(Received 13 March 2002; published 30 August 2002)

We propose and analyze two series of clustered quantum Hall states for rotating systems of spin-1 bosons. The first series [labeled SU(4)_k], includes the exact ground states of a model Hamiltonian at large angular momentum L, and also for N = 3k particles at L = N. The latter is a spin-singlet boson-triplet condensate. The second series, labeled SO(5)_k, includes exact ground states at large L for different parameter values.

DOI: 10.1103/PhysRevLett.89.120401 PACS numbers: 05.30.Jp, 73.43.Cd

In the phenomenon of Bose-Einstein condensation (BEC) of cold atoms, the possibility of using bosons with internal degrees of freedom (spin 1 in particular) and of rotating the condensate has led to fascinating new possibilities for the states of matter that can be formed and observed. A multicomponent BEC can be realized by trapping higher spin atoms such as ^87Rb [1] and ^23Na [2] in optical traps, which do not affect the spin degeneracy, and spin-1 or “vector” BEC’s have been realized and studied [2,3]. In a model description, the two-body interactions of the spin-1 atoms are written as = \[2,3\]. In a model description, the two-body interactions of spin-1 bosons are written as \([2,3]\). In a model description, the two-body interactions of spin-1 bosons are written as \([2,3]\).

We consider the interaction Hamiltonian for bosons \(i, j = 1, \ldots, N\), restricted to the LLL,

\[ H_{\text{int}} = \sum_{i<j} \delta(r_i - r_j)[c_0 + c_2 S_i \cdot S_j] \]  

The ground state (GS) for the system rotating at frequency \(\omega\) is found by minimizing \(H_{\text{tot}} = H_{\text{int}} + (\omega_0 - \omega)L\) [8], where \(L = \sum_m m_i\) is the total angular momentum. For \(N\) particles in the LLL with zero center-of-mass angular momentum, the average “filling factor” of the occupied states can be defined as \(\nu = N/(N_V + 1)\), where \(N_V = 2L/N\) is the number of vortices there would be if there were a Bose condensate (we assume here a uniform average occupation of states up to \(m = N_V\)). The use of only the LLL states is physically reasonable when \(\omega_0 - \omega \ll \omega_0/N_V\) (so that particles in the LLL with \(m = N_V\) cannot lower their energy by moving to a non-LLL state with \(m = 0\)) and \(\nu c_s \ll \omega_0, \ S = 0, 2\) (so that perturbative corrections from mixing non-LLL states into the GS are negligible).

For the scalar case (in the LLL, without \(c_2\)), a study [9] using periodic boundary conditions found that the vortex lattice melts at a critical \(\nu = \nu_c \sim 10\), that incompressible fluid states occur at \(\nu = 1, 1/2, 1/3, \ldots < \nu_c\), and that the corresponding GS wave functions have large overlaps with the Read-Rezayi (RR) [10] series of fractional qH states.

Here, for the case of vector bosons, we first propose two series of spin-singlet generalizations of the RR states [labeled SU(4)_k and SO(5)_k, respectively, and \(k = 1, 2, \ldots\)] and explain their structure. In a thermodynamic limit \(N \rightarrow \infty\) with \(\nu\) fixed, they each represent incompressible liquid phases of the system, with \(\nu = 3k/4\) for the SU(4)_k states and \(\nu = k\) for the SO(5)_k series. Then we present results for the GS’s of \(H_{\text{int}}\) as a function of \(L, c_0, c_2\), and \(\nu\). We identify a region in the \(\nu_0 - c_2\) plane where the

length \((\hbar/M_b \omega_0)^{1/2}\) of the trap, and \(\hbar\), have been set to 1; they correspond to the lowest Landau level (LLL) [8].

We consider the interaction Hamiltonian for bosons \(i, j = 1, \ldots, N\), restricted to the LLL,

\[ H_{\text{int}} = \sum_{i<j} \delta(r_i - r_j)[c_0 + c_2 S_i \cdot S_j] \]  

The ground state (GS) for the system rotating at frequency \(\omega\) is found by minimizing \(H_{\text{tot}} = H_{\text{int}} + (\omega_0 - \omega)L\) [8], where \(L = \sum_m m_i\) is the total angular momentum. For \(N\) particles in the LLL with zero center-of-mass angular momentum, the average “filling factor” of the occupied states can be defined as \(\nu = N/(N_V + 1)\), where \(N_V = 2L/N\) is the number of vortices there would be if there were a Bose condensate (we assume here a uniform average occupation of states up to \(m = N_V\)). The use of only the LLL states is physically reasonable when \(\omega_0 - \omega \ll \omega_0/N_V\) (so that particles in the LLL with \(m = N_V\) cannot lower their energy by moving to a non-LLL state with \(m = 0\)) and \(\nu c_s \ll \omega_0, \ S = 0, 2\) (so that perturbative corrections from mixing non-LLL states into the GS are negligible).

For the scalar case (in the LLL, without \(c_2\)), a study [9] using periodic boundary conditions found that the vortex lattice melts at a critical \(\nu = \nu_c \sim 10\), that incompressible fluid states occur at \(\nu = 1, 1/2, 1/3, \ldots < \nu_c\), and that the corresponding GS wave functions have large overlaps with the Read-Rezayi (RR) [10] series of fractional qH states.

Here, for the case of vector bosons, we first propose two series of spin-singlet generalizations of the RR states [labeled SU(4)_k and SO(5)_k, respectively, and \(k = 1, 2, \ldots\)] and explain their structure. In a thermodynamic limit \(N \rightarrow \infty\) with \(\nu\) fixed, they each represent incompressible liquid phases of the system, with \(\nu = 3k/4\) for the SU(4)_k states and \(\nu = k\) for the SO(5)_k series. Then we present results for the GS’s of \(H_{\text{int}}\) as a function of \(L, c_0, c_2\), and \(\nu\). We identify a region in the \(\nu_0 - c_2\) plane where the
proposed qH states with \( k = 1 \) give the exact GS’s at high values of \( L \). We demonstrate that the \( k = N/3 \) member of the SU(4)\(_{\text{q}} \) series is an exact eigenstate and, apparently, the GS of \( H_{\text{int}} \) with \( c_2 = 0, c_0 > 0 \), at angular momentum \( L = N \). In second quantization, this state, a spin-singlet boson-triplet condensate ( boson form the equation)

\[
|\text{BTC}\rangle = \left[ e^{\mu_1 \mu_2} b_{1 \mu_1} b_{1 \mu_2} b_{2 \mu_3} b_{2 \mu_4} \right]^{N/3}|0\rangle,
\]

where \( b_{1 \mu_1} \) is a creation operator for the single-particle state \( |\psi_{\mu_1}\rangle \) with spin \( \mu \), where \( \mu = x, y, z \). Finally, we show the GS’s of \( H_{\text{tot}} \) as a function of \( \omega \).

We now explain our analysis, starting with the construction of spin-singlet qH states for spin-1 bosons. This construction is a generalization of similar constructions for scalar and spin-1/2 particles (either of which could be electrons or bosons) [10–12]. These papers all employed a correspondence [13] between qH states and specific conformal field theories (CFT’s). This connection allows one to obtain trial qH wave functions as chiral correlators in CFT’s that are associated to a Lie algebra \( G \) and integers \( k \geq 1 \) and \( M \geq 0 \), where \( M \) is even (odd) for bosons (fermions). These states generalize the pairing familiar from the theory of superconductivity to the formation of “clusters.” The resulting qH wave functions have a property that guarantees that they are exact zero-energy eigenstates of \( H_{\text{int}} \) and specific SO(3) subgroups of SO(5). The general construction guarantees that, for \( N \) divisible by 3k, this state is a singlet under SU(3), and hence also under the SO(3) subgroup, the usual spin-rotation group. The wave function for \( N = 3k \) particles can be written in terms of its components for particular spin states \( \mu = x, y, z \) specified for each particle (similar to [15]), as

\[
\hat{\Psi}_{SU(4)}^{k} = S_{\text{groups}}[P_{\text{groups}} \hat{\Psi}_{2.2.2.1.1.1}],
\]

where

\[
\hat{\Psi}_{2.2.2.1.1.1} = \prod_{x=y,z} \prod_{i<j} (z_i^x \ldots z_j^x - z_j^x \ldots z_i^x) = \prod_{x=y,z} \prod_{i<j} (z_i^x - z_j^x). \tag{6}
\]

In words, the operations \( P_{\text{groups}} \) and \( S_{\text{groups}} \) in Eq. (5) tell each to divide the \( 3pk \) bosons into \( k \) groups of \( 3p \) bosons each ( \( p \) of each spin polarization), to write a factor \( \hat{\Psi}_{2.2.2.1.1.1} \) as in Eq. (6) for each group, and, finally, to symmetrize over all ways the particles can be divided over the \( k \) groups. For \( k = 1 \) there is a single group, and one finds a state of total degree \( L = 3p(2p - 1) \) that generalizes the Laughlin and Halperin states for scalar and spin-1/2 particles, respectively, and which is a zero-energy eigenstate of \( H_{\text{int}} \) for all \( c_0, c_2 \), and the unique GS when both \( g_0, g_2 \geq 0 \) since \( H_{\text{int}} \) is then positive. Putting instead \( k = N/3 \) gives \( k \) groups of three particles each, the resulting state being the \( L = N \) BTC, Eq. (2). The fundamental quasi-particles over the SU(4), qH liquids have fractional charge equal to \( -1/4 \), and spin 1, for all \( k \). We note, however, that such assignments, while meaningful for \( N \gg k \), may be meaningless when \( N \sim 3k \), where the quasiparticle size is comparable to the size of the fluid drop.

An important point is that for \( c_2 = 0 \), the Hamiltonian \( (1) \) has SU(3), not just SO(3), spin-rotation symmetry. Therefore, we expect the SU(4)\(_{\text{q}} \) state to be relevant near this line when \( c_0 > 0 \), for sufficiently large \( L \).

Our second series of qH states for spin-1 bosons is obtained from a CFT with \( G = SO(5) \) and generalizes the construction in Ref. [12]. The GS’s possess a symmetry under an SO(3) subgroup of SO(5). The general construction, which involves spin-singlet clusters of \( 2k \) particles, gives states of filling factor \( \nu = k/(kM + 1) \). Putting \( M = 0 \), we obtain qH states with \( \nu = k \). For \( k = 1 \), the wave function with values in the spin space of \( N \) spin-1 particles can be written as

\[
\hat{\Psi}_{k=1}^{SO(5)}(z_j) = \text{Pf} \left[ \frac{\sigma_i \sigma_j + \tau_i \tau_j}{(z_i - z_j)} \right] \hat{\Psi}_{1}^{k}(z_j). \tag{7}
\]

Here \( \hat{\Psi}_{1}^{k}(z_j) = \prod_{i<j} (z_i - z_j) \) is a spin-independent

\[
\nu(n, k, M) = \frac{nk}{nkM + n + 1}. \tag{4}
\]
Laughlin factor in all $N$ particle coordinates; the Pfaffian Pf is defined by $\text{Pf}(M_{ij}) = \mathcal{A}(M_{12}M_{34} \cdots M_{N-1,N})$, where $M_{ij}$ are the elements of an antisymmetric matrix and $\mathcal{A}$ denotes the operation of antisymmetrization; $\rho$, $\sigma$, $\tau$ are basis vectors in the spin space for particle $i$, which correspond to $x$, $y$, $z$, and the product is the tensor product. For $k = 1$, $N$ must be even, and the clustering (or pairing) of particles is seen explicitly. Clearly, there must be even (but otherwise arbitrary) numbers of particles in each of the three spin states $\rho$, $\sigma$, $\tau$. The $k = 1$ wave function for $N = 2q$ particles has total degree $L = 2q(q - 1)$. The function (7) can be viewed as spin-singlet $p$-wave pairing of composite fermions of spin 1 (for a review, see Ref. [16]). There are also excited states with unpaired charge-neutral spin-1 fermions. We note that, in the state $|00\rangle$, the preferred behavior is singlet formation via $\text{SU}(2)$ for $N$ even and $\text{SU}(3)$ for $N$ odd. For $c_2 > 0$ (antiferro regime). For $c_2 = 0$, there is a single $\text{SU}(3)$ multiplet of spin states, decomposing into unique $\text{SO}(3)$ multiplets of each spin $S = N, N - 2, \ldots$.

As $L$ increases, these two phases survive in part of the phase diagram, as compact drops of fluid, with the center of mass (CM) carrying all the angular momentum. Meanwhile, the positive $c_0$ axis gradually opens into a region that contains other phases. By the time $L$ is $\geq N$, the $c_0$-$c_2$ plane contains the three regions labeled Ia, Ib, and II in Fig. 1. The GS’s in regions Ia and Ib are similar to the GS in the “attractive” regime in the scalar case [8]. The orbital part of the GS wave function is of the form $\Psi(z_i) \propto z_i^L$, with $z_i = \sum z_i/N$ the CM coordinate. In region Ia ($c_0 < 0$, $c_2 > 0$), the spin state is the same spin singlet as for the $L = 0$ GS, and the GS energy becomes $[c_0N(N - 1)/2 - Nc_2](2\pi)^{-3/2}$ [17]. In region Ib ($c_2 < 0$, $c_0 < -c_2$), the spin state is ferro, $S = N$, giving energy $c_0 + c_2N(N - 1)(2\pi)^{-3/2}/2 < 0$ [8]. At $c_2 = 0$, $c_0 < 0$, the spin states again form the $\text{SU}(3)$ multiplet. In the “repulsive” region II, the GS is in general not a common eigenstate of the $c_0$ and $c_2$ parts of the interaction, and the GS energy depends nonlinearly on the ratio $c_2/c_0$. The $L = N$ GS’s all have $S = 0$ or $S = 1$ (depending on the value of $N$ modulo 6, and on the ratio $c_2/c_0$). For $L > N$, larger values of $S < N$ do occur near the boundary at $c_2 = -c_0 (g_2 = 0)$.

Turning to $L \gg N$ in region II, we have already pointed out that the $\text{SU}(4)_k$ state is the zero-energy GS for $N = 3p$ particles at $L = 3p(2p - 1)$ when $g_0$ and $g_2 > 0$, while the $\text{SO}(5)_k$ state is the zero-energy GS for $N = 2q$ particles at $L = 2q(q - 1)$ for $g_0 = 0$. (For $N = 3, 4$, these states occur at $L = N$). For even larger $L$, each of these model cases possesses many degenerate GS’s of zero energy. This implies that, within our model, the $\text{SU}(4)_k$ and $\text{SO}(5)_k$ GS’s are those found (for the parameters as stated) at the critical rotation frequency $\omega = \omega_0$, and so the lowest possible filling factor is $3/4$ in the region $g_0, g_2 > 0$, but is 1 when $g_0 = 0$.

At intermediate $L > N$ values in this region, we expect similar physics. Thus, for $c_2 = c_0/2 > 0$, (4) does not have exact eigenstates, but we expect that, similar to Ref. [9], for $\nu = k$ less than some critical value $\nu' > 1$, the bulk of the fluid will be in the $\text{SO}(5)_k$ state. For $c_2 = 0$, $c_0 > 0$, the preferred behavior is singlet formation via triples of bosons of spin zero; each such three bosons must be in an antisymmetric orbital state as well. For $L < 3p(2p - 1)$ ($N = 3p > 3$), we do not generally have exact eigenstates, but we expect the bulk of the fluid to be the $\text{SU}(4)_k$ states for $\nu = 3k/4$ less than another critical $\nu'' > 3/4$.

We also found that the exact GS for $N = 6, L = 6$ at $c_2 = 0$ is the $\text{SU}(4)_2$ or BCT state (2). Prompted by this, we have proved analytically that for $N = 3p$ particles the $\text{SU}(4)_p$ state is an exact eigenstate of $H_{\text{int}}$ with $c_2 = 0$, with eigenvalue

![Fig. 1. Overview of $c_0$-$c_2$ plane, with special regions and directions marked.](image)
probably not think of the limit form is independent of signature, that is, the density profile given in Fig. 2, whose

\[ L = \frac{11}{48} N(N - 3)(2\pi)^{-3/2}c_0. \quad (8) \]

We have numerically checked that for \( N = 3, 6, 9, 12 \) this state is the GS and believe this is true for all \( N = 3p \).

The BTC state in Eq. (2) has a clear experimental signature, that is, the density profile given in Fig. 2, whose form is independent of \( N \). We caution again that one should probably not think of the limit \( N = 3k \) as a qH state, since the drop is so small. We identified the state as an extreme member of the SU(4) \( k \) qH series, but it might be more useful to view it as a boson-triplet analog of the BCS paired electron states, or alternatively as an SU(3) analog of a Skyrmion spin texture (see Ref. [18]).

The response of the spin-1 boson system to a rotation frequency \( \omega \) is found by minimizing \( H_{\text{tot}} \). In Fig. 3 we display the result for \( N = 6 \) particles. The BTC is at \( L = 6 \), and the SU(4) \( 1 \) state is at \( L = 18 \). The degenerate spin multiplets listed at the steps at \( L < 6 \) each form a single SU(3) multiplet. The wave functions of these GS's at \( L = N \) are uniquely determined by their SU(3) and \( L \) quantum numbers.

The SO(5) \( 1 \) state found here will survive for some distance off \( g_0 = 0 \). For \( N \) large at fixed \( \nu \), there will be several phases within region II, and, in particular, a boundary between the SO(5) \( 1 \) and SU(4) \( 1 \) phases that approaches \( g_0 = 0 \) as \( \omega \rightarrow \omega_0 \).

Our constructions for \( c_2 = 0 \) directly generalize to an \( n \)-component rotating Bose gas with repulsive spin-independent \( \delta \)-function interactions, implying SU\((n)\) symmetry. In particular, we expect a “boson \( n \)-plet condensate” at \( L = (n - 1)N/2 \), and SU\((n + 1)k\) states at sufficiently small \( \nu = nk/(n + 1) \).

To conclude, we have found several interesting states of matter, not containing vortices, in rotating spin-1 bosons.

We thank E. Rezayi, M. Kasevich, S. M. Girvin, T.-L. Ho, and E. Mueller for helpful discussions. This research was supported by the Netherlands Organisation for Scientific Research, NWO, and the Foundation FOM of the Netherlands (J.W.R., F.J.M.v.L., and K.S.), and by the NSF under Grants No. DMR-98-18259 (N.R) and No. DMR-98-02813 (K.S.).

As this manuscript was being prepared, two e-prints appeared [19,20] that also address a rotating BEC. These papers point out the relevance of the SU\((n + 1)\) \( 1 \) states at large \( L \) but do not discuss the other qH states or the BTC state that we consider.
