A new defect of peroxisomal function involving pristanic acid: a case report

B N McLean, J Allen, S Ferdinandusse, R J A Wanders

Peroxisomes are subcellular organelles found in all mammalian cell types, and are particularly abundant in oligodendrocytes with 40 times the amounts of neurons or astrocytes, and in cells specialising in lipid metabolism. Their main function is \( \text{H}_2\text{O}_2 \) metabolism, ether-phospholipid biosynthesis, \( \beta \)-oxidation of fatty acids and other compounds (very long chain fatty acids (VLCFAs)), monounsaturated and polyunsaturated fatty acids, prostaglandins, dihydroxycholestanolic acid/trihydroxycholestanolic acid (DHCA/THCA), xenobiotics), glyoxylate metabolism, polyamine catabolism, cholesterol and dolichol synthesis, and pipecolic and phytanic acid degradation.

Pristanic acid is derived from phytanic acid by \( \alpha \)-oxidation, followed by decarboxylation, and also directly from exogenous dietary sources. Phytanic acid is derived from purely exogenous sources, mainly dairy products and ruminant fats.

Peroxisomes contain more than 60 enzymes so disorders of peroxisomal function result in several syndromes combining neurological and systemic features. Until 1999, 17 disorders had been described,\(^1\)\(^-\)\(^16\) with neurological involvement. The first well defined disorder described in 1946 was a hereditary ataxia, later to be given the eponym Refsum’s disease,\(^1\) combining retinitis pigmentosa and a hypertrophic neuropathy associated with increased phytanic acid. It was, however, only in 1997 that the true peroxisomal localisation of the disorder was confirmed, with the enzyme \( \alpha \)-methylacyl-CoA racemase identified and the gene cloned and partially controlled with phenobarbital and phenytoin. An adult onset novel disorder of peroxisomal function is described, characterised by retinitis pigmentosa resulting in progressive visual failure, learning difficulties, a peripheral neuropathy, and hypogonadism. The defect results in accumulation of pristanic acid, and the bile acid intermediates, dihydroxycholestanolic and trihydroxycholestanolic acid, and is due to a deficiency of \( \alpha \)-methylacyl-CoA racemase, making this the first fully characterised description of this defect. Screening of patients with retinitis pigmentosa should be extended to include pristanic acid and/or bile acid intermediate concentrations, as dietary measures offer a potential treatment for the disorder.

In general, peroxisomal disorders present either at birth with deficits resulting in severe hypotonia and craniofacial dysmorphism or as later onset psychomotor retardation, seizures, and hepatomegaly. There is, however, a considerable range of clinical problems within a disorder and overlap between disorders, so that some can only be differentiated on biochemical grounds.

We present a case of adult onset neurological disease the features of which were reminiscent of a peroxisomal disorder, but in a novel combination. The biochemical defect has been recently elucidated, and has been shown to be due to a deficiency of \( \alpha \)-methylacyl-CoA racemase (AMACR) making our patient one of the first adults to be described with this condition.\(^{19}\)

**CASE REPORT**

A 44 year old man presented with failing vision, having been suspected by his general practitioner of malingering.

He was born of non-consanguineous parents, one of six children, his brother and four sisters being in good health. He had left school at the age of 14. He had been a poor scholar with reading difficulties and after leaving had a succession of unskilled jobs from which he was invariably dismissed. At the age of 18 he presented with an encephalitic illness characterised by 3 days of severe headache, nausea, and photophobia, with a single blackout followed by progressive confusion, irrational behaviour, and resulting in coma.

He developed focal seizures, with eye deviation to the left and jerking of the neck muscles, which on one occasion generalised. He had tonic deviation of his eyes to the right, sometimes with slow deviation, bilateral papilloedema, but no other focal neurological signs. He had a mild pyrexia and a neutrophil leucocytosis (\( 13\times10^9/\text{l} \)). He underwent cerebral angiography and CSF analysis, including protein estimation, both of which were normal. An EEG showed gross disturbances with generalised slowing and loss of \( \alpha \) activity. He required ventilation, but then underwent spontaneous recovery, whereupon he was found to be blind. This was initially suspected to be due to occipital lobe infarction, but pigmented retinal changes were seen extensively in the periphery of both fundi, and a neuroretinitis was proposed. His EEG improved, but did not return to normal, remaining slowed. Vision slowly recovered, initially with perception of light, then colours, and finally acuity, achieving a distance acuity of 6/12 bilaterally and a reading acuity of N24 right N18 left. A neuropsychometric assessment showed a premorbid verbal IQ of 86, a reading age of 7.5 years, and a long term problem with vision was suspected.

At the age of 22 he developed generalised seizures, only partially controlled with phenobarbital and phenytoin. An

**SHORT REPORT**

AN adult onset novel disorder of peroxisomal function is described, characterised by retinitis pigmentosa resulting in progressive visual failure, learning difficulties, a peripheral neuropathy, and hypogonadism. The defect results in accumulation of pristanic acid, and the bile acid intermediates, dihydroxycholestanolic and trihydroxycholestanolic acid, and is due to a deficiency of \( \alpha \)-methylacyl-CoA racemase, making this the first fully characterised description of this defect. Screening of patients with retinitis pigmentosa should be extended to include pristanic acid and/or bile acid intermediate concentrations, as dietary measures offer a potential treatment for the disorder.
EEG showed excessive slowing with a right temporal focus and a photoconvulsive response.

At the age of 25 he had an episode of status epilepticus, by which time his vision had declined to 6/36 right and 6/60 left uncorrected.

At the age of 34 he was involved in a road traffic accident and sustained a small right frontal extradural haematoma with confusion, not requiring surgery. After this he developed drop attacks and frequent headaches.

At the age of 41 he became aware of declining vision, and was found to have VA 1/18 L+R, constricted fields, and a generalised “retinopathy”.

When he presented at the age of 44, he was complaining of migraineous headaches daily from his accident, and a recent episode of amnesia with automatic behaviour. He had not been employed since his encephalopathy.

There was a family history of ischaemic heart disease, his father dying aged 67 of a heart attack. He was single without children, and taking only phenytoin and phenobarbital. There was a previous episode of depression with an overdose, and he had been admitted to hospital for minor surgery as an adult after his encephalitic illness suggested a longstanding premorbid problem with functional and language skills.

Encephalitis presented with seizures, agitation, disorientation, and confusion. He was known to have a low renal glucose threshold.

His brain MRI did not show white matter abnormalities, as expected. He had micrognathia with a high arched palate, but sparse body hair and a feminine habitus. Both testes were atrophic. He had hyperplasia of the auxiliary enzymes involved in peroxisomal function.

Table 1 lists the results of fatty acid and bile acid analyses in serum from the patient. The results show normal very long chain fatty acids, a slightly increased pristanic acid concentration, and profoundly increased pristanic acid concentration. Furthermore, both dihydroxycholestanoic acid and trihydroxycholestanoic acid are greatly increased.

These data pointed to a defect in the β-oxidation system which was supported by the finding of a reduced pristanic acid β-oxidation capacity (table 2). Subsequent studies showed that the primary defect in this patient was not at the level of one of the β-oxidation enzymes themselves but rather in one of the auxiliary enzymes involved in β-oxidation called α-methyl-acyl-CoA-racemase.

DISCUSSION

Our patient had learning difficulties and his psychometric testing as an adult after his encephalitic illness suggested a longstanding premorbid problem with functional and language skills. Encephalitis presented with seizures, agitation, disorientation, and confusion. He was known to have a low renal glucose threshold.

There was a family history of ischaemic heart disease, his father dying aged 67 of a heart attack. He was single without children, and taking only phenytoin and phenobarbital. There was a previous episode of depression with an overdose, and he had been admitted to hospital for minor surgery as an adult after his encephalitic illness suggested a longstanding premorbid problem with functional and language skills.

Encephalitis presented with seizures, agitation, disorientation, and confusion. He was known to have a low renal glucose threshold.

His brain MRI did not show white matter abnormalities, as was expected. He had micrognathia with a high arched palate, but sparse body hair and a feminine habitus. Both testes were atrophic. He had hyperplasia of the auxiliary enzymes involved in peroxisomal function.

seen in adrenomyeloneuropathy, nor neuronal migration deficits as seen in a postmortem of infantile Refsum’s disease. The biochemical defect causing Refsum’s disease lies “upstream”, yet the clinical phenotype of the disorders diverges, although with considerable overlap. Why there should be this distinction is uncertain, but there may be a differential effect on tissues depending on the proportions of product accumulation (phytanic and pristanic acid and bile acid intermediates), or loss of lipid functions “downstream”.

In humans, the only peroxisomal disorders of β-oxidation so far identified are those relating to VLCFAs, DHCA/THCA, and pristanic acid. Multiple enzymes are involved (fig 1) and abnormalities of pristanic acid metabolism were first associated with generalised peroxisomal disorders. This currently described patient showed highly increased pristanic acid concentrations and mildly raised phytanic acid concentrations. Analysis of both enzymes is required to establish the precise defect.

He therefore has a unique combination of features, distinct from the other peroxisomal disorders, but with many features in common, particularly with Refsum’s disease. His disease course has been relatively benign. Presumably this is autosomal recessive as are most of the other peroxisomal disorders, but his family have refused blood testing and skin biopsy. The presence of hypogonadism does raise the possibility of an X linked disorder, but we have been made aware of a woman with the condition (personal communication), so this seems unlikely.

Figure 1 The peroxisomal β-oxidation pathway, showing the steps involved in the oxidation of pristanic acid and THCA/DHCA. The site of activity of AMACR, where the defect occurs in this disorder, is indicated. *
