Chapter 2

The finite sample accuracy of inference procedures for dynamic panel data models

2.1 Introduction

Least-squares estimation techniques for static panel data models give consistent estimators in a dynamic setting only when the number of time observations $T$ in the data set approaches infinity. Since in micro-economics the typical dimension of a panel data set is a short time span for a large cross-section various authors\(^1\) have paid attention to this problem and have proposed IV and GMM alternatives, which are consistent for fixed $T$ and an infinite number of cross-sectional observations $N$ (Anderson and Hsiao, 1982; Arellano and Bond, 1991; Ahn and Schmidt, 1995; Blundell and Bond, 1998). GMM estimators typically use more orthogonality conditions than their simple IV counterparts and they take the covariance structure of the disturbances into account. Therefore they are asymptotically more efficient. In an attempt to avoid the problem of weak instruments, Kiviet (1995) follows another route to achieve large $N$ consistent estimation and to enhance efficiency. An asymptotic approximation formula for the finite sample bias of the inconsistent LSDV estimator is exploited to remove inconsistency and to reduce mean squared error. In Kiviet (1999) this approximation formula has been slightly refined by taking a particular further higher-order term into account, but its actual performance has not been examined yet.

Although IV and especially GMM estimators have attractive asymptotic properties,

\(^1\)See Section 1.2.2 for more details.
Monte Carlo experiments (Arellano and Bond, 1991; Kiviet, 1995; Harris and Mátýás, 1996; Judson and Owen, 1999) have shown that for these techniques the quality of the asymptotic approximations in finite samples depends heavily on the actual parameter values of the model and on the dimensions of the available data set. In most of these simulation experiments short time series and reasonably large cross-section samples have been examined and attention has been focused on bias and mean squared error of coefficient estimators. Not much is known yet (for an exception, see Judson and Owen, 1999) about the performance of the various techniques when both dimensions are small, e.g. \( N = 10, T = 10 \) or \( N = 10, T = 20 \). Such dimensions can be relevant in both macro- and micro-economic applications, where the time span is one or two decades and the cross-section consists of a small number of countries or sectors. Although some attention has been paid to assessing the accuracy of variance estimators (Arellano and Bond, 1991), little is known about the actual reliability of asymptotic test procedures in panels of a limited sample size.

The purpose of this chapter is to produce further insights into the finite sample properties of various inference techniques for dynamic panel data models, especially when both dimensions of the data set are small. By simulation we examine for this situation the bias and mean squared error of various coefficient estimators, the bias in related estimators for the disturbance variance and the accuracy of estimators of the coefficient standard errors. Also we examine the actual size of simple asymptotic coefficient tests. More in particular, we will focus on various possible implementations of the bias corrected LSDV estimator (LSDVc) as proposed by Kiviet (1995, 1999). First, we will analyse the magnitude of the contributions of the separate terms in the bias approximation. Second, as the bias approximation depends on the unknown model parameters, we also investigate the sensitivity of the LSDVc estimator with respect to the choice of the preliminary consistent estimator. Third, we develop an appropriate estimator for the standard error of the LSDVc estimator, which proves to be not trivial for the small \( T \), large \( N \) case. We examine whether it is possible to exploit such an estimator in tests on coefficient values. Here, we also analyse the accuracy of estimators and tests in dynamic panel data models including non-stationary variables, since this situation is likely to arise in applied research.

In a rather extensive Monte Carlo study Kiviet (1995) examines the bias and mean squared error of the corrected LSDV estimator and compares these with IV and GMM alternatives for the small \( T \), relatively large \( N \) panel with stationary variables. One conclusion is that in samples of such a size there is no superior technique yet over a broad range of relevant parameter values of the model. More recent simulation results of Harris and Mátýás (1996) and Judson and Owen (1999) indicate, however, that especially in
samples with smaller values for $N$ the semi-consistent IV and GMM techniques often perform rather poorly as far as the bias and efficiency of coefficient estimators are concerned. Regarding variance estimators the simulation results of Arellano and Bond (1991) show that in the panel with small $T$ and large $N$ the asymptotic approximation of the standard errors of their two-step GMM estimator is biased downward, but that one-step estimators of the asymptotic standard errors are quite accurate. Here, less favourable results for the one-step GMM estimator are obtained when both $N$ and $T$ are small. Often the simulation results show a substantial downward bias for estimated asymptotic standard errors of coefficient estimators. We also find that for all procedures presently available the actual size of $t$-type tests may differ substantially from the nominal level.

The outline of this chapter is as follows. In Section 2.2 a detailed description of the model will be given, which is the starting point for the analysis in this chapter and Chapter 3. In Section 2.3 we will review the principles of higher-order asymptotic bias approximation and bias correction by evaluating the first few terms of an asymptotic expansion of the LSDV estimation error. An overview of estimators analysed in the simulations together with their asymptotic distributions will be given in Section 2.4. In this section also an expression for an estimator for the variance of corrected LSDV estimators, derived in Appendix 2.A, is given. In Section 2.5 the simulation design is described, with further details in Appendix 2.B, and the finite sample behaviour of the various estimators and tests are compared. Section 2.6 contains an application of the various procedures in a panel analysis of so-called dynamic externalities and local economic development in Morocco, and Section 2.7 concludes.

### 2.2 Model

We consider estimation methods for the standard linear first-order dynamic panel data model

$$y_{it} = \gamma y_{i,t-1} + \beta' x_{it} + u_{it}, \quad i = 1, \ldots, N; \quad t = 1, \ldots, T. \quad (2.1)$$

In this model the dependent variable $y_{it}$ is regressed on a vector of $K$ exogenous explanatory variables $x_{it}$ and the one-period lagged value of the dependent variable. All the explanatory variables in $x_{it}$ are time variant. The disturbance term $u_{it}$ is defined by

$$u_{it} = \eta_{it} + \varepsilon_{it}. \quad (2.2)$$
Chapter 2. Finite sample accuracy in dynamic panel models

It contains two error components, viz. an unobserved individual specific effect $\eta_i$ and a general disturbance term $\varepsilon_{it}$. We assume

$$
\begin{align*}
\eta_i &\sim \mathcal{N}[0, \sigma_{\eta_i}^2] \\
\varepsilon_{it} &\sim \mathcal{N}[0, \sigma_{\varepsilon_i}^2]
\end{align*}
$$

We also define $\varepsilon_{i0}$ because it enables to specify the random characteristics of the start-up values $y_{i0}$ and possible weak exogeneity of $x_{it}$, as we shall see. We also assume that the two error components are uncorrelated, i.e.

$$
E[\eta_i \varepsilon_{jt}] = 0, \quad \forall i, j, t,
$$

and that

$$
E[y_{i0} \varepsilon_{jt}] = 0, \quad \forall i, j, t > 0,
$$

i.e. all initial observations $y_{i0}$ are uncorrelated with the disturbances $\varepsilon_{it}$, $t > 0$. Furthermore, we assume that the model in (2.1) is dynamically stable, i.e. $|\gamma| < 1$.

Following Kiviet (1999) we decompose $y$ and $x$ into a relevant random component, denoted by a tilde, and irrelevant random plus deterministic components, denoted by a bar. The relevant random components are in some way related to either the individual effect $\eta_i$ or the disturbance term $\varepsilon_{it}$, while the irrelevant components are not. Regarding $x$ we start by using the same setup as in Kiviet (1999), viz.

$$
\begin{align*}
\begin{align*}
x_{it} &= \tilde{x}_{it} + \hat{x}_{it} \\
\tilde{x}_{it} &= \phi \varepsilon_{i,t-1} + \pi \eta_i
\end{align*}
\end{align*}
$$

where $\pi$ and $\phi$ are $K \times 1$ vectors of unknown constants. Furthermore, $\tilde{x}_{it}$ is uncorrelated with the random error components, i.e.

$$
\begin{align*}
E[\tilde{x}_{it} \eta_j] &= 0 \\
E[\tilde{x}_{it} \varepsilon_{js}] &= 0
\end{align*}
\quad \forall i, j, t, s.
$$

In the relevant random component $\tilde{x}_{it}$ of (2.6) the elements in $\pi$ express any correlation between observed and unobserved heterogeneity and the parameter vector $\phi$ determines the feedback of the lagged disturbance into the explanatory variables $x_{it}$.

For the relevant and irrelevant random components of $y$ we have

$$
\begin{align*}
\begin{align*}
\tilde{y}_{it} &= \gamma \tilde{y}_{i,t-1} + \beta \tilde{x}_{it} + \eta_i + \varepsilon_{it} \\
\hat{y}_{it} &= \gamma \hat{y}_{i,t-1} + \beta \hat{x}_{it}
\end{align*}
\end{align*}
$$

i.e. $i = 1, ..., N$; $t = 1, ..., T.$
2.2. Model

To be able to decompose the relevant random components of \( \tilde{y}_{it} \) into the two error components we assume that

\[
E[\tilde{y}_{it} | \eta_i] = \alpha \eta_i, \quad i = 1, ..., N; \quad t = 0, ..., T,
\]

where \( \alpha = \frac{1+\beta^\pi}{1-\gamma} \). Hence, we assume that the full long-run impact of the individual effect \( \eta_i \) on \( y_{it} \) is already present in \( y_{i0} \). Defining

\[
\tilde{v}_{it} = \tilde{y}_{it} - \alpha \eta_i, \quad i = 1, ..., N; \quad t = 0, ..., T,
\]

and using (2.8) and (2.6) we find

\[
\tilde{v}_{it} = \gamma \tilde{v}_{i,t-1} + \varepsilon_{it} + \beta^\phi \varepsilon_{i,t-1},
\]

and for the initial values we assume

\[
\tilde{v}_{i,0} = \omega \varepsilon_{i,0}, \quad \forall i,
\]

where \( \omega \) is either 0 or 1. In case of weak exogeneity, \( x_{it} \) depends on \( \varepsilon_{i,0} \). Conditioning on \( \varepsilon_{i,0} \) seems inappropriate in this case because \( \varepsilon_{i,0} \) is a relevant random component then. Hence, when \( \phi \neq 0 \) we therefore take \( \omega = 1 \), because it seems selfevident that like \( x_{it} \) also \( y_{i0} \) should depend on \( \varepsilon_{i0} \) and \( \omega = 1 \) provides the usual weight. However, we choose to take \( \omega = 0 \) in case of \( \phi = 0 \), because when \( x_{it} \) is strongly exogenous the normal procedure is to condition on \( x_{it} \) and on \( y_{i0} \), and then the latter should not contain any relevant random components. Note that the assumptions made so far imply stationary processes for both \( y_{it} \) and \( x_{it} \).

Stacking the observations over time we get \( (i = 1, ..., N) \)

\[
y_i = \gamma y_{i,-1} + X_i \beta + \eta_i \iota_T + \varepsilon_i,
\]

\[
X_i = \tilde{X}_i + \eta_i \iota_T \pi' + \varepsilon_{i,-1} \phi',
\]

where \( y_{i,-1} = (y_{i,0}, ..., y_{i,T-1})' \), \( X_i = (x_{i,1}, ..., x_{i,T})' \), \( \varepsilon_{i,-1} = (\varepsilon_{i,0}, ..., \varepsilon_{i,T-1})' \) and \( \iota_T = (1, ..., 1)' \) a \( T \times 1 \) vector of ones. From the above it follows that

\[
\tilde{y}_i = \gamma \tilde{y}_{i,-1} + \beta^\phi \varepsilon_{i,-1} + (\beta^\pi + 1) \eta_i \iota_T + \varepsilon_i
\]

\[
= \gamma (L_T \tilde{y}_i + \tilde{y}_{i,0} \varepsilon_{T,1}) + \beta^\phi (L_T \varepsilon_i + \varepsilon_{i,0} \varepsilon_{T,1}) + (\beta^\pi + 1) \eta_i \iota_T + \varepsilon_i,
\]

where we introduced a \( T \times T \) matrix \( L_T \) with ones on the first subdiagonal and zeros elsewhere and where \( e_{q,p} \) is the \( q \times 1 \) unit vector with its \( p^{th} \) element equal to one. Defining

\[
\Gamma_T = (I_T - \gamma L_T)^{-1},
\]
and using $y_{i0} = \omega \varepsilon_{i,0} + \alpha \eta_i$, the relevant random part of $y_i$ can now be written in terms of the error components as

$$
\tilde{y}_i = \alpha \eta_i \Gamma_T + \Gamma_T (I_T + \beta' \phi L_T) \varepsilon_i + (\omega \gamma + \beta' \phi) \Gamma_T e_{T,1} \varepsilon_{i0}.
$$

(2.16)

Stacking the observations over time and across individuals one gets

$$
y = W \delta + u,
$$

(2.17)

where $\delta = (\gamma, \beta')'$, $y$ and $u$ are $NT \times 1$, $W = [y_{-1}; X]$ is $NT \times (K + 1)$, $u = S \eta + \varepsilon$ with $S = I_N \otimes I_T$ an $NT \times N$ matrix and $\eta = (\eta_1, ..., \eta_N)'$. Using (2.6) and (2.16) the relevant random parts of $y$ and $X$ can be written as

$$
\tilde{y} = \alpha S \eta + \Gamma (I_{NT} + \beta' L) \varepsilon + (\omega \gamma + \beta' \phi) \Gamma (I_N \otimes e_{T,1}) \varepsilon_0,
$$

(2.18)

and

$$
\tilde{X} = S \eta \pi' + (L \varepsilon + (I_N \otimes e_{T,1}) \varepsilon_0) \phi',
$$

(2.19)

where $\Gamma = I_N \otimes \Gamma_T$, $L = I_N \otimes L_T$ and $\varepsilon_0 = (\varepsilon_{10}, ..., \varepsilon_{N0})'$.

### 2.3 Bias approximation and correction for the LSDV estimator

In this section we review some aspects of bias approximation and bias correction by means of a specific example. We consider model (2.17) with strictly exogenous regressors $X$ and fixed initial observations $y_{i, 0}$, hence we choose $\phi = 0$ and $\omega = 0$. Using earlier results (Kiviet, 1995, 1999) we derive a bias expression for the LSDV estimator (1.9) of $\delta$ in (2.17), i.e.

$$
\hat{\delta}_{LSDV} = (W' AW)^{-1} W' Ay,
$$

(2.20)

where $A$ is the within transformation which wipes out the individual effects. In the next subsection we will introduce $O$ and $O_p$ notation for samples with two dimensions. Next, we will expand the LSDV estimation error and evaluate the expected value of the first few terms. Finally, we will propose several possible bias corrected estimators based on the bias approximations derived.
2.3. Bias approximation and correction for the LSDV estimator

2.3.1 Order of magnitude

In order to employ the usual $O$ and $O_p$ notation unambiguously for panel data, where the sample has two dimensions, we put this notation into a wider context defined as follows: Let $\phi$ and $\psi$ be real numbers. If the elements $g_{k,l}$ (where $k = 1, ..., K$ and $l = 1, ..., L$) of a non-stochastic $K \times L$ matrix $G$ constitute sequences $\{g_{k,l}(i,t)\}$ for $i = 1, ..., N$ and $t = 1, ..., T$, where we allow either $N \rightarrow \infty$ or $T \rightarrow \infty$ or both, then $G = O(N^\phi)$ indicates that there exists a finite constant $\tilde{g}_\phi > 0$ such that $|N^{-\phi}g_{k,l}(i,t)| < \tilde{g}_\phi$, $\forall k, l, i, t$. Similarly $G = O(T^\psi)$ indicates that there exists a finite constant $\tilde{g}_\psi > 0$ such that $|T^{-\psi}g_{k,l}(i,t)| < \tilde{g}_\psi$, $\forall k, l, i, t$. In addition, $G = O(N^\phi T^\psi)$ indicates that there exists a finite constant $\tilde{g}_{\phi, \psi} > 0$ such that $|N^{-\phi}T^{-\psi}g_{k,l}(i,t)| < \tilde{g}_{\phi, \psi}$, $\forall k, l, i, t$.

When $G = O(N^\phi)$ we say that the elements of $G$ are at most of order $N^\phi$, which is equivalent with $O(N^\phi T^0)$, i.e. the quantities $N^{-\phi}g_{k,l}$ are finite, even when $T$ approaches its limit. More generally, $G = O(N^\phi T^\psi)$ indicates that all the elements of $G$ are at most of order $N^\phi T^\psi$.

In addition we define that when the matrix $G$ contains random elements, $G = O_p(N^\phi)$ indicates that for all $\varepsilon > 0$ there exists a finite constant $\tilde{g}_\varepsilon > 0$ and a positive integer $N_\varepsilon$ such that $\text{Prob}(N^{-\phi}g_{k,l}(i,t) > \tilde{g}_\varepsilon) < \varepsilon$, $\forall k, l, t$ and $i > N_\varepsilon$. Similarly, $G = O_p(T^\psi)$ indicates that for all $\varepsilon > 0$ there exists a finite constant $\tilde{g}_\varepsilon > 0$ and a positive integer $T_\varepsilon$ such that $\text{Prob}(T^{-\psi}g_{k,l}(i,t) > \tilde{g}_\varepsilon) < \varepsilon$, $\forall k, l, i$ and $t > T_\varepsilon$. And finally, $G = O_p(N^\phi T^\psi)$ indicates that for all $\varepsilon > 0$ there exists a finite constant $\tilde{g}_\varepsilon > 0$ and positive integers $N_\varepsilon$ and $T_\varepsilon$ such that $\text{Prob}(N^{-\phi}T^{-\psi}g_{k,l}(i,t) > \tilde{g}_\varepsilon) < \varepsilon$, $\forall k, l$ and $i > N_\varepsilon, t > T_\varepsilon$.

When $G = O_p(N^\phi)$ we say that the elements of $G$ are bounded in probability by order $N^\phi$, which is equivalent with $O_p(N^\phi T^0)$, and implying that $N^{-\phi}g_{k,l}$ is of order unity in probability, irrespective of the value of $T$. More generally, $G = O_p(N^\phi T^\psi)$ indicates that the elements of $G$ converge at least at rate $N^\phi T^\psi$.

Having defined the $O$ and $O_p$ notation we now also state a result regarding asymptotic expansions of stochastic matrices. Suppose that the matrix $G$ is square ($K = L$) and that $I_K + G$ is invertible whereas $G = O_p(n^{-\frac{1}{2}})$ with $n = NT$, then we have

$$(I_K + G)^{-1} = I_K - G + G^2 - ... = I_K - G + G^2 + O_p(n^{-\frac{3}{2}}),$$

(2.21)

which is a stochastic matrix generalisation of a Taylor expansion.
2.3.2 Bias approximation

The above terminology on rates of convergence and orders of magnitude of double-indexed deterministic and stochastic sequences of vectors or matrices will be employed now for estimators in panel data models, in particular for the LSDV estimator. Kiviet (1995) derives an approximation formula for the bias of the LSDV estimator (2.20) in the normal stationary dynamic panel data model such that the approximation error has a magnitude which is of order \( O(N^{-1}) \) and of order \( O(T^{-2}) \) at the same time. In Kiviet (1999) this analysis is extended and an approximation to the bias is produced which is not only accurate to order \( O(T^{-1}) \) again, but now it is accurate to order \( O(N^{-1}) \) as well. These expressions for the approximate bias are rather complicated, but here we shall show that they can be simplified considerably. In the simulations to follow we shall examine closely the actual magnitude of the various contributions to the finite sample bias of terms of decreasing orders with respect of both \( T \) and \( N \). This will help to select an implementation of a bias corrected LSDV estimator with attractive properties in finite samples.

The estimation error of the LSDV estimator (2.20) can be expressed as

\[
\hat{\delta}_{LSDV} - \delta = (W'AW)^{-1} W'\varepsilon,
\]

which is depending on \( \varepsilon \) in a complicated, non-linear way. Note that the estimation error in (2.22) is not depending on the vector of individual effects \( \eta \) as they are wiped out by the within transformation \( A \).

The right-hand expression of (2.22) has two factors. First, we will consider the order of both \( W'AW \) and \( W'A\varepsilon \) and their expectations for which we need the stochastic structure of the model as outlined in Section 2.2. As we assume stationarity it is clear that \( W'AW = O_p(n) \). In this chapter we restrict ourselves to strictly exogenous regressors, i.e. \( \phi = 0 \), and we condition on \( y_{t,0} \), i.e. \( \omega = 0 \). In this case we have (Kiviet, 1995, 1999)

\[
AW = A\bar{W} + AW = A\bar{W} + \Pi \varepsilon e_1',
\]

where \( \Pi = I_N \otimes \Pi_T \) with \( \Pi_T = A_T L_T \Gamma_T \). We use in this chapter the shorthand notation \( e_1 \) for \( \varepsilon_{K+1,1} \), which has been defined in Section 2.2 as the \( K + 1 \) unit vector with its first element equal to one. This yields

\[
E[W'AW] = Q^{-1} = W'\bar{W} + \sigma_v^2 tr(\Pi' \Pi) e_1 e_1' = O(n),
\]

and it can be shown (Kiviet, 1995) that \( W'AW - Q^{-1} = O_p(n^{1/2}) \). Also

\[
E[W'\varepsilon] = E[\varepsilon' \Pi \varepsilon] e_1 = \sigma_v^2 tr(\Pi) e_1 = \sigma_v^2 N tr(\Pi_T) e_1 = O(N),
\]

(2.25)
2.3. Bias approximation and correction for the LSDV estimator

because

\[ \text{tr}(\Pi_T) = - \left( \frac{1}{1 - \gamma} - \frac{1 - \gamma^T}{T (1 - \gamma)^2} \right) = O(1). \]  

(2.26)

From (2.23) we also find

\[
\text{Var}[W'A \varepsilon] = \text{Var}[\hat{W}'A \varepsilon + \varepsilon' \Pi \varepsilon e_1] = \sigma^2 W'A \hat{W} + \sigma^2 \varepsilon N [\text{tr}(\Pi_T \Pi_T) + \text{tr}(\Pi_T \Pi_T)] e_1 e_1' = O(n),
\]

(2.27)

hence we conclude that \( W'A \varepsilon - E [W'A \varepsilon] = O_p(n^{\frac{1}{2}}) \).

In order to evaluate the expected estimation error, we have to expand (2.22). We may express the first factor in (2.22) as follows

\[
W'AW = Q^{-1} + W'AW - Q^{-1} = \left[ I + (W'AW - Q^{-1})Q \right] Q^{-1}.
\]

(2.28)

Noting that \( W'AW = O_p(n) \) and \( W'AW - Q^{-1} = O_p(n^{\frac{1}{2}}) \) and using (2.21), we can write

\[
(W'AW)^{-1} = Q \left[ I + (W'AW - Q^{-1})Q \right]^{-1} = Q[I - (W'AW - Q^{-1})Q]
\]

\[
+ Q(W'AW - Q^{-1})Q(W'AW - Q^{-1})Q - ...
\]

\[
= Q - Q(W'AW - Q^{-1})Q + Q(W'AW - Q^{-1})Q(W'AW - Q^{-1})Q + O_p(n^{-\frac{1}{2}}).
\]

(2.29)

Regarding the second factor in (2.22) we write

\[
W'A \varepsilon = E[W'A \varepsilon] + W'A \varepsilon - E[W'A \varepsilon]. \quad (2.30)
\]

It has been shown in Kiviet (1995, 1999) that combining (2.29) and (2.30) and taking expectations gives

\[
E[\delta_{LSDV} - \delta] = E[(W'AW)^{-1} W'A \varepsilon] = c_1(T^{-1}) + c_2(N^{-1}T^{-1}) + c_3(N^{-1}T^{-2}) + O(N^{-2}T^{-2}), \quad (2.31)
\]

where

\[
c_1(T^{-1}) = QE[W'A \varepsilon] = O(T^{-1})
\]

\[
c_2(N^{-1}T^{-1}) = -QE \left[ (W'AW - Q^{-1})Q(W'AE - E[W'A \varepsilon]) \right] = O(N^{-1}T^{-1})
\]

\[
c_3(N^{-1}T^{-2}) = -QE \left[ ((W'AW - Q^{-1})Q)^2 \right] E[W'A \varepsilon] = O(N^{-1}T^{-2}),
\]

(2.31)
At this point it is illuminating to consider an alternative approximation based on small sigma asymptotics. Using the shorthand notation

\[ q_1 = Qe_1 \quad , \quad q_{11} = e_1'q_1, \]

and

\[ F = tr(\Pi'\Pi)q_1q_1' \quad , \quad f = tr(\Pi'\Pi)q_{11}, \]

it can be shown using similar derivations as in Kiviet and Phillips (1998) that

\[ Q = (W'AW)^{-1} - (\sigma_\varepsilon^2 - \sigma_\varepsilon^4f + \sigma_\varepsilon^6f^2 - \sigma_\varepsilon^8f^3 + \ldots) F, \tag{2.32} \]

where \( f = O(1) \) and \( F = O(n^{-1}) \). In the large \( n = NT \) terminology of Section 2.3.1 all terms in (2.32) are of order \( O(n^{-1}) \). As \( Q \) enters the bias approximation (2.31) everywhere, the large \( NT \) approximation will include terms in \( \sigma_\varepsilon^2 \) of all orders. On the other hand, a finite order small sigma approximation will delete terms that are not ignorable from a large \( NT \) perspective. Like Kiviet and Phillips (1998) we conclude that a small sigma approximation is inferior here. In fact, the situation is worse here because the small sigma approach will neglect terms of order \( O(T^{-1}) \), which cause the inconsistency of LSDV in small \( T \), large \( N \) panels.

Following the derivations as presented in Kiviet (1995, 1999), one obtains

\[ c_1(T^{-1}) = \sigma_\varepsilon^2tr(\Pi)q_1 \quad \tag{2.33} \]

\[ c_2(N^{-1}T^{-1}) = -QE[W'AWQW'A\varepsilon] + QE[W'A\varepsilon] \]

\[ = -\sigma_\varepsilon^2[QW'\Pi A\bar{W} + tr(QW'\Pi A\bar{W})I_{K+1}] \\
+ 2\sigma_\varepsilon^2q_{11}tr(\Pi'\Pi I_{K+1})q_1 \tag{2.34} \]

\[ c_3(N^{-1}T^{-2}) = QE[W'AWQW'AW]QE[W'A\varepsilon] - QE[W'A\varepsilon] \]

\[ = \sigma_\varepsilon^4tr(\Pi)[2q_{11}QW'\Pi \Pi'W'q_{11} + (q_1'W'\Pi \Pi'Wq_1) \\
+ q_{11}tr(QW'\Pi \Pi'W) + 2tr(\Pi'\Pi \Pi'\Pi)q_1^2]q_1]. \tag{2.35} \]

In Kiviet (1995) only the first two terms (2.33) and (2.34) have been taken into account, so the approximation error is still \( O(N^{-1}T^{-2}) \). The more general result with approximation error of order \( O(N^{-2}T^{-2}) \) can already be found in Kiviet (1999) but here the expressions are simpler due to removing factors \( \bar{W}'A\bar{W} \) by exploiting \( \bar{W}'A\bar{W} = Q^{-1} - \sigma_\varepsilon^2tr(\Pi'\Pi)e_1e_1' \).

Note that all components given above implicitly contain contributions which are in fact of smaller order than the order indicated. For example, upon exploiting the simple structure of \( \Gamma_T \) given in (2.15) we obtain for (2.33), see also (2.26),

\[ c_1(T^{-1}) = \sigma_\varepsilon^2tr(\Pi)q_1 = -\sigma_\varepsilon^2 \left( \frac{N}{1-\gamma} - \frac{N}{T(1-\gamma)^2} + \frac{N\gamma^T}{T(1-\gamma)^2} \right) q_1, \tag{2.36} \]
2.3. Bias approximation and correction for the LSDV estimator

and so, since \( q_1 = O(N^{-1}T^{-1}) \), \( c_1(T^{-1}) \) also contains contributions of order \( O(T^{-2}) \) and smaller. Note that such is fully in accordance with our definitions given above, i.e. \( O(T^{-1}) \) refers to "is at most of order \( T^{-1} \)" (but could even be smaller, or be a combination of terms of order \( T^{-1} \) and smaller terms). The approximation to the LSDV bias established by the first of the three components of (2.36), i.e.

\[
E(\hat{\delta}_{LSDV} - \delta) = -\sigma^2 \epsilon q_1 \frac{N}{1 - \gamma} + O(T^{-2}) + O(N^{-1}T^{-1}),
\]

(2.37)
is an extremely simple one, which may work well for moderately large \( N \) and \( T \), because the "pure" \( O(T^{-1}) \) contribution to the bias has been separated here from \( O(N^{-1}T^{-1}) \) and "pure" \( O(T^{-2}) \) contributions, together constituting a hybrid remainder term.

In numerical calculations for relevant data generating processes we shall examine the bias approximation

\[
B_{LSDV}^{(0)} = -\sigma^2 \epsilon q_1 \frac{N}{1 - \gamma},
\]

(2.38)
and make comparisons with the approximations produced by

\[
B_{LSDV}^{(j)} = \sum_{h=1}^{j} c_h, \quad \text{for} \ j = 1, 2, 3,
\]

(2.39)
where \( c_h (h = 1, 2, 3) \) refers to the contributions to the bias given in (2.33), (2.34) and (2.35) respectively. By assessing the true bias from Monte Carlo simulations we shall examine the relative accuracy of the various approximations and examine the importance of the inclusion of higher-order terms.

2.3.3 Bias correction

It is known from simulation studies that, despite its serious bias, the LSDV estimator has a relatively small variance as compared with IV and GMM techniques. Therefore, on basis of a mean squared error criterion, a reasonably efficient procedure may result when a bias approximation is used to correct for the bias in the LSDV estimator. We shall examine the LSDVc implementations

\[
\hat{\delta}_{LSDVc,h}^{(j)} = \hat{\delta}_{LSDV} - \hat{B}_{LSDV,h}^{(j)}, \quad j = 0, \ldots, 3,
\]

(2.40)
where any consistent preliminary estimators \( \hat{\delta}_h \) and \( \hat{\sigma}^2_{\epsilon,h} \), obtained from estimation technique \( h = AHL, GMM \) (as defined in the next section), can be used to estimate the correction term.
Chapter 2. Finite sample accuracy in dynamic panel models

2.4 Asymptotic properties

In this section we establish limiting distributions for the various estimators, either for $N \to \infty$ and $T$ finite or vice versa. We will not consider the limiting behaviour of the estimators when both $N$ and $T$ go to infinity (see Alvarez and Arellano, 1998). Note that an appropriate asymptotic variance for LSDV estimators (2.40) has not been derived yet for the case $N \to \infty$ and $T$ finite. The last subsection is about the asymptotic distribution of simple $t$-ratios for the various estimators.

2.4.1 IV and GMM estimators

In the simulations we will compare bias corrected LSDV estimators with some commonly used IV and GMM techniques. More in particular, we will consider estimators for the model in first differences (1.15), i.e.

$$Dy = \gamma Dy_{-1} + DX\beta + D\varepsilon. \quad (2.41)$$

As outlined in Section 1.2.2 Anderson and Hsiao (1982) proposed two simple IV estimators for the parameter vector $\delta$, which make use of either $Dy_{-2}$ or $J^*y_{-1}$ as instrument for $Dy_{-1}$. In this chapter we will analyse the second option only, i.e. using $J^*y_{-1}$ as instrument. Then estimation of (2.41) leads to the estimator

$$\hat{\delta}_{AHL} = (Z'DW)^{-1}Z'Dy, \quad (2.42)$$

where $Z = [J^*y_{-1} : DX]$ and $DW$ are $N(T-1) \times (K+1)$ matrices and $Dy$ is a $N(T-1) \times 1$ vector.

The GMM estimator used in this chapter is that of Arellano and Bond (1991). In their simulation study and empirical application they do not use all available overidentifying restrictions concerning the exogenous variables. Their $(T-1) \times (\frac{1}{2}T(T-1)+K)$ matrix $Z_{i}$ of instruments for individual $i$ is as in (1.19). The moment conditions can be written conveniently as $E[Z_{i}D\varepsilon] = 0$ and the GMM estimator equals

$$\hat{\delta}_{GMM} = (W'DZ_{i}\hat{V}^{-1}Z_{i}'DW)^{-1}W'DZ_{i}\hat{V}^{-1}Z_{i}'Dy. \quad (2.43)$$

The estimator of $V$ used in this chapter is $\hat{V} = \frac{1}{N}Z_{i}'HZ_{i}$, which is equivalent with the one-step estimator\(^2\) of Arellano and Bond (1991). The $N(T-1) \times N(T-1)$ matrix $H = I_{N} \otimes H_{T-1}$ multiplied by the disturbance variance $\sigma_{\varepsilon}^2$ is the variance matrix of

\(^2\)The estimator (2.43) is identical to the estimator labelled $GMM_{dif}$ in Section 1.3, but for ease of notation here the subscript $dif$ has been supressed.
2.4. Asymptotic properties

$D\varepsilon$, which is an MA(1) process under the assumption that $\varepsilon$ is white noise. The matrix $H_{T-1} = D_T D_T'$ has twos on the main diagonal, minus ones on the first subdiagonals and zeros elsewhere.

Under standard regularity conditions, and upon defining

\[
\Sigma_{ZW} = \lim_{N \to \infty} \frac{1}{N} Z'DW
\]
\[
\Sigma_{ZHZ} = \lim_{N \to \infty} \frac{1}{N} Z'D\varepsilon\varepsilon'DZ
\]
\[
\Sigma_{ZtW} = \lim_{N \to \infty} \frac{1}{N} Z_t'DW
\]
\[
\Sigma_{ZtHZt} = \lim_{N \to \infty} \frac{1}{N} Z_t'D\varepsilon\varepsilon'DZ_t,
\]

the usual asymptotic reasoning yields the normal limiting distributions for the IV and GMM estimators for fixed $T$, viz.

\[
\sqrt{N} \left( \hat{\delta}_{AHL} - \delta \right) \xrightarrow{d} N \left[ 0, \sigma_\varepsilon^2 \Sigma_{ZW}^{-1} \Sigma_{ZHZ}(\Sigma_{ZW}')^{-1} \right],
\]
\[
\sqrt{N} \left( \hat{\delta}_{GMM} - \delta \right) \xrightarrow{d} N \left[ 0, \sigma_\varepsilon^2 (\Sigma_{ZW} \Sigma_{ZHZ} \Sigma_{ZtW})^{-1} \right].
\]

From the above, we obtain the asymptotic approximations

\[
\hat{\delta}_{AHL} \xrightarrow{N \to \infty} N \left[ \delta, \sigma_\varepsilon^2 (Z'DW)^{-1} Z'HZ(W'DZ)^{-1} \right],
\]
\[
\hat{\delta}_{GMM} \xrightarrow{N \to \infty} N \left[ \delta, \sigma_\varepsilon^2 ((DW)'Zl\hat{\varepsilon}^{-1}Z_l'DW)^{-1} \right].
\]

Consistent estimators for $\sigma_\varepsilon^2$, the variance of the disturbance term $\varepsilon$, are given by

\[
\hat{\sigma}^2_{\varepsilon,h} = \frac{\hat{u}_h'A\hat{u}_h}{N(T-1)-(K+1)}, \quad h = AHL, GMM,
\]

where

\[
\hat{u}_h = y - W\hat{\delta}_h.
\]

Note that the numerator in (2.52) is the sum of squares of the group-demeaned (in order to account for the estimated individual effect coefficients) residuals, and the denominator contains a degrees of freedom correction for the $N + K + 1$ estimated coefficients. Obviously, $\hat{\sigma}^2_{\varepsilon,AHL}$ and $\hat{\sigma}^2_{\varepsilon,GMM}$ are semi-consistent, like $\hat{\delta}_{AHL}$ and $\hat{\delta}_{GMM}$, for $N \to \infty$ and any $T$. 

2.4.2 LSDV estimator

To obtain similar results for the LSDV estimator, where
\[ \hat{\delta}_{LSDV} - \delta = (W'AW)^{-1} W' \varepsilon, \]
we have to be a little bit more careful. We will obtain results for \( T \rightarrow \infty \) and \( N \) finite and \( N \rightarrow \infty \) and \( T \) finite. We define both

\[ \Sigma_{WAW} = \lim_{N \rightarrow \infty} \frac{1}{N} W'AW, \]
for \( T \) finite, and

\[ \Upsilon_{WAW} = \lim_{T \rightarrow \infty} \frac{1}{T} W'AW, \]
for \( N \) finite. First consider

\[ \lim_{T \rightarrow \infty} (\hat{\delta}_{LSDV} - \delta) = \Upsilon_{WAW}^{-1} \lim_{T \rightarrow \infty} \frac{1}{T} W' \varepsilon. \]

Since it follows from (2.25) and (2.27) respectively that, for \( N \) finite, \( E \left[ \frac{1}{T} W' \varepsilon \right] = O(T^{-1}) \) and \( \text{Var} \left[ \frac{1}{T} W' \varepsilon \right] = O(T^{-1}) \), we have \( \lim_{T \rightarrow \infty} \frac{1}{T} W' \varepsilon = 0 \). Hence,

\[ \lim_{T \rightarrow \infty} \hat{\delta}_{LSDV} = \delta, \]
i.e. \( \hat{\delta}_{LSDV} \) is consistent for \( T \rightarrow \infty \).

Employing an appropriate central limit theorem yields

\[ \sqrt{T} \left( \hat{\delta}_{LSDV} - \delta \right) \xrightarrow{d} N \left[ 0, \sigma_{\varepsilon}^2 \Upsilon_{WAW}^{-1} \right], \]
leading to the asymptotic approximate distribution

\[ \hat{\delta}_{LSDV} \xrightarrow{T \rightarrow \infty} N \left[ \delta, \sigma_{\varepsilon}^2 (W'AW)^{-1} \right]. \]

Also, for

\[ \hat{\sigma}_{\varepsilon,LSDV}^2 = \frac{\hat{\psi}_{LSDV} \hat{\lambda}_{LSDV}}{N(T - 1) - (K + 1)}, \]
with \( \hat{\psi}_{LSDV} = y - W \hat{\delta}_{LSDV}, \) we find

\[ \lim_{T \rightarrow \infty} \hat{\sigma}_{\varepsilon,LSDV}^2 = \sigma_{\varepsilon}^2. \]

In principle, of course, these large \( T \) approximations will be useful only when \( T \) is large relative to \( N \).
2.4. Asymptotic properties

However, for $T$ finite and $N \to \infty$ the situation is much more complicated. It follows from (2.25) and (2.27) that $E \left[ \frac{1}{N} W' A \varepsilon \right] = O(1)$ and $\text{Var} \left[ \frac{1}{N} W' A \varepsilon \right] = O(N^{-1})$. Hence, using $\lim_{N \to \infty} \frac{1}{N} (W' A \varepsilon - E [W' A \varepsilon]) = 0$, we find

$$
\delta^* = \lim_{N \to \infty} ( \hat{\delta}_{LSDV} - \delta ) = \Sigma_{WAW}^{-1} \lim_{N \to \infty} \frac{1}{N} W' A \varepsilon
$$

$$
= \Sigma_{WAW}^{-1} \lim_{N \to \infty} \frac{1}{N} (W' A \varepsilon - E [W' A \varepsilon]) + \Sigma_{WAW}^{-1} \lim_{N \to \infty} \frac{1}{N} E [W' A \varepsilon]
$$

$$
= - \sigma^2 (1 - \gamma T) \Sigma_{WAW}^{-1} e_1 = O(1),
$$

which defines $\delta^*$ as the inconsistency (asymptotic bias) of LSDV for $N \to \infty$ and finite $T$, earlier addressed in Nickell (1981) and Sevestre and Trognon (1996).

It is interesting to examine whether, in addition to (2.58), the LSDV estimator has a limiting distribution for $N \to \infty$ and fixed $T$, and what the situation is for LSDVc estimators like (2.40). From (2.27) and (2.24) we obtain

$$
\text{Var} [W' A \varepsilon] = \sigma^2 Q^{-1} + \sigma^4 N tr ( \Pi_T \Pi_T ) e_1 e_1',
$$

and with (2.55) this yields

$$
\frac{1}{\sqrt{N}} (W' A \varepsilon - E [W' A \varepsilon]) \xrightarrow{d} N [0, \sigma^2 \Sigma_{WAW} + \sigma^4 tr (\Pi_T \Pi_T ) e_1 e_1'].
$$

Hence,

$$
\left( \frac{1}{N} W' AW \right)^{-1} \left( \frac{1}{\sqrt{N}} W' A \varepsilon - \frac{1}{\sqrt{N}} E [W' A \varepsilon] \right) \xrightarrow{d} N [0, \sigma^2 \Sigma_{WAW}^{-1} + \sigma^4 tr (\Pi_T \Pi_T ) \Sigma_{WAW}^{-1} e_1 e_1' \Sigma_{WAW}^{-1}],
$$

and, using (2.54) and (2.62), we obtain from the above

$$
\sqrt{N} ( \hat{\delta}_{LSDV} - \delta^* - \delta ) \xrightarrow{d} N [0, \sigma^2 \Sigma_{WAW}^{-1} + \sigma^4 tr (\Pi_T \Pi_T ) \Sigma_{WAW}^{-1} e_1 e_1' \Sigma_{WAW}^{-1}].
$$

So, we find that for $N \to \infty$ and fixed $T$ the estimator $\hat{\delta}_{LSDV}$ has a limiting distribution, but it is not centered at $\delta$. Note that this limiting distribution depends not only on $\sigma^2$ and $\Sigma_{WAW}$, but via $\Pi_T$ also on $\gamma$. If $\delta^*$ were known, the corrected LSDV estimator $\hat{\delta}_{LSDV} - \delta^*$ would provide a $\sqrt{N}$-consistent estimator of $\delta$ with limiting distribution (2.66). Hence, even if $\delta^*$ were known and could also be used to obtain a consistent estimator $\hat{\sigma}^2$ for $\sigma^2$. 
then \( \hat{\sigma}^2(W'AW)^{-1} \) would not provide an adequate expression for the asymptotic variance. Thus, for \( N \to \infty \) we find at least two striking differences with the \( T \to \infty \) results: bias correction is indispensable for achieving consistency and the asymptotic variance of a consistent estimator is non-standard.

### 2.4.3 Corrected LSDV estimator

We will now analyse the limiting behaviour of corrected LSDV estimators as proposed in (2.40). From (2.31) it follows that as \( T \to \infty \) and \( N \) finite the limiting behaviour of corrected LSDV estimators is equivalent to that of the ordinary LSDV estimator. Note that in this case the ordinary LSDV estimator can be used as a preliminary consistent estimator of \( \delta \) in the bias approximation. However, GMM is ruled out because it is inconsistent for finite \( N \). Hence, for \( T \to \infty \) and \( N \) finite \( h = LSDV, AHL \) in (2.40) yields consistency.

For \( T \) finite and \( N \to \infty \) we have for the ordinary LSDV estimator the limiting result in (2.66). In practice \( \delta^* \) of (2.62) is unknown, but we can estimate it. Employing a \( \sqrt{N} \)-consistent estimator \( \hat{\delta}_h \), for instance \( \hat{\delta}_{AHL} \) of (2.42) or \( \hat{\delta}_{GMM} \) of (2.43) and corresponding \( \hat{\sigma}^2_{\hat{\delta},h} \), yields

\[
\hat{\delta}^*_h = -\hat{\sigma}^2_{\hat{\delta},h} \left( \frac{1}{1 - \hat{\gamma}_h} - \frac{1 - \hat{\gamma}_h^T}{T(1 - \hat{\gamma}_h)^2} \right) \left( \frac{1}{N}W'AW \right)^{-1} e_1, \quad h = AHL, GMM. \tag{2.67}
\]

We shall examine now the asymptotic distributions of the LSDVc estimators

\[
\hat{\delta}_{LSDV,c,h} = \hat{\delta}_{LSDV} - \hat{\delta}^*_h, \quad h = AHL, GMM. \tag{2.68}
\]

Note that this implementation corresponds to \( \hat{\delta}^{(1)}_{LSDV,c,h} \) given in (2.40). The higher order implementations with \( j > 1 \) have the same limiting distribution. To derive this limiting distribution we use

\[
\sqrt{N} \left( \hat{\delta}_{LSDV,c,h} - \delta \right) = \sqrt{N} \left( \hat{\delta}_{LSDV} - \delta^* - \delta \right) - \sqrt{N} \left( \hat{\delta}^*_h - \delta^* \right). \tag{2.69}
\]

The first right-hand term has already been dealt with in (2.66) and in Appendix 2.A the limiting distribution of the second term is derived and also of their difference. Since the second term has a finite limiting distribution indeed, i.e. is \( O_p(1) \), the asymptotic variance of the corrected estimator with estimated \( \delta^* \) is found to be different from that where \( \delta^* \) is known, which was already found to be non-standard itself.

In Appendix 2.A we find

\[
\sqrt{N} \left( \hat{\delta}_{LSDV,c,h} - \delta \right) \xrightarrow{d} \mathcal{N} \left[ 0, \Omega_{LSDV,c,h} \right], \quad h = AHL, GMM, \tag{2.70}
\]
2.4. Asymptotic properties

which leads to

$$\hat{\delta}_{LSDV_{c,h}} \sim_{N \to \infty} \mathcal{N}[\delta, V_{LSDV_{c,h}}], \quad h = AHL, GMM. \quad (2.71)$$

For $h = AHL$ the expression for the asymptotic variance matrix has been derived and we find

$$V_{LSDV_{c,AHL}} = \sigma_{\varepsilon}^2 (W'AW)^{-1}$$

$$+ \sigma_{\varepsilon}^4 N tr(\Pi_T \Pi_T)(W'AW)^{-1} e_1 e_1' (W'AW)^{-1}$$

$$+ \sigma_{\varepsilon}^4 N (W'AW)^{-1} W'AD'Z (W'D'Z)^{-1} e_1 d'$$

$$+ \sigma_{\varepsilon}^4 N d_1 e_1' (Z'DW)^{-1} Z'D'AW (W'AW)^{-1}$$

$$+ \sigma_{\varepsilon}^4 (6N/(T-1)) d_2$$

$$+ \sigma_{\varepsilon}^6 N^2 e_1' (Z'DW)^{-1} Z'HZ (W'D'Z)^{-1} e_1 d_1'$$

$$+ \sigma_{\varepsilon}^6 N^2 tr(\Pi_T \Gamma_T' L_T J_T' D_T)(W'AW)^{-1} (W'D'Z)^{-1} e_1 d'$$

$$+ \sigma_{\varepsilon}^6 N^2 tr(\Pi_T \Gamma_T' L_T J_T' D_T) d_1 e_1' (Z'DW)^{-1} (W'AW)^{-1}, \quad (2.72)$$

where

$$d_1 = \left[ \frac{1 + \frac{T-1}{(1-\gamma)^2} - 2 \frac{1 - \gamma^T}{T (1-\gamma)^3} }{1-\gamma} \right] (W'AW)^{-1} e_1,$$

$$d_2 = tr(\Pi_T)(W'AW)^{-1} e_1.$$

The expression in (2.72) can be used to estimate the asymptotic variance matrix of (2.71). For $h = GMM$ we did not derive such an expression due to the complexity of the dependence of the matrix of instruments $Z_t$ on $\varepsilon$.

An alternative way to obtain empirical estimates of $V_{LSDV_{c,h}}$, which avoids the use of complicated analytical expressions as in (2.72), is to bootstrap the standard errors. Exploiting the normality assumption, we may use a parametric bootstrap and the procedure for resampling is then as follows:

1. Obtain the corrected LSDV estimators $\hat{\delta}_{LSDV_{c,h}}, \hat{\sigma}_{\varepsilon,h}^2$ and $\hat{\eta}_{LSDV_{c,h}}$;

2. For $b = 1, \ldots, B$ generate a random sample $\varepsilon^{(b)} \sim \mathcal{N}[0, \hat{\sigma}_{\varepsilon,h}^2 I_{NT}]$;

3. Calculate $y^{(b)} = \hat{\eta}_{LSDV_{c,h}} y_{-1}^{(b)} + X \hat{\beta}_{LSDV_{c,h}} + S \hat{\eta}_{LSDV_{c,h}} + \varepsilon^{(b)}$ where $y_{-1}$ contains the original starting values;

4. Estimate the model with the resampled data to obtain the bootstrap LSDVc estimator $\hat{\delta}_{LSDV_{c,h}}^{(b)}$. 

Chapter 2. Finite sample accuracy in dynamic panel models

Note that the presence of $y_{-1}$ necessitates to use a recursive resampling scheme. The limiting distribution for the bootstrap estimator, conditional on $\hat{\delta}_{LSDV,c,h}$, is

$$\sqrt{N} \left( \hat{\delta}^{(b)}_{LSDV,c,h} - \delta_{LSDV,c,h} \right) \xrightarrow{d} \mathcal{N} \left( 0, \Omega_{LSDV,c,h} \right), \quad h = AHL, GMM.$$  

The variance of $\hat{\delta}^{(b)}_{LSDV,c,h}$ can be estimated from its empirical distribution by

$$\hat{V}_{LSDV,c,h} = \frac{1}{B-1} \sum_{b=1}^{B} \left( \hat{\delta}^{(b)}_{LSDV,c,h} - \delta_{LSDV,c,h} \right) \left( \hat{\delta}^{(b)}_{LSDV,c,h} - \delta_{LSDV,c,h} \right)' ,$$  

with $\delta_{LSDV,c,h} = \frac{1}{B} \sum_{b=1}^{B} \hat{\delta}^{(b)}_{LSDV,c,h}$. Especially when $N$ is large this variance estimator should be appropriate and may replace the estimation by the analytical expression (2.72).

2.4.4 $t$-ratios

The asymptotic distributions presented above can be used to construct asymptotic $t$-ratio tests for the null hypotheses $H_0 : \delta_k = \delta_k^0$ for $k = 1, \ldots, K + 1$. The statistics can be expressed as $(j = 0, 1, 2, 3; \quad h = AHL, GMM)$:

$$t_{AHL}(\delta_k^0) = \frac{\hat{e}_k' \delta_{AHL} - \delta_k^0}{\sqrt{\hat{\sigma}_{,AHL}^2 \hat{e}_k' (Z'DW)^{-1} Z'HZ (W'D'Z)^{-1} \hat{e}_k}},$$  

$$t_{GMM}(\delta_k^0) = \frac{\hat{e}_k' \delta_{GMM} - \delta_k^0}{\sqrt{\hat{\sigma}_{,GMM}^2 \hat{e}_k' \left( W'D'Z, \hat{V}^{-1}Z'DW \right)^{-1} \hat{e}_k}},$$  

$$t^{(j)}_{LSDV,c,h}(\delta_k^0) = \frac{\hat{e}_k' \hat{\delta}^{(j)}_{LSDV,c,h} - \delta_k^0}{\sqrt{\hat{e}_k' \hat{V}_{LSDV,c,h} \hat{e}_k}},$$  

$$T^{(j)}_{LSDV,c,h}(\delta_k^0) = \frac{\hat{e}_k' \hat{\delta}^{(j)}_{LSDV,c,h} - \delta_k^0}{\sqrt{\hat{\sigma}^2_{,LSDV} \hat{e}_k' (W'AW)^{-1} \hat{e}_k}},$$  

$$T_{LSDV}(\delta_k^0) = \frac{\hat{e}_k' \delta_{LSDV} - \delta_k^0}{\sqrt{\hat{\sigma}^2_{,LSDV} \hat{e}_k' (W'AW)^{-1} \hat{e}_k}}.$$  

Because they have been appropriately normalised, the statistics $t_{AHL}(\delta_k^0)$, $t_{GMM}(\delta_k^0)$ and $t^{(j)}_{LSDV,c,h}(\delta_k^0)$ will all converge to a standard normal distribution for $N \to \infty$ under the null hypothesis. For the tests $T^{(j)}_{LSDV,c,h}(\delta_k^0)$, which combines the LSDVc coefficient estimator with the ordinary LSDV variance, and $T_{LSDV}(\delta_k^0)$ this is only the case when $T$ approaches infinity.
2.5 Simulation results

The simulation design is basically the same as in Kiviet (1995), although slightly different values for some of the parameters have been chosen including cases with non-stationary regressors. Data for $y$ have been generated according to equation (2.1) with $K = 1$. The generating equation for the explanatory variable $x$ is

$$x_{it} = \rho x_{i,t-1} + \xi_{it} \quad i = 1, \ldots, N; \ t = 1, \ldots, T,$$  \hspace{1cm} (2.79)

where $\xi_{it} \sim \mathcal{IN}[0, \sigma_{\xi}^2]$. As already noted in the introduction the focus is on samples in which both dimensions are relatively small. Therefore, the following three cases have been analysed: $T = N = 10$; $T = 10$, $N = 20$ and $T = 20$, $N = 10$. Three values for $\gamma$ (viz. 0.8; 0.5; 0.2) and two for $\rho$ (viz. 0.8; 1.0) are considered. Each experiment consists of one thousand replications. The long-run effect $\beta/(1 - \gamma)$ of $x$ on $y$ has been set equal to unity in all experiments. This implies that the impact multiplier $\beta$ varies with the chosen values for $\gamma$. The variance of the disturbance term $\sigma_{\eta}^2$ is set at the value of one. So, for the three chosen sample sizes we consider six different designs concerning $\delta = (\gamma, \beta)'$, $\rho$ and $\sigma_{\xi}$.

Appendix 2.B gives a detailed description on how the remaining design parameters $\sigma_{\eta}$ and $\sigma_{\xi}$ have been determined. By varying $\sigma_{\eta}$ we control the relative impact on $y$ of the two error components $\eta$ and $\varepsilon$. The parameter $\sigma_{\xi}$ has been determined by controlling the signal-to-noise ratio $\sigma_{s}^2$ of the model. In Kiviet (1995) it has been shown that a proper comparison of simulation results over different parameter values requires to exercise control over some of the basic model characteristics such as the signal-to-noise ratio. Appendix 2.B discusses also the modifications of the design required when the exogenous regressor is non-stationary. In this case $\rho$ is equal to one, which is a situation not examined in Kiviet (1995). The signal-to-noise ratio $\sigma_{s}^2$ is now varying with $t$. Hence, we have chosen to fix the signal in the experiments at the mean value of $\sigma_{s}^2$ over the sample, and then the parameters $\sigma_{\eta}$ and $\sigma_{\xi}$ are determined as in the experiments with a stationary regressor $x$.

The following estimators have been analysed: least squares dummy variables (LSDV), the Anderson and Hsiao (1982) simple IV estimator (labelled AHL), the one-step GMM estimator of Arellano and Bond (1991) and the correction method of Kiviet (1995, 1999) based on either an initial GMM estimate (LSDV$_{C}$,GMM) or AHL estimate (LSDV$_{C}$,AHL). In the correction formula we have always included the approximation $B_{LSDV}^{(3)}$, unless stated otherwise. Note that only the uncorrected LSDV estimator relies on asymptotics requiring large $T$.

In the experiments the GMM estimator is calculated for three sets of instruments. Regarding (1.19) one, five and eight lagged values of the dependent variable have been
taken, which results in three different GMM estimators (labelled GMMa, GMMb and GMMc respectively). The GMMc estimator has been used as the preliminary estimator in the operational bias corrected estimator LSDVc.GMM.

We performed 1000 Monte Carlo replications. Results on the bias, variance and mean squared error of the various coefficient estimators are presented in Tables 2.1 and 2.2. To get a quick impression of the general qualities of the estimators (and to save space) we give here average outcomes over the three different \( \gamma \) values only (for particular \( T \) and \( N \)) but do report separate results for the stationary and non-stationary variable cases. We observe the following patterns in the simulation results. First, the sign and magnitude of the bias in estimating \( \gamma \) and \( \beta \) is for LSDV and the GMM procedures more or less comparable when both \( T \) and \( N \) are small. Second, the AHL estimator has almost negligible bias in estimating \( \gamma \) and a rather small bias for \( \beta \), but it yields for both the largest variance. Regarding \( \gamma \) the large dispersion of the AHL estimator is confirmed by the results in the second column of Tables 2.1 and 2.2, which show the high frequency of estimates of \( \gamma \) outside the unit circle. Third, the LSDV procedure has relatively small variance as compared with GMM and AHL. Fourth, bias correction reduces the bias considerably. Fifth, based on a mean squared error criterion the LSDVc procedures are never beaten by the other estimators. In addition, we note that the sensitivity with respect to the preliminary estimator used in the bias approximation, i.e. GMM or AHL, is only marginal. Also when the difference in accuracy of AHL and GMM is large, the extent to which this is carried over to the accuracy of the bias corrected LSDV is minor. Finally, we note for GMM that its variance (but not its bias) decreases with the number of moment conditions employed.

In Tables 2.3 and 2.4 we compare the contributions of the various terms in the bias approximation for LSDV, calculated at the true parameter values, with the actual bias as estimated from the Monte Carlo for the stationary and non-stationary data respectively. We find that the magnitude of the bias depends much more on \( T \) than on \( N \), and relatively little on \( \rho \), the pattern of the regressor variable. The negative bias in the estimator of \( \gamma \) is larger in absolute value when \( \gamma \) is larger, and on the whole it is much more serious than the bias in estimating \( \beta \). In relative terms the bias in estimating \( \gamma \) is certainly serious when \( \gamma \) is small. The decomposition of the bias approximation in terms of different orders in \( T \) and \( N \) shows that the pure \( O(T^{-1}) \) approximation can be reasonably accurate when the bias is moderate but otherwise it may yield a considerable overstatement of the actual bias. Leaving into the approximation the contributions which are \( O(T^{-2}) \), but which are still \( O(N^0) \) at the same time, is often profitable, but not always so. The contributions to the bias which are \( O(N^{-1}T^{-1}) \) and \( O(N^{-1}T^{-2}) \) are found to be of very
2.5. Simulation results

limited actual magnitude, so one could decide to omit them from implementations of the LSDVc procedure.

We return now to results for the various estimation procedures and focus on variance estimates. In Table 2.5 results are presented for the case $\gamma = 0.5$ and $\rho = 0.8$. For reference, the first two columns give the bias of coefficient estimators in estimating $\gamma$ and $\beta$ for this specific experiment. Naturally, some of the results concerning the coefficient estimators will carry over to the findings for the disturbance variance estimators. The table presents the estimated bias in the estimators of $\sigma_e$ as percentage of the true disturbance standard error, which is one in all experiments. Regarding this bias we find first of all that the magnitude of the bias of the LSDV and GMM estimators is more or less equal and always negative. Second, the bias in the AHL estimator is often positive. Third, bias problems seem to be less severe for larger $T$. In this table the bias in estimating the standard deviation of the various coefficient estimators is also presented as percentage of the true standard deviation as estimated from the Monte Carlo. In many cases these relative biases of the coefficient standard deviation are worse than the bias of the disturbance variance (which is one of their determinants, of course). For LSDVc,GMM and LSDVc,AHL we present different variance estimators. The conventional large $T$ expression of (2.59) is always reported. In addition, when $T \leq N$ also the "analytic" (only in case of LSDVc,AHL) and the bootstrap variance estimators as in (2.72) and (2.73) are presented. Especially for $\gamma$ these alternative estimators seem more accurate than the standard expression. Similar results are obtained when allowing for a non-stationary regressor, i.e. $\rho = 1.0$. However, results not reported here show that for larger $\gamma$, i.e. $\gamma = 0.8$, the "analytic" variance estimator breaks down, while the bootstrap estimator is still relatively accurate.

We shall examine now what the implications are of the results on coefficient bias and bias in standard errors for the accuracy in small samples of the usual statistical inference as produced by $t$ statistics. Table 2.6 shows that relying on asymptotic theory in small samples of the type analysed here can be quite misleading as the empirical distribution of the $t$ statistics can differ substantially from the asymptotic standard Normal. The actual size for testing $\beta$ is in many cases still reasonably close to the nominal size. For testing $\gamma$ all the techniques show substantial distortions. For AHL underrejection is more of a problem than overrejection. LSDV (understandably) but GMM too show huge distortions. The LSDVc results are generally much less extreme, but not really satisfactory. The differences in performance of LSDVc implementations when using alternative variance estimators seem to be marginal.

Summarising, regarding the AHL estimator we find little bias, relatively good performance of $t$ tests, but also large dispersion and RMSE. Compared with AHL we find for
Chapter 2. Finite sample accuracy in dynamic panel models

GMM relatively small RMSE, but larger bias and substantial size distortions of t tests. Finally, for bias corrected LSDV we find moderate bias and size distortions. Based on a RMSE criterion this estimation method is never beaten by the other estimators analysed in the simulations.

2.6 Dynamic externalities and local economic development in Morocco

2.6.1 Introduction

In this section the performance of the various estimators will be examined in an empirical application. We analyse the determinants driving local economic development in six major Moroccan urban areas. The existence of cities or urban areas is often explained by localisation and urbanisation economies, which arise as a result of a higher degree of both concentration and differentiation of economic activities. Localisation economies emerge when similar firms cluster, while in case of urbanisation economies it is the diversity of the industrial structure that matters. For example, localisation economies provide firms with better access to natural resources and lower transport costs, while urbanisation economies enhance diversity of products and firms and increase market size.

While localisation and urbanisation economies describe the existing industrial structure of a region, they do not necessarily explain the pattern of economic development through time. Growth theory (Romer, 1986) emphasises the role of knowledge spillovers as an important source for technological change and hence economic growth. As close proximity of firms facilitates the transmission of ideas and innovations between firms, knowledge spillovers are most likely to occur in urban areas. The agglomeration economies arising from knowledge spillovers are called dynamic externalities. In contrast with traditional localisation and urbanisation economies, dynamic externalities explain both the formation of urban areas and local economic growth.

In the literature on dynamic externalities three main theories are distinguished. All these theories agree that knowledge spillovers are important, but they differ regarding their origins. First, Marshall-Arrow-Romer (MAR) externalities arise from intra industry knowledge spillovers, see for example Glaeser et al. (1992). MAR externalities imply that an increase in the concentration of firms of the same industry within a region facilitates knowledge spillovers, which in turn increases productivity. In other words, specialisation of firms within a region will have positive effects on local economic development. Another feature of MAR externalities is that local monopoly rather than competition is better
for growth. Second, contrary to MAR externalities, so called Jacobs (1969) externalities arise from inter industry knowledge spillovers or, in other words, diversity among firms is beneficial. Third, Porter (1990) externalities agree with MAR theory that a higher concentration of similar firms in a region facilitates knowledge spillovers. In contrast to MAR, however, Porter argues that a higher degree of local competition induces firms to innovate in order to remain competitive. In the view of Porter, which is supported also by Jacobs, competition is good for economic growth contrary to the prediction of MAR.

In Bun and El Makhloufi (2001) an attempt has been made to distinguish which type of externality, if any, is predominant for economic development in some major urban areas in Morocco. As the empirical literature on dynamic externalities has focused exclusively on industrialised countries like the United States or European countries, this is a first attempt to quantify these theories for a developing country. It establishes significant MAR externalities, but provides mixed evidence on Jacobs and Porter effects.

An important question not addressed by Bun and El Makhloufi is to what extent the influence of dynamic externalities on local economic development differs between manufacturing sectors. Glaeser et al. (1992) report estimation results on several subsamples of industries to check the robustness of their overall results. Henderson et al. (1995) argue that for large mature industrial sectors MAR externalities should be dominant, while for new industries also Jacobs externalities matter. Moreover, the degree of persistence in economic activity should be higher for large traditional industries as compared with smaller newer industries. Here, we will examine these features by assessing the degree of parameter heterogeneity between industries, i.e. separate regressions will be estimated for five main one-digit sectors available in the data. As these subsamples naturally have few observations in both the time and cross-sectional dimensions, the simulations in the previous section will be informative about the anomalous differences between estimates produced by the various techniques.

2.6.2 Data

The available data contain annual time series on several characteristics including gross value added, employment, wages and number of establishments. The period covered is 1985-1995 and the data are collected for eighteen two-digit manufacturing sectors and six large urban areas in Morocco.3

In order to establish in an econometric analysis the importance of dynamic externalities

3The data are obtained from the "Ministère de l’Industrie, du Commerce et de l’Artisanat" of Morocco.
for local economic activity the various types of externalities have to be quantified. The data include three indicators, which aim to measure these externalities. Data about sectors \( s = 1, \ldots, S \) and regions \( r = 1, \ldots, R \) (with \( S = 18 \) and \( R = 6 \)) are available, so each cross-sectional unit \( i \) has a unique combination of \( s \) and \( r \). We can identify each cross-sectional unit \( i = 1, \ldots, SR \) uniquely with \( i = (r - 1)S + s \). Denote with \( emp_{srt} \) employment of industry \( s \) in region \( r \) at time period \( t \). Furthermore, define \( emp_{st} \), \( emp_{rt} \) and \( emp_{t} \) as employment at time \( t \) in sector \( s \), region \( r \) or the whole country respectively.

Using the notation introduced above the definition of concentration or specialisation becomes

\[
sp_{it} = \frac{emp_{srt}}{emp_{rt}} \frac{emp_{rt}}{emp_{t}}.
\] (2.80)

This ratio measures the fraction of employment in sector \( s \) located in region \( r \) relative to the fraction of total employment in sector \( s \) of total employment in the country. Therefore, high levels for \( sp_{it} \) indicate that production of sector \( s \) is relatively concentrated in region \( r \).

The measure for diversity is

\[
div_{it} = \sum_{k=1,k\neq s}^{S} \left[ \frac{emp_{krt}}{emp_{rt}} - \frac{emp_{rt}}{emp_{t}} \right]^2.
\] (2.81)

The ratio in this indicator is employment in sector \( k \) in region \( r \) relative to the total other manufacturing employment in region \( r \). If this ratio is low for the majority of the sectors then there are many diversified activities in the region. Hence, a low level of \( div_{it} \) implies a high degree of diversity.

The competition indicator is defined as

\[
comp_{it} = \frac{ne_{srt}}{emp_{srt}} \frac{emp_{srt}}{emp_{t}},
\] (2.82)

where \( ne_{srt} \) are the number of establishments of industry \( s \) in region \( r \). If the number of establishments per worker for industry \( s \) and region \( r \) is relatively high to that of industry \( s \) in the whole country, then firms of sector \( s \) in that particular region are assumed to be relatively competitive.

The specialisation and competition indicators given above are similar to those used in Glaeser et al. (1992). The diversity indicator is similar to the so-called Hirschman-Herfindahl index, which has been used also in Henderson et al. (1995) and other studies. Other explanatory variables measuring local market conditions are total regional manu-
facturing production (trp), which reflects market size\(^4\), and real unit wage costs (wcap). Finally, following De Lucio et al. (1998) real value added (va) will be used as a proxy for economic activity.

### 2.6.3 Estimation results

Because of the time series aspect of the data, a general dynamic specification has been estimated including as many lagged explanatory variables as seem required, including the one-period lagged value of the dependent variable. To account for unobserved heterogeneity, e.g. local resources or the institutional, cultural and political environment, individual specific effects have been included. The estimated specification is

\[
\ln va_{it} = \gamma \ln va_{i,t-1} + \beta' x_{it} + \eta_i + \varepsilon_{it},
\]

with

\[
x_{it} = (\ln trp_{it}, \ln trp_{i,t-1}, \ln wcap_{it}, \ln wcap_{i,t-1}, sp_{it}, sp_{i,t-1}, dv_{it}, dv_{i,t-1}, cp_{it}, cp_{i,t-1})'.
\]

Complete data are available over the years 1985-1995 for 95 cross-sectional units. Bun and El Makhlouf (2001) report estimation results of (2.83) for the full sample. In that study, a significant positive net effect for the specialisation indicator has been found, while the net effects of the diversity and competition indicators are negative. These results are in line with MAR theory, but mixed on Jacobs and Porter externalities as the latter should imply positive effects of competition. An interesting question is whether these results hold for all sectors analysed. In other words, do the pooled estimates for the full sample blur sector specific differences?

We address this issue by dividing the full sample into five subsamples corresponding to the five one-digit manufacturing sectors and estimating specification (2.83) sector by sector. These sectors are food and agricultural products, textile and leather, chemical and allied products, metal and machinery, and electric and electronic manufacturing. The first three sectors are considerably larger than the latter two sectors. The cross-sectional dimensions of the subsamples are \(N = \{18, 18, 29, 20, 10\}\), while \(T = 11\) in all cases. Two observations are lost in constructing the AHL and GMM estimators and the number of regressors in (2.83) is \(K = 11\).

\(^4\)To check the robustness of our results we have experimented with other measures, e.g. total regional population and total regional manufacturing employment. The estimation results of these specifications are similar to those presented here.

\(^5\)For example, regarding the one-digit sector food and agricultural products we have \(N = 18\) because data are available for three two-digit subsectors and six regions.

Figures in parentheses are standard errors

Results not reported here suggest that the lag structure of specification (2.83) is adequate. Longer lags of both the dependent and explanatory variables were also tried, but in general these regressors do not seem to have a significant contribution in explaining ln(va). Regarding the estimators employed, apart from LSDV, AHL and GMM results we present two different corrected LSDV estimators, i.e. based on preliminary GMM estimates (LSDVC,GMM) and AHL estimates (LSDVC,AHL) respectively. The corrected LSDV estimators use the approximation $B_{LSDV}^{(3)}$, i.e. $O(T^{-1})$, $O(N^{-1}T^{-1})$ and $O(N^{-1}T^{-2})$ bias terms have been removed. For LSDV, AHL and GMM the estimation of standard errors is based on conventional asymptotic approximations, while for the LSDVC variants

---

6Regarding GMM we use the GMMa, GMMb and GMMc variants as described in Section 2.5.
2.6. Dynamic externalities and local economic development in Morocco

bootstrap standard errors will be reported.

To save space we present some selected estimation results only. Table 2.7 presents
the estimation results for the sector chemical and allied products. Several remarks with
respect to the pattern of the estimation results can be made which apply to the estimates
of the other sectors too. First, regarding the autoregressive parameter all estimators
produce more or less plausible estimates implying a stable autoregressive process for
the dependent variable. Second, the GMM estimates of the autoregressive parameter
are close to the LSDV estimate, while the bias corrected LSDV variants and especially
the AHL estimator produce a relatively high estimate of the coefficient of the lagged
dependent variable regressor. Third, the estimated standard errors of LSDV and bias
corrected LSDV are in general considerably smaller than those of the AHL and GMM
estimators. Especially the AHL estimates are often poorly determined. Fourth, while
there are certainly differences between estimators, the pattern of the remaining estimates
is often similar across estimators. An exception is the immediate effect of the diversity
indicator, which shows differences between (corrected) LSDV and AHL/GMM variants.

Regarding the estimation results for the three indicators of externalities (sp, dv
and cp), the sign and significance of the corresponding coefficients do not vary much across
estimators. The impact multiplier or immediate effect of the specialisation indicator is
significant and positive, while the coefficient for the one-period lagged variable is often
significant and negative. Regarding diversity the immediate effect is positive and its lagged
effect significant and negative. Considering the competition indicator the immediate effect
is significant and negative, while the lagged effect is positive in general.

Table 2.8 reports estimation results for specification (2.83) for each one-digit sector.
Only the LSDV,GM estimates are shown, but the pattern for the other estimators is simi-
lar to that found in Table 2.7, reasserting the differences between estimation techniques.
Note that we have removed any insignificant dynamics. Across sectors the estimate of the
autoregressive parameter lies around 0.5 implying moderate persistence for the process
of the dependent variable. Regarding the indicators, specialisation and competition are in-
fluencing economic activity in all sectors albeit with different dynamics. Considering the
immediate effects we find significant positive specialisation effects and significant negative
competition effects, while the lagged effects are vice versa. The results for the diversity
indicator are less pronounced, i.e. we find significant effects for one sector only.

In general the estimation results in Tables 2.7 and 2.8 suggest that dynamic external-
ities do matter for local economic activity in Morocco. Table 2.9 presents the long-term
effects implied by the estimates of Table 2.8. The long-term effects of regional production
and unit wage costs are elasticities, while those for the externality indicators are semi-

elasticities. We find significant positive long-term effects for the specialisation indicator in four out of five sectors. Regarding diversity we find a significant negative long-term effect in one sector only. For the competition indicator negative long-term effects are present in all sectors.

Summarising the empirical evidence, in most sectors we do find positive specialisation effects and negative diversity and competition effects. Note that the construction of the diversity indicator is such that a negative coefficient implies a positive effect on economic activity. Hence, we conclude that both specialisation and diversity are beneficial for local economic development, while competition is harmful confirming the results of Bun and El Makhloufi (2001). However, in the present study we do find significant differences across

sectors, so actually pooling is not vindicated.

2.6.4 Accuracy of the estimates

The samples analysed have the dimensions $T = 11$ and $N = \{18, 18, 29, 20, 10\}$. Hence, the simulation results of the previous section can shed some light on the differences in estimation results. We will consider only the accuracy of coefficient estimators. Considering the case $N = 10, T = 10$ the simulations show that the bias in the coefficient estimators is small for the AHL estimator, moderate for bias corrected LSDV versions and substantial negative bias is found for ordinary LSDV and GMM estimators. Increasing the number of cross-sectional observations to $N = 20$ leads to an improvement in the accuracy of all estimators, but still ordinary LSDV and GMM estimators have a substantial negative bias in estimating the autoregressive parameter. Note that the AHL estimator is almost unbiased, but its variance is at least twice the variance of the LSDV estimator.

With these simulation results in mind and analysing the estimation results in Table 2.7 a remarkable resemblance is found between the various estimates of the autoregressive parameter and the picture showed by the simulations. Therefore, the ordinary LSDV and GMM results on $\gamma$ are most likely biased downward. On the other hand, bias corrected LSDV variants seem to be much less biased downward. Because of its large dispersion, the AHL estimator sometimes fails completely in producing sensible and accurate estimates.
This unstable behaviour emerges too in the simulations, where in a considerable number of cases the AHL estimate of the autoregressive parameter exceeded one. Hence, it seems wise to use GMM rather than AHL estimates in the construction of bias corrected LSDV estimators. Although the simulations did not show serious differences in performance, bias correction based on implausible estimates is not recommendable.

2.7 Concluding remarks

In this chapter the finite sample properties of various IV and GMM coefficient estimators for dynamic panel data models have been compared through Monte Carlo experiments with the inconsistent LSDV estimator and corrected consistent versions of LSDV. Kiviet (1995) compared in a similar Monte Carlo study the bias and efficiency of these estimators in panel data sets with T small and N moderately large and concluded that there is not a superior technique over a broad range of parameter values for this model. However, we find that when both T and N are rather small the bias corrected LSDV estimator has almost uniformly lower mean squared error in comparison to IV and GMM methods. This result is in line with results of Judson and Owen (1999) who used a slightly different design regarding the parameter values and sample dimensions. Also results of Harris and Mátéyás (1996), who used a totally different design, coincide with the findings in this chapter.

Adding an extra term to the approximation formula for the bias of the LSDV estimator, as derived in Kiviet (1999), does not improve the finite sample performance of this estimator notably. In fact, the present simulation results indicate that including $O(T^{-1})$ and $O(T^{-2})$ terms and omitting the $O(N^{-1}T^{-1})$ contributions accounts for most of the bias in the LSDV estimator. Also the sensitivity of the corrected LSDV estimator to the choice of the preliminary consistent estimator (AHL or GMM) is found to be low, although the finite sample performance of AHL is rather different as compared with GMM.

As far as the variance estimators are concerned, we find that for the corrected LSDV estimator variance estimation is highly non-standard when T is finite. For a particular implementation of corrected LSDV, i.e. when the estimate of the bias approximation is based on the AHL estimator, an analytical expression of its asymptotic variance has been found. In addition, bootstrap consistent variance estimators of LSDVc,GMM and LSDVc,AHL have been examined. The simulation results show that the analytical variance expression performs poorly for high values of the autoregressive parameter, which can be explained by the unstable behaviour of the AHL estimator for these parameter values. On the other hand, the bootstrap variance estimator is relatively accurate in many cases.
2.7. Concluding remarks

Also it is found that biases in LSDV and GMM variance estimators can be considerable, especially when \( T \) is small as is the case in many micro-economic panel data sets. The anomalies of these methods in small samples are even more evident when the empirical null distributions of ordinary \( t \) statistics are considered. The actual rejection probabilities of asymptotic \( t \) tests can differ substantially from the nominal size.

The available simulation evidence becomes helpful when analysing the relationship between dynamic externalities and local economic development in Morocco. We find some differences in estimation results when analysing five one-digit industrial sectors in isolation. In general, the sector specific results show that both specialisation and diversity are beneficial for local economic development, while competition is harmful confirming the results of Bun and El Makhroufi (2001) but revealing significant heterogeneity at the same time. As the available samples have both \( T \) and \( N \) relatively small, the simulation results can clarify the differences between estimators. The pattern of the coefficient estimates is remarkably in line with the corresponding simulation results. The anomalies of some estimation techniques are clearly visible and the superior performance of the corrected LSDV coefficient estimator in finite samples with both \( T \) and \( N \) small is apparent here.
Chapter 2. Finite sample accuracy in dynamic panel models

2.A The limiting distribution of LSDVc

First we derive the limiting distribution of $\sqrt{N}(\delta_h^* - \delta^*)$, the second term of (2.69), with $\delta^*$ given in (2.62) and $\delta_h^*$ given in (2.67). Next, we combine both terms in (2.69) and show that the resulting estimator is a sum of three zero-mean vectors. A central limit theorem applies and the corrected LSDV estimator is found to have a limiting Normal distribution. The derivation of the asymptotic covariance matrix is pursued only for the case that the AHL estimator (2.42) is used as a preliminary consistent estimator. Because of the complexity of the dependence of the instruments on $\varepsilon$ for the GMM estimator we have not derived the expression for the variance in that case.

The expression (2.67) for $\delta_h^*$ contains a factor

$$\hat{\delta}_{\varepsilon,h}^2 \left( \frac{1}{1 - \gamma_h^T} - \frac{1 - \gamma_h^T}{T(1 - \gamma_h^T)^2} \right), \quad h = AHL, GMM, \quad (2.A.1)$$

whose components can be approximated as follows. First we have

$$\hat{\delta}_{\varepsilon,h}^2 = \sigma_\varepsilon^2 + (\hat{\delta}_{\varepsilon,h}^2 - \sigma_\varepsilon^2)$$

$$= \sigma_\varepsilon^2 + \left( \frac{(y - W\delta_h)'A(y - W\delta_h)}{N(T - 1) - (K + 1)} - \sigma_\varepsilon^2 \right)$$

$$= \sigma_\varepsilon^2 + \left( \frac{[\varepsilon - W(\delta_h - \delta)]'A[\varepsilon - W(\delta_h - \delta)]}{N(T - 1) - (K + 1)} - \sigma_\varepsilon^2 \right)$$

$$= \sigma_\varepsilon^2 + \left( \frac{\varepsilon'A\varepsilon}{N(T - 1) - (K + 1)} - \sigma_\varepsilon^2 \right) + O_p(N^{-1}),$$

where the second term is $O_p(N^{-1/2})$. This follows from

$$E \left[ \frac{\varepsilon'A\varepsilon}{N(T - 1) - (K + 1)} - \sigma_\varepsilon^2 \right] = \sigma_\varepsilon^2 \left( \frac{N(T - 1)}{N(T - 1) - (K + 1)} - 1 \right) = O(N^{-1})$$

and

$$\text{Var} \left[ \frac{\varepsilon'A\varepsilon}{N(T - 1) - (K + 1)} - \sigma_\varepsilon^2 \right] = O(N^{-1}),$$

which results from $\text{Var} [\varepsilon'A\varepsilon] = 2\sigma_\varepsilon^4 \text{tr}(AA) = 2N(T - 1)\sigma_\varepsilon^4$. The order of the remainder term can be established from $W'A\varepsilon = O_p(N^{1/2})$ and $(\delta_h - \delta) = O_p(N^{-1/2})$. Given the magnitude of the remainder term we can simplify the second term using

$$\left( \frac{\varepsilon'A\varepsilon}{N(T - 1) - (K + 1)} - \sigma_\varepsilon^2 \right) = \left( \frac{\varepsilon'A\varepsilon}{N(T - 1)} - \sigma_\varepsilon^2 \right) + O_p(N^{-1}),$$

so we have

$$\hat{\delta}_{\varepsilon,h}^2 = \sigma_\varepsilon^2 + \left( \frac{\varepsilon'A\varepsilon}{N(T - 1)} - \sigma_\varepsilon^2 \right) + O_p(N^{-1}). \quad (2.A.2)$$
A next component of (2.A.1) is

\[
\frac{1}{1 - \gamma - (\gamma_h - \gamma)} = \frac{1}{1 - \gamma - (\gamma - \gamma)} \quad (2.A.3)
\]

\[
= \frac{1}{1 - \gamma} \left[ 1 - \frac{1}{1 - \gamma} (\gamma - \gamma) \right]^{-1}
\]

\[
= \frac{1}{1 - \gamma} \left[ 1 + \frac{1}{1 - \gamma} (\gamma - \gamma) \right] + O_p(N^{-1})
\]

\[
= \frac{1}{1 - \gamma} + \left( \frac{1}{1 - \gamma} \right)^2 (\gamma - \gamma) + O_p(N^{-1}),
\]

where the second term is \(O_p(N^{-1/2})\). From (2.A.3) we easily find

\[
\left( \frac{1}{1 - \gamma_h} \right)^2 = \left( \frac{1}{1 - \gamma} \right)^2 + 2 \left( \frac{1}{1 - \gamma} \right)^3 (\gamma_h - \gamma) + O_p(N^{-1}). \quad (2.A.4)
\]

Next we obtain

\[
1 - \gamma_h^T = 1 - [(\gamma_h - \gamma)^T] = 1 - \gamma^T - T \gamma^{-1} (\gamma_h - \gamma) + O_p(N^{-1}). \quad (2.A.5)
\]

For the second factor of (2.A.1) the results (2.A.3) - (2.A.5) yield

\[
\left. \frac{1}{1 - \gamma_h} - \frac{1 - \gamma_h^T}{T (1 - \gamma_h)^2} \right| = \frac{1}{1 - \gamma} - \frac{1 - \gamma^T}{T (1 - \gamma)^2}
\]

\[
+ \left[ \left( \frac{1 + \gamma^T}{(1 - \gamma)^2} - \frac{2}{T (1 - \gamma)^3} \right) \frac{\gamma - \gamma}{(1 - \gamma)^3} \right] (\gamma_h - \gamma) + O_p(N^{-1}). \quad (2.A.6)
\]

From (2.A.2) and (2.A.6) we obtain

\[
\sigma_{\varepsilon, h}^2 \left( \frac{1}{1 - \gamma_h} - \frac{1 - \gamma_h^T}{T (1 - \gamma_h)^2} \right) - \sigma_{\varepsilon}^2 \left( \frac{1}{1 - \gamma} - \frac{1 - \gamma^T}{T (1 - \gamma)^2} \right) =
\]

\[
\sigma_{\varepsilon}^2 \left[ \frac{1 + \gamma^T}{(1 - \gamma)^2} - \frac{2}{T (1 - \gamma)^3} \right] (\gamma_h - \gamma)
\]

\[
+ \left( \frac{1}{1 - \gamma} - \frac{1 - \gamma^T}{T (1 - \gamma)^2} \right) \left( \varepsilon' A \varepsilon \right) \left( \frac{1}{N(T - 1)} - \sigma_{\varepsilon}^2 \right)
\]

\[+ O_p(N^{-1}).]
Chapter 2. Finite sample accuracy in dynamic panel models

giving

\[
\sqrt{N} \left( \hat{\delta}_n - \delta^* \right) = -\sigma^2 \left[ \frac{1 + \gamma^{T-1}}{(1 - \gamma)^2} - \frac{2}{T} \frac{1 - \gamma^T}{(1 - \gamma)^3} \right] \Sigma_{W,AW}^{-1} e_1 e_1' \sqrt{N} \left( \hat{\delta}_n - \delta \right) - tr(\Pi_T) \Sigma_{W,AW}^{-1} e_1 \sqrt{N} \left( \frac{\epsilon' A \epsilon}{N(T - 1)} - \sigma^2 \right) + O_p(N^{-1/2})
\]

\[= -\sigma^2 d_1 e_1' \sqrt{N} \left( \hat{\delta}_n - \delta \right) - d_2 \sqrt{N} \left( \frac{\epsilon' A \epsilon}{N(T - 1)} - \sigma^2 \right) + O_p(N^{-1/2}), \tag{2.8}
\]

where \(d_1\) and \(d_2\) have been defined implicitly.

Now we find from (2.69) that the limiting distribution of \(\sqrt{N}(\hat{\delta}_{SDV,c,h} - \delta)\) must be the same as the limiting distribution of the sum of the three zero-mean vectors \(v_0, v_{1,h}\) and \(v_2\), where

\[
v_0 = \Sigma_{W,AW}^{-1} \left( \frac{1}{\sqrt{N}} [W'A \epsilon + (\epsilon' \Pi \epsilon - \sigma^2 tr(\Pi)) e_1] \right)
\]

\[
v_{1,AHL} = \sigma^2 d_1 e_1' \Sigma_{Z,AW}^{-1} \left( \frac{1}{\sqrt{N}} Z'D \epsilon \right)
\]

\[
v_{1,GMM} = \sigma^2 d_1 e_1' (\Sigma_{Z,AW}^{-1} \Sigma_{Z,HW}^{-1} \Sigma_{Z,W})^{-1} \Sigma_{Z,AW}^{-1} \Sigma_{Z,HW}^{-1} \left( \frac{1}{\sqrt{N}} Z'D \epsilon \right)
\]

\[
v_2 = d_2 \sqrt{N} \left( \frac{\epsilon' A \epsilon}{N(T - 1)} - \sigma^2 \right).
\]

Hence, the limiting distribution of the corrected LSDV estimator is

\[
\sqrt{N}(\hat{\delta}_{SDV,c,h} - \delta) \xrightarrow{d} N[0, \Omega_{SDV,c,h}], \tag{2.9}
\]

where

\[
\Omega_{SDV,c,h} = \lim_{N \to \infty} \text{Var} [v_0 + v_{1,h} + v_2]. \tag{2.10}
\]

Taking now the AHL estimator \(\hat{\delta}_{AHL}\) for \(\hat{\delta}_h\), some of the components of \(\Omega_{SDV,c,h}\) have been established before, so we easily find for \(N \to \infty\)

\[
\text{Var} [v_0] = \sigma^2 \Sigma_{W,AW}^{-1} + \sigma^4 tr(\Pi_T \Pi_T) \Sigma_{W,AW}^{-1} e_1 e_1' \Sigma_{W,AW}^{-1}
\]

\[
\text{Var} [v_{1,AHL}] = \sigma^2 d_1 e_1' \Sigma_{Z,AW}^{-1} \Sigma_{Z,HW}^{-1} (\Sigma_{Z,W})^{-1} e_1 d_1' \tag{2.7}
\]

\[
\text{Var} [v_2] = \frac{2\sigma^4}{T - 1} d_2 d_2'.
\]
2.A. The limiting distribution of LSDVc

where we used results of (2.64), (2.48) and one mentioned above (2.A.2) respectively. Next we obtain for $N \to \infty$

\[
E[v_0v_2'] = \sum_{WAW}^{-1}E\left[\bar{W}'A\varepsilon + (\varepsilon'\Pi\varepsilon - \sigma^2 tr(\Pi)) e_1 \left(\frac{\varepsilon'A\varepsilon}{N(T-1)} - \sigma^2\right)\right] d_2
\]
\[
= \sum_{WAW}^{-1}e_1 d_2 E\left[(\varepsilon'\Pi\varepsilon - \sigma^2 tr(\Pi)) \left(\frac{\varepsilon'A\varepsilon}{N(T-1)} - \sigma^2\right)\right]
\]
\[
= 2\sigma^4 \frac{tr(\Pi_T)}{T-1} \sum_{WAW}^{-1} e_1 d_2
\]
\[
= \frac{2\sigma^4}{T-1} \bar{d}_2 d_2.
\]

To derive covariances with $v_{1,AHL}$ we have to express the stochastic nature of the instruments $Z = [J*_{y_{-1}:DX}]$ and the disturbances $D\varepsilon$ explicitly. Analogue to (2.23) we may write

\[
Z = \bar{Z} + \bar{Z} = \bar{Z} + J^*L\Gamma\varepsilon e_1',
\]

see Kiviet (1999). This can be used to obtain

\[
E\left[v_0v_{1,AHL}'\right] = \frac{\sigma^2}{N} \sum_{WAW}^{-1} E\left[(\bar{W}'A\varepsilon + (\varepsilon'\Pi\varepsilon - \sigma^2 tr(\Pi)) e_1\right]
\]
\[
\times (\varepsilon'D'\bar{Z} + \varepsilon'D'J^* L\Gamma\varepsilon e_1') \left(\Sigma_{ZW}\right)^{-1} e_1 d_1'
\]
\[
= \frac{\sigma^2}{N} \sum_{WAW}^{-1} E\left[(\varepsilon'\Pi\varepsilon - \sigma^2 tr(\Pi)) \varepsilon'D'J^* L\Gamma\varepsilon e_1'e_1'\right] \left(\Sigma_{ZW}\right)^{-1} e_1 d_1'
\]
\[
= \frac{\sigma^4}{N} \sum_{WAW}^{-1} \bar{W}'AD'\bar{Z}(\Sigma_{ZW})^{-1} e_1 d_1'
\]
\[
+ \frac{\sigma^6}{N} \left(tr(\Pi D'J^* L\Gamma) + tr(\Pi' L'J^* D)\right) \sum_{WAW}^{-1}(\Sigma_{ZW})^{-1} e_1 d_1',
\]

and

\[
E\left[v_{1,AHL}v_2'\right] = \sigma^2 d_1 e_1' \sum_{ZW}^{-1} e_1 E\left[\varepsilon'\Gamma' D\varepsilon\left(\frac{\varepsilon'A\varepsilon}{N(T-1)} - \sigma^2\right)\right] d_2
\]
\[
= 2\sigma^6 tr(D'J^* L\Gamma A)d_1 e_1' \Sigma_{ZW}^{-1} e_1
\]
\[
= O,
\]

noting that $tr(D'J^* L\Gamma) = 0$ and $tr(D'J^* L\Gamma A) = 0$. Defining

\[
\Sigma_{WADZ} = \lim_{N \to \infty} \left(\frac{1}{N} \bar{W}'AD'\bar{Z}\right)
\]
\[
= \lim_{N \to \infty} \left(\frac{1}{N} \bar{W}'AD'\bar{Z}\right) + \sigma^2 tr(\Pi_T D_T J^* L_T \Gamma T)e_1 e_1',
\]
we find
\[
\lim_{N \to \infty} E \left[ v_0 \nu_{L,AHL} \right] = \sigma^2_\epsilon \Sigma^{-1}_{W, AW} \Sigma_{WADZ}(\Sigma'_{ZW})^{-1} e_1 \bar{d}_1^2 \\
+ \sigma^2_\epsilon tr(\Pi_T \Gamma'_T L'_T J'_T D_T) \Sigma^{-1}_{W, AW}(\Sigma'_{ZW})^{-1} e_1 \bar{d}_1^2.
\]

Collecting terms this yields
\[
\Omega_{LSDVC,AHL} = \sigma^2_\epsilon \Sigma^{-1}_{W, AW} + \sigma^2_\epsilon tr(\Pi_T \Pi_T) \Sigma^{-1}_{W, AW} e_1 e'_1 \Sigma^{-1}_{W, AW} \\
+ \sigma^2_\epsilon [\Sigma^{-1}_{W, AW} \Sigma_{WADZ}(\Sigma'_{ZW})^{-1} e_1 \bar{d}_1^2 + (6/ (T - 1)) \sigma^2_\epsilon \bar{d}_2^2] \\
+ \sigma^2_\epsilon [\Sigma^{-1}_{W, AW} \Sigma_{WADZ}(\Sigma'_{ZW})^{-1} e_1 \bar{d}_1^2 + \bar{d}_1 e'_1 (\Sigma_{ZW})^{-1} \Sigma_{WADZ} \Sigma^{-1}_{W, AW}] \\
+ \sigma^2_\epsilon tr(\Pi_T \Gamma'_T L'_T J'_T D_T) [\Sigma^{-1}_{W, AW}(\Sigma'_{ZW})^{-1} e_1 \bar{d}_1^2 + \bar{d}_1 e'_1 (\Sigma_{ZW})^{-1} \Sigma^{-1}_{W, AW}].
\]

For the case where the \( \sqrt{N} \)-consistent estimator \( \hat{\delta}_{GMM} \) of (2.49) is employed, we find that \( \sqrt{N} \left( \hat{\delta}_{LSDVC,GMM} - \delta \right) \) has a limiting distribution where the variance \( \Omega_{LSDVC,GMM} \) can be obtained in the same way. The only difference is that we then have to evaluate \( v_{1,GMM} \) as in (2.A.8). Because of the complexity of the dependence of the instruments \( Z_t \) on \( \varepsilon \) we have not derived the expression for the variance \( \Omega_{LSDVC,GMM} \), but it is feasible.

### 2.B Details on the simulation design

The simulation design is basically the same as in Kiviet (1995), especially for the case where all variables are stationary. The generating equation for \( y_{it} \) is
\[
y_{it} = \gamma y_{i,t-1} + \beta x_{it} + \eta_i + \varepsilon_{it}, \tag{2.B.1}
\]
for individuals \( i = 1, ..., N \) and time periods \( t = 1, ..., T \). Substitution of the latent variable \( v_{it} \) (2.10), free of the individual effect, in (2.B.1) leads to
\[
v_{it} = \gamma v_{i,t-1} + \beta x_{it} + \varepsilon_{it}, \tag{2.B.2}
\]
For \( K = 1 \) and upon omitting the index \( i \), the model for every cross-sectional unit becomes
\[
\begin{align*}
v_{t} &= \gamma v_{t-1} + \beta x_{t} + \varepsilon_{t} \\
x_{t} &= \rho x_{t-1} + \xi_{t}.
\end{align*}
\tag{2.B.3}
\]
Using \( L \) for the lag-operator and substituting the second equation of (2.B.3) into the first, we obtain for \( |\rho| < 1 \)
\[
v_{t} = \frac{1}{(1 - \gamma L)(1 - \rho L)} \xi_{t} + \frac{1}{1 - \gamma L} \varepsilon_{t} \\
= \beta \phi_{t} + \psi_{t}. \tag{2.B.4}
\]
2.B. Details on the simulation design

The latent variable \( v_t \) consists of two independent components, viz. \( \beta \phi_t \) and \( \psi_t \), which are an AR(2) and AR(1) process respectively. Data for the processes \( \xi_t \) and \( \epsilon_t \) are obtained through sampling independently from \( \mathcal{IN}(0, \sigma^2_\xi) \) and \( \mathcal{IN}(0, \sigma^2_\epsilon) \). Next \( \sigma^2_\xi \) is determined through fixing the signal-to-noise ratio, which is a measure of the explanatory power of the regressors, defined as \( \text{Var}(v_t - \epsilon_t)/\text{Var}(\epsilon_t) \). This is in the stationary case

\[
\sigma^2_\xi = \beta^2 \frac{\sigma^2_\epsilon}{\sigma^2_\xi} \left[ \frac{1 + (\gamma + \rho)^2}{1 + \gamma \rho} (\gamma \rho - 1) - (\gamma \rho)^2 \right]^{-1} + \frac{\gamma^2}{1 - \gamma^2}.
\] (2.B.5)

When values for \( \gamma, \beta, \rho \) and for \( \sigma^2_\xi \) have been chosen, \( \sigma^2_\xi \) is determined through

\[
\sigma^2_\xi = \frac{\sigma^2_\epsilon}{\beta^2} \left[ \sigma^2_\xi - \frac{\gamma^2}{1 - \gamma^2} \right] \left[ 1 + \frac{(\gamma + \rho)^2}{1 + \gamma \rho} (\gamma \rho - 1) - (\gamma \rho)^2 \right]^{-1}.
\] (2.B.6)

The series \( \phi_t, \psi_t \) and \( x_t \), including starting values \( \phi_0, \phi_1, \psi_0 \) and \( x_0 \), are obtained by employing a procedure described in McLeod and Hipel (1978). Let \( z_t \) be a normal stationary AR(\( p \)) process, i.e.

\[
z_t = \alpha_1 z_{t-1} + \ldots + \alpha_p z_{t-p} + u_t, \quad t = 1, \ldots, T
\] (2.B.7)

with \( u_t \sim \mathcal{IN}(0, \sigma^2_u) \). It is easy to generate a series \( u_1, \ldots, u_T \). Consider now the first \( p \) observations \( z = (z_1, \ldots, z_p) \) and \( u = (u_1, \ldots, u_p) \). Let \( \sigma^2_u \Sigma \) be the covariance matrix of \( z \) and consider the Cholesky decomposition of \( \Sigma \),

\[
\Sigma = MM',
\] (2.B.8)

where the matrix \( M \) is lower triangular. It is easily seen that \( z \) and \( Mu \) have the same distribution, and hence a \( p \) element vector \( z \) can be generated easily from the first \( p \) elements of \( u \) upon making use of the autocovariance function of the AR(\( p \)) process (which determines \( \Sigma \)) and the Cholesky decomposition \( M \) of the covariance matrix \( \Sigma \). The remaining \( T - p \) observations \( t = p + 1, \ldots, T \) can be generated now recursively according to (2.B.7).

Hence, once starting values have been obtained, series \( x \) and \( y \) can be generated according to

\[
\begin{align*}
\phi_t &= (\gamma + \rho) \phi_{t-1} - \gamma \rho \phi_{t-2} + \xi_t \\
\psi_t &= \gamma \psi_{t-1} + \epsilon_t \\
x_t &= \rho x_{t-1} + \xi_t \\
y_t &= \beta \phi_t + \psi_t + \frac{1}{1 - \gamma} \eta_t
\end{align*}
\] (2.B.9)

where the vector of individual specific effects \( \eta \) is drawn from \( \mathcal{IN}(0, \sigma^2_\eta) \). The standard deviation \( \sigma_\eta \) of the individual specific effect is determined by

\[
\sigma_\eta = \mu \sigma_\epsilon (1 - \gamma).
\] (2.B.10)
In this way the impact on $y$ of both the individual specific effect $\eta$ and the general disturbance term $\varepsilon$ are independent of the values of $\gamma$ and $\beta$, and the relative importance of both shocks can be varied through choosing different values for $\mu$. For example, when $\mu$ is unity the impact on $y$ of both shocks is the same.

A different situation arises when the exogenous variable $x$ is non-stationary. In this case model (2.B.3) for the latent variable $v_t$ becomes

$$
\begin{align*}
  v_t &= \gamma v_{t-1} + \beta x_t + \varepsilon_t \\
  x_t &= x_{t-1} + \xi_t.
\end{align*}
$$

(2.B.11)

The exogenous variable can be written as

$$
x_t = x_0 + \sum_{s=1}^{t} \xi_s.
$$

(2.B.12)

Now a similar expression as in (2.B.4) can be obtained through substitution of (2.B.12) into the equation for $v_t$, i.e.

$$
v_t = \frac{\beta}{1-\gamma} x_0 + \beta \sum_{s=1}^{t} (1 - \gamma L)^{-1} \xi_s + (1 - \gamma L)^{-1} \varepsilon_t
$$

$$
= \frac{\beta}{1-\gamma} x_0 + \beta \sum_{s=1}^{t} \phi^*_s + \psi_t.
$$

(2.B.13)

The latent variable has again two random components, viz. the $AR(1)$ process $\psi_t$ and the partial sum of an $AR(1)$ process. Starting values for the processes $\phi^*_s$ and $\psi_t$ can be obtained again by using the procedure described above. Drawings for $y$ and $x$ can now be generated from

$$
\begin{align*}
  \phi^*_t &= \gamma \phi^*_{t-1} + \xi_t \\
  \psi_t &= \gamma \psi_{t-1} + \varepsilon_t \\
  x_t &= x_{t-1} + \xi_t \\
  y_t &= \frac{\beta}{1-\gamma} x_0 + \beta \sum_{s=1}^{t} \phi^*_s + \psi_t + \frac{1}{1-\gamma} \eta.
\end{align*}
$$

(2.B.14)

after choosing a value for $x_0$. This has been set equal to zero, without loss of generality.

While the generation of the data in case of a non-stationary exogenous variable does not cause any complications, the control over the signal is not so straightforward. The signal in the non-stationary case is not constant through time, but increasing. We find

$$
\sigma^2_{s,t} = \frac{\beta^2}{(1 - \gamma^2)} \frac{\sigma^2_{\varepsilon}}{\sigma^2_{\xi}} \left[ t(1 + \frac{2\gamma}{1-\gamma}) - \frac{2\gamma(1 - \gamma')}{(1 - \gamma)^2} \right] + \frac{\gamma^2}{1 - \gamma^2},
$$

(2.B.15)
2.B. Details on the simulation design

for \( t = 1, \ldots, T \). To control the signal in the experiments the mean value of \( \sigma_{s,t}^2 \) (over \( t = 1, \ldots, T \)) has been fixed. In this way it was tried to make the outcomes for \( \rho = 1 \) more or less comparable with the results for the stationary case.
