1 (table 1).

The 34 studies were scored by each reviewer independently using the scoring system from table 1. Differences in scores between the three reviewers were resolved as follows: when two reviewers agreed, their score was taken as the final score. When all three reviewers disagreed, the article was jointly reviewed again and discussed until agreement was reached between at least two reviewers.

Studies with a methodology score of less than two points were excluded. One study22 was excluded because the population under study had already been used in an earlier study included by us.21 Finally, 10 studies were considered for final reviewing (table 3).23-32

1For each subject the FEV₁/FVC value was determined, no clinical diagnosis of COPD was established.
2No FEV₁ value given, though a clinical diagnosis and chronic irreversible airflow obstruction is described.
3FEV₁/FVC expressed as % of predicted value.
4FEV₁/FVC expressed as % of predicted value.
5Matched for age, sex, race, education, and socioeconomic status.
6Matched for age, sex, and education.
7Range 0–6.
8Post hoc power calculated using the nQuery Advisor program (second version), given α = 0.05, using a two tailed test.

Results

Only four studies used a case-control design to compare results between patients with COPD and a control group.24–27 All of these detected a higher prevalence of depression among COPD patients than among controls, but in the two best rated studies24 25 (with equal points for methodology) the differences were not statistically significant. One study, conducted on a sample of patients with severe COPD,24 found a difference in depression prevalence of 6% between patients and controls (7% in patients and 1% in controls); the other study25 conducted on a community sample of patients with an FEV₁/FVC of less than 66% of the predicted value found a difference of 9% (28% in patients and 19% in controls). The severity of COPD cannot be detected as no mean FEV₁ is given but it is probably in the mild to moderate range as it was conducted on a community sample. The two case-control studies where a statistically significant difference was found26 27 used patients with severe COPD (both with a long term oxygen treatment indication). To estimate whether the controlled studies had adequate sample sizes a post hoc power was calculated on the difference in prevalences of depression found in the study using the nQuery Advisor 2.0 program. For one study27 this calculation was not possible because only the mean t scores were reported without standard deviations. This also applies to the remaining six studies23 28–31 which all lacked a control group. The (baseline) depression prevalences among the COPD patients in these studies lie within the range of 6–42%; in five of these the prevalence was reported to be 12% or higher.

One of these studies28 was a rehabilitation trial on patients with COPD and the combined baseline data of the study and control groups were included in the review.

The majority of the studies described patient groups with moderate to severe COPD (FEV₁ <50% or <1.5 l/s); only one study25 described patients with mild to moderate COPD.

Discussion

The methodologically best rated studies24 25 in this review did not find a statistically significant difference in the prevalence of depression between patients with COPD and controls.

The prevalence of depression (using the Hospital Anxiety and Depression (HAD) scale) in the study on Swedish subjects24 was strikingly low in both patients with severe COPD and controls compared with the prevalences found in the other studies. The difference between patients and controls was 6% which was not statistically significant. Calculation of the post hoc power, however, revealed that the study sample was too small. In fact, 141 patients with COPD would have been needed to reach a power of 80% (which is the minimum required value23).

The only study using a community sample, a study on Finnish subjects,25 found a relatively high prevalence of depression (using the Zung SDS) in both patients and controls. Among the healthy controls the prevalence (19%) was much higher than that found in the controls in the Swedish study. The difference detected between patients and controls was 9%, which was not statistically significant. Post hoc power calculation revealed that this study, like the

Swedish one, was too small to detect a clinically relevant and statistically significant difference of 9%; to reach a power of 80% 229 patients needed to have been included. In accounting for the differences between the two studies the main attention should focus on the instruments used to measure depression and the cut off values chosen. The HAD scale has the advantage of being rather insensitive to age and to somatic symptoms. The use of the Zung SDS in the Finnish study in which the patients were on average older than in the Swedish study (72 years versus 65 years) could thus have resulted in higher prevalences, although by itself this is unlikely to explain the large differences found between the two studies. In the Swedish study a rather high cut off value of ≥11 was applied to the HAD scale scores, which has been shown to have a low sensitivity (50%) for detection of clinically relevant depression in a validation study on general medical outpatients. In a study on elderly stroke patients a lower cut off score of ≥5 was reported to be optimal, giving a sensitivity of 83%. The cut off value chosen for the Zung SDS in the Finnish study was shown to have acceptable sensitivity (76%) in a group of elderly stroke patients. The high cut off value in the Swedish study could have resulted in a lower prevalence at the same time of more severe depressive disorders.

The other two controlled studies, which were concluded to be of lesser methodological quality, were conducted on patients with severe COPD who were reported to be statistically significantly more depressed than healthy controls. In one of these studies the prevalence of depression was much higher in patients with COPD than in controls (42% versus 9%). The post hoc power calculated for this study was excellent (99%). However, the quality of the depression instrument (MMPI) has been questioned; although widely used it is considered to be outmoded and has not been cross-validated with DSM-III criteria. Moreover, no cut off scores have been described, only t scores which indicate the probability of belonging to a group of subjects with a certain disorder.

The study by Prigatano et al reported higher t scores for patients with COPD than for controls using the MMPI depression scale. Because no standard deviation of these scores was reported, the post hoc power could not be calculated. An indication of the relative credibility of this study may be that it included slightly more patients with COPD (n = 89) than the underpowered Finnish study but a much smaller group of controls (n = 24).

In the two studies using community samples the controls were matched only for age and sex, whereas in the other two studies the matching variables included education and social class. Not taking into account the possible confounding effect of variables which are clearly related to COPD as well as to depression could result in the association between the two being obscured. Whether this is the case for education or social class is as yet not certain.

In summary, apart from the difference in nationality of the populations from which the samples were drawn, the striking difference between the prevalence of depression among the controls of the first three controlled studies seems to be caused by two factors: the depression instrument and the cut off score used to detect the depressive disorder.

The empirical evidence for a significant risk of depression in patients with COPD is thus inconclusive. Possibly the most striking result of this review has been the observation of the poor quality of most studies. Only four studies satisfied what seems an absolute minimum requirement: a case-control design.

What about the other studies? Three out of the six studies reported a prevalence of around 30% which is substantially higher than the prevalence in the general adult population as reported in recent large community surveys. The “past 12 month” prevalence of a major depressive episode among persons aged 15–34 years was found to be 10.3% in the USA and 5.8% in those aged 18–64 years in the Netherlands. The comparison of these figures is, of course, limited as patients with COPD belong to an older age group which was not included in these surveys. Because of the inconsistent results of the best quality studies it is impossible to attribute reported depression levels to the presence of COPD, to the length of the illness, to a chronic illness per se, or to the age group.

The occurrence of depression in association with medical illness has been studied particularly for cardiovascular diseases, stroke and several other neurological diseases, diabetes,
and hypertension. These studies have shown that, before constructing any aetiologi-
cal model, it is important to consider con-
founding explanations of an association. The
most important confounder is an artefact of
depression measurement due to an overlap
between symptoms of the somatic illness and
those considered indicative of depression. The
Geriatric Depression Scale (GDS) and the
HAD questionnaire are examples of instru-
ments developed to counter this problem.
Depression may also be a temporary adjust-
ment as a result of the diagnosis of a potentially
life threatening disease or a side effect of the
medication used to treat the somatic illness
(lit corticosteroids). Unlike the disorders
mentioned above, the occurrence of depression
in association with COPD has not been ade-
quately studied.

In conclusion, an association between
COPD and depression was found in the four
controlled studies reviewed. In the two studies in
which the better measuring instruments (HAD scale and Zung SDS) were
used the association was not statistically
significant, although the studies lacked power.
The only controlled study that did have enough
power detected a statistically significant rela-
tionship, but used a questionable depression
measure without a certain cut off score (MMPI).
Three of the six remaining studies included in our review did find a higher than
normal prevalence of depression but the meth-
ology of these studies was of much poorer
quality and the results are therefore dubious.

Based on the current literature the associ-
ation between COPD and depression has been
neither proved nor rejected. In order to detect a
clinically relevant association between COPD
and depression, studies are needed that have a
good methodological design, sufficient power,
and use of a depression measure specifically
validated for patients with COPD.
