Percutaneous evacuation (PEVAC) of multivesicular echinococcal cysts with or without cystobiliary fistulas which contain non-drainable material: first results of a modified PAIR method

H G Schipper, J S Laméris, O M van Delden, E A Rauws, P A Kager

Background: Surgery is the treatment of choice in echinococcal cysts with cystobiliary fistulas. PAIR (puncture, aspiration, injection, and reaspiration of scolecidals) is contraindicated in these cases.

Aim: To evaluate a modified PAIR method for percutaneous treatment of multivesicular echinococcal cysts with or without cystobiliary fistulas which contain non-drainable material.

Patients: Twelve patients were treated: 10 patients with multivesicular cysts which contained non-drainable material and were complicated by spontaneous intrabiliary rupture, secondary cystobiliary fistulas, cyst infection, or obstructed portal or hepatic veins; and two patients with large univesicular cysts and a ruptured laminated membrane, one obstructing the portal and hepatic veins and one a suspected cystobiliary fistula.

Methods: The methods used, termed PEVAC (percutaneous evacuation of cyst content), involved the following steps: ultrasound guided cyst puncture and aspiration of cyst fluid to release intracystic pressure and thereby to avoid leakage; insertion of a large bore catheter; aspiration and evacuation of daughter cysts and endocyst by injection and reaspiration of isotonic saline; cystography; injection of scolecidals only if no cystobiliary fistula was present; external drainage of cystobiliary fistulas combined with endoprosthesis or splinenterotomy; catheter removal after complete cyst collapse and closure of the cystobiliary fistula.

Results: In all 12 patients initial cyst size was 13.1 (6–20) cm (mean (range)). At follow up 17.9 (4–30) months after PEVAC, seven cysts had disappeared and five cysts had decreased to 2.4 (1–4) cm (p=0.002). In eight patients with multivesicular cysts, a cystobiliary fistula, and infection, cyst size was 12.5 (6–20) cm, catheter time 72.3 (28–128) days, and hospital stay 38.1 (20–55) days. At 17.3 (4–28) months of follow up, six cysts had disappeared and in two cysts residual size was 1 and 2.9 cm, respectively (p=0.012). In four patients without a cystobiliary fistula, cyst size was 14.4 (12.7–16) cm, catheter time 8.8 (3–13) days, and hospital stay 11.5 (8–14) days. At 19.3 (9–30) months of follow up, one cyst had disappeared and three cysts were 85 (69–94)% smaller (2.2 (1–4) cm) (p=0.068).

Conclusion: PEVAC is a safe and effective method for percutaneous treatment of multivesicular echinococcal cysts with or without cystobiliary fistulas which contain non-drainable material.
Inclusion criteria
Patients with multivesicular echinococcal cysts (Gharbi type 3) with or without a cystobiliary fistula and containing non-drainable debris were included (fig 1). Patients with univesicular cysts (Gharbi types 1 and 2) were included only if there was a cystobiliary communication or compression of the hepatic or portal veins or bile ducts. Exclusion criteria were: age <18 years or >75 years; no informed consent; serious coagulation abnormalities; known allergy to local anaesthetics or albendazole; pregnancy or women who refused contraception for the time of albendazole treatment; and cysts or albendazole; pregnancy or women who refused contraception for the time of albendazole treatment; and cysts or at least 50% reduction in cyst size at follow up imaging, and disappearance of complications such as pain, cystobiliary fistulas, vascular or biliary compression, and infection. Direct treatment results were evaluated at the end of the procedure: early results at six months and late results two years after PEVAC. The secondary end points of the study were recurrence of cyst cavity to >50% of its initial size, vascular or biliary compression, fistulas, pain and infection within two years after PEVAC, and death, withdrawal from the study, or loss to follow up. Three examples of cyst appearance before and after PEVAC are shown in figs 3–5.

PEVAC treatment was approved by the Institutional Review Board of the Academic Medical Centre, Amsterdam. Informed consent was obtained from all patients.

Statistics
The Mann-Whitney rank sum test was used to compare results between patient groups and the Wilcoxon signed ranks test for paired observations within patient groups (SPSS for Windows).

PATIENTS AND RESULTS
Patients
Twelve patients with hepatic echinococcosis, mean age 38 years (range 22–61), immigrants from Morocco (five), Turkey (three), Pakistan (one), Syria (one), Afghanistan (one), and Greece (one) were treated for recurrent and severe upper abdominal pain. Ten patients had multivesicular so-called “mother and daughter” cysts (Gharbi type 3) containing non-drainable material. Two patients had univesicular cysts...
A primary cyst infection was diagnosed in two patients and a secondary cyst infection in seven patients. All patients were successfully treated with antibiotics. In one patient with a primary infection, S milleri and anaerobes were cultured from the cyst cavity. In the other patient, culture was negative due to antibiotic treatment. S morbillorum, S epidermidis, and C freundii were cultured from the cyst cavity in two patients who were readmitted with cyst infection one and five months, respectively, after a PAIR procedure. Remarkably, in both patients bacterial culture of cyst fluid at the end of PAIR was negative.

Contrast injection at endoscopic retrograde cholangiopancreatography (ERCP) caused cholangitis and secondary cyst infection in five patients; three also developed a mild transient pancreatitis. S milleri, C freundii, C albicans, S sanguis, K pneumoniae, H influenzae, anaerobes, and enterococci were cultured from their blood, cyst cavity, or bile.

**Cyst viability**

In the initially sampled cyst fluid of nine patients, viable protoscolices were diagnosed in addition to fragments of the laminated membrane or hooklets. Remarkably, in both patients with multivesicular cysts which became infected following a PAIR procedure, protoscolices were still viable. In two patients with spontaneously infected cysts, viability of daughter cysts could not be assessed because cyst content was too purulent. In one patient with a multivesicular cyst, no protoscolices or hooklets were diagnosed.

**Catheter time**

In patients with a cystobiliary fistula, catheters were removed 72.3 (28–128) days after PEVAC, 53.6 (7–120) days after endoscopic treatment of the cystobiliary fistulas (mean (range) (table 1). Hospital stay was 38.1 (20–55) days. In patients without a cystobiliary fistula, catheters were removed after 8.8 (3–13) days and hospital stay was 11.5 (8–14) days. Catheter time and hospital stay were significantly longer in patients with a cystobiliary fistula (p=0.007).

**Cyst size**

Before treatment, cyst size was 12.5 (6–20) cm in patients with and 14.4 (12.7–16) cm in patients without a cystobiliary fistula (p=0.570). At the end of the procedure, when the catheters were removed, all complaints and complications had disappeared. Cavities had collapsed in all but one patient in whom the daughter cysts were partially evacuated. At follow up, 17.3
(4–28) months after treatment, cyst cavities had disappeared in six of eight patients with a cystobiliary fistula and were reduced to 1 and 2.9 cm, respectively, in the other two (p=0.012). In four patients without a fistula, cyst cavity had disappeared in one and cyst size reduced to 2.2 (1–4) cm in the other three, 19.3 (9–30) months after treatment. This 89 (69–100)% reduction in cyst size was not significant for this small number of patients (p=0.068). When all 12 patients were considered as a group, cyst size was significantly smaller 17.9 (4–30) months after treatment than before: 1.6 (0–7) cm versus 13.1 (6–20) cm (p=0.002). In none of the patients had complaints or complications recurred. No patient died, withdrew from the study, or was lost to follow up.

**Serology**

In comparison with cyst size, the response of total IgG echinococcal antibody titres was slow and started to occur...
were the most frequent complications. Death rate was 1.2–4% (5.4%). In the postoperative period, wound infections (6–12
days) became bile stained in the course of the procedure. In two spontaneously infected cysts, viability and possible infection of daughter cysts could not be diagnosed accurately. PEVAC was performed to support antibiotic treatment.

Most infections were secondary to a prior intervention. Two patients were readmitted with a cyst infection at one and five months, respectively, after a PAIR procedure. Despite the infection both cysts were still viable. Contrast injection at ERCP also appeared to be a risk for cyst infection. All five patients who underwent ERCP developed cholangitis and cyst infection. In two spontaneously infected cysts, viability and possible infection of daughter cysts could not be diagnosed accurately. PEVAC was performed to support antibiotic treatment.

DISCUSSION
Surgery is the treatment of choice for patients with complicated echinococcal cysts in the liver. Multivesicular cysts, ruptured into the biliary system, are considered to be contraindicated for percutaneous treatment with scolicidal agents. We went beyond the limits of PAIR and treated these complicated cysts percutaneously but avoided the use of scolicidal agents. Elimination of the mass effect by evacuation of cyst content was a prerequisite for success because bile ducts or portal or hepatic veins were compressed and cyst cavities infected. Therefore, we modified the original PAIR method to obtain appropriate access to the cyst cavity and to facilitate evacuation of daughter cysts, laminated membrane, and non-drainable content. By doing so, PEVAC mimics what is achieved at surgical endocyst removal. Unlike surgery, it takes at least two sessions to complete the procedure.

PEVAC is primarily indicated in patients with multivesicular hepatic echinococcal cysts containing non-drainable content, especially in cases of spontaneous intrabiliary rupture or secondary cystobiliary fistulas, vascular or biliary obstruction, or centrally located lesions. In univesicular cysts, PEVAC is only indicated in cases of cystobiliary fistula, or vascular or biliary obstruction. In these latter cases, we consider PEVAC as a safer option than PAIR because possible damage to bile ducts or blood vessels by scolicidal agents entering the pericyst space is avoided.

Due to the negative selection of patients, pretreatment and post-treatment morbidity was high but comparable with that of surgery. In surgically treated patients with intrabiliary rupture, pretreatment morbidity is characterised by jaundice (56–100%), fever (56–70%), chills (37–56%), and cyst infection (5.4%). In the postoperative period, wound infections (6–15%), pneumonia (3.7–7.5%), liver abscess (2.5%), and allergy were the most frequent complications. Death rate was 1.2–4% and mean hospital stay 19.8–34.6 days. Not surprisingly, the main complications we noted were cyst infections and cystobiliary fistulas. These complications occurred only in patients with multivesicular cysts and not in those with large univesicular cysts.

after about one year. At serological follow up, a sixfold decrease in antibody titres was observed in three patients, a fourfold decrease in two, and no change or a twofold decrease in four patients. A sixfold increase was observed in two patients, one of whom had a marked allergic reaction. Data for one patient are not yet available.
PEVAC of multivesicular echinococcal cysts

the cyst cavity would be closely related. Therefore, catheter
time and hospital stay were long. In the case of a cystobiliary
fistula, catheter time was 72.3 (28–128) days and hospital stay
38.1 (20–58) days; without a fistula, these times were 8.8
(3–13) days and 11.5 (8–14) days, respectively (p=0.007 and
0.007, respectively). This is comparable with a mean hospital
stay reported in surgically treated patients with cystobiliary
fistulas of 19.8–34.6 days. Hospital stay in our patients with
cystobiliary fistulas might have been shorter if we had
accepted some residual cyst size by removing the catheter ear-
cly. Another option is to discharge the patient and monitor
recurrence rate following PEV AC.

In summary, PEV AC is a safe and effective method for per-
cutaneous treatment of multivesicular echinococcal cysts with
or without cystobiliary fistulas which contain non-drainable
content, especially in cases of vascular or biliary obstruction.
In univesicular cysts, PEVAC is only indicated in selected cases
with a cystobiliary communication, or vascular or biliary
obstruction. Following PEVAC, cysts disappeared completely
or became >60% smaller. Compression of bile ducts and por-
tal or hepatic veins resolved. Cyst infections and cystobiliary
fistulas were the main complications. In patients with a cysto-
biliary fistula, pretreatment and post-treatment morbidity
was high and hospital stay was long but comparable with that
of surgery. PEVAC may be improved to reduce morbidity and
hospital stay. PEVAC will not replace surgery but may simply
create access to a less invasive treatment for more patients.
Whether PEVAC reduces the relapse rate will need to be dem-
onstrated in future studies. The observation period of our
study was too short to draw any conclusions regarding the
recurrence rate following PEVAC.

ACKNOWLEDGEMENT

We thank Professor C Filice (University of Pavia, Italy) for his support;
Dr T van Gool (Laboratory of Parasitology, AMC) for parasitological
examination of the cyst fluid; and Dr AM Polderman (Laboratory of
Parasitology, Leiden University Medical Centre) for the serological
tests.
