CHAPTER 2

H. pylori co-localizes with MUC5AC
in the human stomach

Abstract

Background
The bacterium *H. pylori* is able to adhere to and to colonize the human gastric epithelium, yet the primary gene product responsible as a receptor for its adherence has not been identified.

Aims
To investigate the expression of the gastric mucins MUC5AC and MUC6 in the the gastric epithelium in relation to *H. pylori* colonization in order to examine their possible roles in the binding of *H. pylori*.

Patients
Seventy two consecutive patients suspected of having *H. pylori* infection.

Methods
MUC5AC, MUC6, and *H. pylori* were detected in single sections of antral biopsy specimens using immunohistochemical triple staining.

Results
MUC5AC was expressed in the superficial epithelium, and the upper part of the gastric pits. MUC6 expression was detected in the lower part of the gastric pits. The expression of both mucins in the epithelium was complementary. In each patient, there was a sharply delineated transition between MUC5AC- and MUC6-producing cell populations. In all *H. pylori*-positive patients there was a striking colocalization of *H. pylori* and MUC5AC; more than 99% of the bacteria were associated with either extracellular MUC5AC or the apical domain of MUC5AC-producing cells.

Conclusions
*H. pylori* is very closely associated with extracellular MUC5AC and epithelial cells that produce MUC5AC. This indicates that MUC5AC, but not MUC6, plays a role in the adhesion of *H. pylori* to the gastric mucosa.
Introduction

The Gram-negative bacterium *Helicobacter pylori* has the unique ability to colonize the human stomach. Infection is widespread with a prevalence of more than 90% in some developing countries.\(^1\) Colonization results in chronic infection, and leads to gastric inflammation.\(^2\) The presence of the bacterium is associated with peptic ulcer disease,\(^3\) atrophic gastritis, gastric adenocarcinoma,\(^4,5\) and gastric MALT lymphoma.\(^6\) *H. pylori* does not invade the gastric mucosa, but resides in the gastric mucosal layer of the superficial epithelium, and can attach to gastric epithelial cells, with a preference for the intercellular junctions.\(^7\) In *in vitro* experiments, the attachment to the epithelial cells has been shown to induce signal transduction in gastric cells, with activation of the transcription factor NF-κB.\(^8-11\) Subsequently, the cytokine interleukin-8 (an important T-cell and neutrophil chemoattractant and critical mediator in the *H. pylori*-induced inflammatory process) is produced. Thus, physical contact of the bacterium with the epithelial cell plays a pivotal role in the outcome of infection.\(^12\) It seems likely that homing to the mucosal layer and attachment to mucosal cells are separate processes and may be mediated by different bacterial adhesins and host receptors.

An interesting example of this exists in colonization of the intestine by another Gram negative bacterium, the enteropathogenic *Escherichia coli*. This bacterium uses its pili to bind specifically to intestinal mucin in various models,\(^13-15\) possibly accounting for its colonization pattern. The bacterial membrane protein intimin and a receptor, Hp90, on the intestinal cell however mediate intimate adhesion to the intestinal cells. It has recently been demonstrated that this receptor is not of host cell origin but actually encoded by the bacterium and translocated into the mammalian cell membrane,\(^16\) thus renamed Tir (for translocated intimin receptor). This intimin-Tir adhesion can of course not account for its tissue specificity. Thus, separate interactions are involved in the tropism of this *E. coli* for the intestine, and adherence to the intestinal cells. This provides yet another instructive example of the multimolecular nature of enteropathogen-host cell interactions. *H. pylori* resides only in an ecological niche of mucus produced by gastric epithelium, so the putative receptor has to be specific for gastric mucus. Interestingly, it was shown that *H. pylori* is able to bind to gastric mucin *in vitro*.\(^17\) Mucin is the most important structural component of the mucus gel layer.\(^18,19\) These highly O-glycosylated molecules form hydrated multimeric complexes. To date, nine human epithelial mucin genes have been identified and designated *MUC1-4*, *MUC5B*, *MUC5AC*, and *MUC6-8*.\(^19\) Most of these genes are expressed in a cell type- and tissue-specific manner.\(^20-26\) Several of these mucins show a tissue-specific regional distribution along the cephalo-caudal axis of the gastrointestinal mucosa. On the other hand some of these, particular *MUC1* and *MUC4*, are expressed in most regions of the gastrointestinal tract. *MUC7* is only expressed in the salivary glands,\(^25\) *MUC5B* is also expressed in the salivary glands and is the predominant
mucin in the gallbladder, and MUC2 and MUC3 are expressed in the intestine. The secretory mucins MUC5AC and MUC6 are expressed in the epithelium of the stomach. The superficial epithelium and the cells in the upper part of the gastric pits produce MUC5AC. MUC6 expression is confined to the lower mucous neck cells and the cells of the antral glands. As *H. pylori* binds gastric mucin in vitro and seems to reside in the mucus layer overlaying the MUC5AC-producing cells of the superficial epithelium, we sought to determine a possible colocalization of MUC5AC and *H. pylori* in the human stomach. Furthermore, we were interested to determine if the presence of the bacterium would alter the expression pattern of the gastric mucins, MUC5AC and MUC6.

**Materials & Methods**

**Patients**

Gastroduodenoscopy was performed on 72 consecutive patients referred to the endoscopy unit of the Academic Medical Center in Amsterdam for chronic upper abdominal complaints. These patients were enrolled in a prospective study investigating the prevalence of *H. pylori* infection in patients on antacid therapy, which was approved by the Ethics Committee of the Academic Medical Center. Biopsies were taken from the antrum of the stomach as part of these investigations. Specimens were fixed in phosphate buffered saline (PBS) buffered paraformaldehyde, and embedded in paraffin. *H. pylori* status was determined by culturing the bacteria, and confirmed by an independent pathologist by routine histology (H&E stain). The histological grade of gastritis was scored according to the Sydney classification.

**Antibodies**

To detect MUC5AC, we used either the mouse monoclonal antibody 45M1 (Novocastra, Newcastle upon Tyne, England), rabbit polyclonal antihuman gastric mucin (anti-HGM), or mouse monoclonal CLH2 kindly provided by C.A. Reis. To detect MUC6, we used MUC6.1 a polyclonal antibody raised in rabbit, kindly provided by C. de Bolós. For MUC2 detection, WE9, a monoclonal antibody against MUC2, raised in mouse was used, a kind gift of D.K. Podolsky. M3P, a polyclonal antibody against MUC3, was generously provided by Y.S. Kim. For staining of *H. pylori* we used either a rabbit polyclonal antibody (DAKO, Glostrup, Denmark) or pooled serum of seven different *H. pylori*-immunized rabbits, a gift of F. Namavar.

**Immunohistochemistry**

To detect MUC5AC, MUC6, and *H. pylori* in a single section, for optimal investigation of their possible colocalization, an immunohistochemical triple staining method was developed. Paraffin sections (6 μm) were deparaffinated. Endogenous peroxidase was blocked using 1.5% H₂O₂ in PBS for 30
H. pylori co-localizes with MUC5AC in the human stomach

...min at room temperature (RT), and washed in PBS. Sections were heated for 10 min at 100°C in 0.01 M sodium citrate pH 6.0 to enhance antigen retrieval. After cooling on ice for 15 min and washing in PBS, sections were blocked in TENG-T (10 mM Tris, 5 mM EDTA, 0.15 M NaCl, 0.25% gelatin, 0.05% (v/v) Tween-20, pH 8.0) at RT. After washing in PBS, the rabbit anti-MUC6 polyclonal antiserum (MUC6.1) was applied (1:200 dilution), and incubated overnight at 4°C. Thereafter, sections were washed in PBS, incubated with a secondary biotinylated antibody (goat anti-rabbit Ig/BIO, DAKO) in a 1:500 dilution for 1 h at RT, and washed in PBS. Sections were incubated with AComplex (Vector laboratories, Burlingame, CA) for 1 h at RT, and washed with PBS. Enzyme activity was detected with diaminobenzidine (DAB, Sigma, St Louis, MO), 5 mg of DAB, and 10 µl of 30% H$_2$O$_2$, in 10 ml 50 mM Tris pH 7.8, resulting in a brown color. Subsequently samples were heated at 90-100°C in 10 mM sodium citrate for 5 min and after cooling, blocked with TENG-T, and washed in PBS. Sections were incubated overnight at 4°C, with a mixture of mouse anti-MUC5AC (i.e. 45M1), and rabbit anti-H. pylori antibodies in 1:50 and 1:5000 dilutions, respectively. On the third day, sections were washed in PBS, and incubated with a mixture of two secondary antisera, one labeled with alkaline phosphatase and the other biotinylated, at RT for 1 h (goat anti-rabbit Ig/AP, and goat anti-mouse Ig/BIO in 1:20 and 1:100 dilutions respectively, DAKO). After washing in PBS, sections were incubated for 30 min in streptavidin β-galactosidase (strept β-gal, Boehringer Mannheim, Mannheim Germany) diluted 1:40 in PBS at RT. The strep β-gal was detected using 1% X-gal (DAKO) in iron phosphate buffer (0.02% MgCl$_2$.6H$_2$O, 0.099% potassium ferriyanide, 0.127% potassium ferrocyanide) at 37°C for 15-30 min, resulting in a blue/turquoise color. After washing in Tris-buffered saline, the alkaline phosphatase was detected using the Fast Red detection method (DAKO), staining H. pylori in a reddish purple. Sections were briefly counterstained with hematoxillin, and mounted in Ultramount (DAKO), an aqueous mounting medium.

Two investigators (GRvdB, KMAJT) scored the sections independently in a blinded manner. The distribution patterns of MUC5AC and MUC6 were assessed, and the sections were evaluated for the presence of H. pylori, and when present, the percentage of bacteria associated with MUC5AC- or MUC6-producing cells was scored.

**Immunohistochemical controls**

Controls included staining of normal human gastric tissue sections with antibodies against MUC2 and MUC3, and staining of normal human duodenal sections with anti-MUC2, -MUC3, -MUC5AC and -MUC6. This showed that anti-MUC5AC and anti-MUC6 reacted specifically with gastric mucins, whereas anti-MUC2 and anti-MUC3 reacted exclusively with duodenal epithelium, but not with gastric epithelium. Also, when each of the primary or secondary antibodies were omitted no immunoreactivity was observed with any of the detection methods.

H. pylori-positive patients are denoted in italics.

Results

Patient characteristics

The 72 endoscopic procedures were performed in 64 patients; eight patients underwent endoscopy twice, for evaluation of eradication treatment. Four of these eight patients were successfully treated. Of the 72 biopsies studied, 34 were from H. Pylori-positive patients, four after failed eradication treatment. Thirty eight biopsies were from H. pylori-negative patients (19 after successful eradication therapy). The presence of H. pylori was independently assessed by both culturing the bacterium and by a pathologist. We were able to detect the bacterium by immunohistochemistry in all infected patients, and thus the concordance with the independent pathologist and the microbiological detection method was 100%. The severity of gastritis was scored according to the Sydney classification (Table 1).

Mucin Expression Patterns

In each patient, we examined the expression patterns of MUC5AC and MUC6, and their relation to H. pylori colonization of the gastric mucus layer. We were able to visualize the entire pit-gland axis in the antral mucosa of each patient. Single sections were stained for MUC5AC, MUC6 and H. pylori using an immunohistochemical triple staining method. Virtually all epithelial cells of the superficial epithelium and the antral glands express mucin, either MUC5AC or MUC6.

The expression of MUC5AC was localized to cells the superficial epithelium of the stomach and the upper parts of the gastric glands (Fig. 1A-F). In separate experiments we found that these cells were detected by each of the antibodies used to detect MUC5AC (Data not shown). The anti-HGM antiserum and the monoclonal antibody 45M1, which both recognize the MUC5AC precursor as well as the mature MUC5AC molecules, gave near indistinguishable results, staining the intracellular storage granules as well as the secreted mucin (Shown in Fig. 1 for 45M1). Based on the immunohis-
tochemical staining of consecutive antrum sections of many patients, it appeared that the monoclonal antibody CLH2 only stained the perinuclear region of MUC5AC expressing cells (Data not shown). This was in accordance with the fact that CLH2 is only able to recognize the MUC5AC precursor. As 45M1 was able to stain intracellular as well as extracellular MUC5AC we chose to use this antibody in our triple labeling experiments. Using 45M1, the distribution of MUC5AC staining among the epithelial cells appeared uniform and continuous in all examined biopsies, and this basic expression pattern was not affected in H. pylori-infected patients (compare Fig. 1A and 1C with 1D-F).

The anti-MUC6 antibody showed strong perinuclear reactivity in the cells of the lower parts of the antral glands (Fig. 1A-F and 1H-J). This antibody is able to recognize the MUC6 precursor, explaining the perinuclear staining. We did not observe reactivity of the anti-MUC6 antiserum with cells of the superficial epithelium or upper part of the glands in any of the biopsies. We found complementary expression of MUC5AC and MUC6 in each patient, but virtually no co-localization of both mucins (Fig. 1). The area of transition between MUC5AC- and MUC6-producing cells was always sharply delineated (Fig. 1A-F, and 1I).

In many H. pylori-positive patients we noted a considerable decrease in the number of MUC5AC expressing cells, concomitant with a seeming increase in MUC6-producing cells (compare e.g. Fig. 1C and 1D). This apparent shift in number of MUC5AC and MUC6 expressing cells did however not correlate with any change in staining intensity or with the continuity of the staining patterns of either mucin.

**H. pylori localization**

Using the triple staining method, we were able to study the relationship between mucin expression in the stomach and H. pylori colonization. We found a striking co-localization of H. pylori with MUC5AC in each of the patients infected with the bacterium (Fig. 1E-I). In all biopsy material more than 99% of the bacteria were associated with extracellular MUC5AC, or closely associated with MUC5AC producing cells (Fig. 1E-I). We never detected more than 1% of H. pylori associated with the MUC6 producing cells in the gastric glands. If bacteria were detected in proximity of MUC6 producing cells, this was always in the area of transition between MUC5AC and MUC6 producing cells (Fig. 1I). In most sections we observed dense colonization by H. pylori of the MUC5AC producing epithelium, with a uniform distribution until the margins of MUC5AC containing mucus (Figs 1E, 1F, and 1I). The bacterium abruptly disappeared at the area of transition to MUC6 expression. In two of the sections examined some of the bacteria were detected in a transected gastric pit containing MUC6 only (Data not shown). Although this was very rarely observed, this provided an essential positive control for the ability to detect the purple-stained bacteria against the brown background of DAB stained MUC6.
Figure 1. Immunohistochemical staining of sections of human stomach. All sections were immunohistochemically triple stained using antibodies against MUC5AC, MUC6, and H. pylori. Detection of MUC5AC yielded a turquoise blue color. MUC6 was detected using a DAB-staining, staining MUC6 brown. Detection of H. pylori yielded a reddish purple staining. All sections were counterstained with hematoxyline. (A) Section from an individual without H. pylori infection. Note the complementary expression of MUC5AC and MUC6 within the epithelium. There is some yellow/orange staining in the mucosa. This is caused by erythrocytes that appear yellow/orange in this particular quadruple staining. (B) Higher magnification of A showing the transition zone of MUC5AC and MUC6 expression. (C) Distribution of MUC5AC and MUC6 along the pit-gland axis in a H. pylori-negative patient. (D) A H. pylori-positive patient at the same magnification as C (The bacteria cannot be discerned at this magnification in this patient). Notice in C and D that the glands have approximately the same length, but that the number of MUC6 expressing cells has increased, whereas the number of MUC5AC expressing cells has diminished. (E) and (F) Sections of H. pylori-positive patients, showing heavy infection of the mucus layer and epithelium. The asterisks indicate glands that are shown at higher magnification in panels G and I. (G-I) Higher magnifications of sections form H. pylori-positive patients. Notice in E-I that the H. pylori bacteria co-localize with MUC5AC and with MUC5AC-producing cells, but not with MUC6. (J) Section of a H. pylori-negative patient (i.e. after successful eradication of the bacterium), showing a focal area of intestinal metaplasia (im). Notice that the areas of intestinal metaplasia contain characteristic 'intestinal-type' goblet cells, but stained neither for MUC5AC or MUC6. Arrows in E-G, and I indicate purple stained, clustered H. pylori bacteria. In all patients the detection of H. pylori in the sections was completely in accordance with the culturing of the bacterium and routine histology using H&E staining. (Original magnifications: A, 62.5x; B, 125x; C, 62.5x; D, 62.5x; E, 31x; F, 31x; G, 250x; H, 250x; I, 50; J, 125x)

In 2 patients we found focal areas of intestinal metaplasia. H. pylori was absent in these areas. It has previously been shown that areas of intestinal metaplasia show abundant expression of MUC2 and MUC3, the predominant intestinal mucins, and not MUC5AC or MUC6. As expected, we did not detect MUC5AC or MUC6 expression in these cells (Fig. 1J). We did, however, detect endogenous alkaline phosphatase activity on the brush border of these cells as typical for intestinal cells (Data not shown).

Discussion

The mechanism underlying the tissue specificity of bacterial adhesion is poorly understood. As this host cell type dependent colonization is the first step in the infectious process for most bacteria, it is important to elucidate the underlying mechanisms. In general, the mucus gel of the gas-
The gastrointestinal tract is thought to be an important barrier in the cytoprotection against pathogenic organisms. In recent years however, it has become increasingly clear that a range of epithelial pathogens can use mucin, its most important structural component, to colonize this mucus barrier. However, many different mucins are expressed along the gastrointestinal tract, and we now show for the first time that a bacterium preferentially associates with one of these mucins.

The bacterium *H. pylori* is adapted to an environment of gastric mucus. In the duodenum, gastric metaplasia is very likely a prerequisite for the presence of the bacterium, and reports exist of *H. pylori* colonization of gastric metaplastic tissue in Meckel's diverticula, and even in the rectum. Although the prevalence of *H. pylori* colonization at these distant sites of gastric metaplasia is low, these cases provide very interesting examples of the organism's specificity for gastric type epithelium. Additionally, areas of complete intestinal metaplasia in the stomach mucosa provide a hostile environment to *H. pylori*, as this bacterium is generally not detected in the mucus overlaying this epithelium, nor attached to these metaplastic epithelial cells.

From the above, it follows that the putative receptor responsible for *H. pylori* colonization of the stomach should meet the following criteria: (i) present in mucus, (ii) specific for mucus produced by gastric type epithelium, (iii) not present in mucus overlaying areas of complete intestinal metaplasia, (iv) not present in the normal duodenum, and (v) present in areas of gastric metaplasia in the duodenum. A number of different receptors for *H. pylori* have been characterized in vitro (for review see Moran), importantly none of them meet the necessary criteria.

In the present study we focussed on the distribution of two important gastric epithelial secretory gene products and their relation to the colonization pattern of *H. pylori*. We hypothesized that MUC5AC could be a putative *H. pylori* receptor that could account for its colonization pattern.

The secretory mucins MUC5AC and MUC6 are expressed in gastric epithelium. In studies investigating mucin expression in the gastrointestinal tract, these mucins have only been found in the stomach, and they are normally not expressed in the esophagus or intestines. The cells of the superficial epithelium and the upper part of the gastric pits produce MUC5AC, whereas cells of the gastric glands and the lower part of the gastric pits express MUC6. The presence of MUC5AC in the superficial gastric epithelium makes it an attractive putative receptor for the tissue-specific colonization displayed by *H. pylori*, since this bacterium is known to reside in this habitat.

We show, and to our knowledge for the first time, that expression of MUC5AC and MUC6 is complementary in the human stomach, and that gastric epithelial cells specifically express only one of both mucins. Interestingly, we also observed that *H. pylori* colonizes the mucus gel layer overlaying cells producing MUC5AC and that the bacterium does not associate with cells producing MUC6. In all sections of the 34 *H. pylori*-positive biopsies examined, we noted a clear demarcation of the extent of *H. pylori* colo-
H. pylori co-localizes with MUC5AC in the human stomach

nization. This demarcation always corresponded to the sharply delineated transition between MUC5AC- and MUC6-producing cell populations even in densely colonized biopsy specimens. No clear difference in staining intensity of either MUC5AC or MUC6 was observed in any of the examined biopsy specimens, and the expression of both mucins was always found to be continuous. Importantly, we did not detect any MUC6 expression in superficial epithelial cells in these patients. This contrasts with earlier findings by Byrd et al.,\textsuperscript{40} who reported aberrant expression of MUC6 in the surface epithelium of 21 of 29 H. pylori-infected patients as well as focal areas where surface mucous cells did not stain with anti-MUC5AC-antibodies. We showed that H. pylori can cause a shift in the relative sizes of the two gastric epithelial cell populations, expressing either MUC5AC or MUC6, as was observed in several H. pylori-infected patients. Although we observed the same tendency of the gastric epithelium to produce increased numbers of MUC6-positive cells, as did Byrd and co-workers,\textsuperscript{40} this never resulted in the expression of MUC6 in surface mucous cells. Presently, we have no explanation why our results are at variance with those of Byrd et al., other than differences in reagents and methodology to detect the mucins. Mechanistically, the observed change in the size of the MUC5AC- and MUC6-producing cell populations by our group and Byrd's work could be caused by an altered turnover of one or both cell populations, or alternatively by a change in mucin expression.

The H. pylori binding receptor that has been characterized most carefully so far is Lewis B (Le\textsuperscript{b}), a blood group antigen, and a terminal carbohydrate chain on glycoproteins and glycolipids. The affinity of H. pylori towards this carbohydrate was demonstrated in an \textit{in situ} adherence assay.\textsuperscript{41} In this assay fresh H. pylori adhered to fixed sections of human gastric tissue. Both soluble Le\textsuperscript{b} and a monoclonal antibody to Le\textsuperscript{b} interfered with this adhesion. The bacterial adhesin responsible for Le\textsuperscript{b} antigen binding, BabA, has recently been identified.\textsuperscript{42} Although a pathophysiological role remains to be shown for infection of the human stomach, the BabA- Le\textsuperscript{b} interaction may be an important factor in the outcome of infection, since it worsened the severity of gastritis in transgenic mice, expressing human Le\textsuperscript{b}.\textsuperscript{12} Nevertheless, both transgenic animals and their controls were colonized. Importantly, Le\textsuperscript{b} does not fulfill the five above-mentioned criteria. Although Le\textsuperscript{b} is present in gastric mucus, as a carbohydrate side chain of mucin, it is also expressed in the normal esophagus,\textsuperscript{43} the duodenum\textsuperscript{43,44} and in areas of intestinal metaplasia.\textsuperscript{45,46} Indeed, it was shown that Le\textsuperscript{b} does not seem play a critical role in the colonization process of H. pylori in experiments in other model systems both \textit{in vitro}, and \textit{in vivo}.\textsuperscript{47,48}

It is not unimportant to place two technical aspects of our results in perspective. Firstly, we have found a strong co-localization of H. pylori and MUC5AC. Yet, we cannot exclude that the bacterium does not bind to MUC5AC directly. If is also possible that the bacterium associates with molecules that co-localize with MUC5AC. MUC5AC provides the structural
framework for the gastric mucus layer. Therefore, it seems likely that the bacterium may try to get a foothold onto either the MUC5AC itself or to a molecule physically associated with MUC5AC. We are unable to discriminate between these possibilities. Secondly, our anti-MUC6 antibody only recognizes the MUC6 precursor, and not the mature MUC6. Therefore, the bacteria could be associated with secretory MUC6 that is not recognized by the anti-MUC6 antibody. The most important counterargument is that the \textit{H. pylori} bacteria are not associated with the MUC6-producing cells, or located anywhere near the MUC6-producing cells in the lower part of the gastric glands, as one would expect when the bacteria would associate to secretory MUC6.

In conclusion, we provide the first evidence that MUC5AC constitutes an attractive candidate for the gastric mucus specific \textit{H. pylori} receptor. In the present study we show that MUC5AC fulfils the necessary criteria in the human stomach. Because: \(i\) MUC5AC is the structural component of the superficial gastric mucus gel layer; \(ii\) the expression of MUC5AC is specific for superficial gastric epithelial cells, MUC5AC is not expressed in normal duodenum or intestinal metaplasia of the duodenum; \(iii\) in the stomach, the colonization pattern of \textit{H. pylori} matches the area expression of MUC5AC more than 99\%, the bacterium colocalizes with extracellular MUC5AC as well as with the apical domain of MUC5AC producing epithelial cells, and not with MUC6. It remains to be shown whether MUC5AC is expressed in gastric metaplasia in the duodenum. This seems likely however as MUC5AC expression is highly specific for gastric epithelial cells. Finally, we did not observe any gross disturbances in the gastric mucin expression pattern. However, we did observe a shift in MUC5AC- and MUC6-producing cell populations in some but not all of the \textit{H. pylori}-infected patients with a relative increase in MUC6 producing cells. The pathophysiologica l meaning of this finding remains unclear.
