Lentiviral shRNA silencing of murine bone marrow cell CCR2 leads to persistent knockdown of CCR2 function in vivo

Ilze Bot, Jian Guo, Miranda Van Eck, Peter J. Van Santbrink, Pieter H. E. Groot, Reeni B. Hildebrand, Jurgen Seppen, Theo J. C. Van Berkel, and Erik A. L. Biessen

A major barrier in hematopoietic gene function studies is posed by the laborious and time-consuming generation of knockout mice with an appropriate genetic background. Here we present a novel lentivirus-based strategy for the in situ generation of hematopoietic knockdowns. A short hairpin RNA (shRNA) was designed targeting murine CC-chemokine receptor 2 (CCR2), which was able to specifically blunt CCR2 expression at the mRNA, protein, and functional levels in vitro. Reconstitution of irradiated recipient mice with autologous bone marrow that had been ex vivo transduced with shRNA lentivirus led to persistent down-regulation of CCR2 expression, which translated into a 70% reduction in CCR2-dependent recruitment of macrophages to an inflamed peritoneal cavity without noticeable side effects on related chemokine receptors or general inflammation status. These findings clearly demonstrate the potential of shRNA lentivirus–infected bone marrow transplantation as a rapid and effective method to generate hematopoietic knockdowns for leukocyte gene function studies. role in the recruitment of monocytes to sites of inflammation and during atherogenesis. An shRNA construct was developed against CCR2 (shCCR2), which proved highly efficient in down-regulating CCR2 expression both at an mRNA as well as at a protein level in CCR2-transfected HEK 293 cells. Furthermore, we have efficiently transduced bone marrow cells and reconstituted irradiated C57Bl/6 mice with shCCR2-transduced bone marrow cells, which considerably attenuated macrophage recruitment to the site of inflammation to a level comparable with that of mice reconstituted with Ccr2–/– bone marrow.

Materials and methods

Cloning and expression of murine CCR2-GFP in HEK 293 cells

Total RNA was extracted from the murine monocytic cell line WEH1, reverse transcribed using M-MuLV reverse transcriptase (RevertAid; MBI Fermentas, Leon-Roth, Germany) and the cDNAs were amplified by polymerase chain reaction (PCR) to obtain full-length cDNA for murine CCR2 using the following primers: forward: 5′-AGCTGGGTTT GCAGTGGGTTTT-3′ and reverse: 5′-ATAAAGCTTTTACAACTCGAG-3′. Primers contained extra XhoI and HindIII restriction sites to facilitate cloning (underlined). Purified PCR products were subsequently cloned into pCR2.1 (Invitrogen, Breda, The Netherlands) and subcloned into pEGFP-N1 (Clontech, Palo Alto, CA). Murine CCR2 and GFP were fused at the GFP N-terminus via removal of the stop codon, allowing the pEGFP-N1/CCR2 fusion vector. A CCR2 expression vector was generated by cloning full-length Ccr2 into pcDNA3.1(-) (Invitrogen), designated as pcDNA3.1(-)/CCR2. All constructs were sequenced to confirm the identity of murine Ccr2.

Design and cloning of shRNA directed against murine CCR2

A pair of 64-nucleotide oligonucleotides encoding a 19-nucleotide CCR2 shRNA (5′-GATCCCCGTGTGATTGACAAGCACTTC-3′ and 5′-AGCTGGGTTT GCAGTGGGTTTT-3′) were designed, which contained extra BglII and HindIII restriction sites to facilitate cloning. The position of the core 19–nucleotide sequence (underlined) targeted nucleotides 867 to 885 of the murine Ccr2. Blast search was performed using the National Center for Biotechnology Information (NCBI) Expressed Sequence Tags (EST) database to ensure that the shRNA construct was targeting only murine CCR2. The 64-nucleotide oligonucleotides were annealed and cloned into the BglII and HindIII sites of the pSUPER vector (kindly provided by Dr Agami, The Netherlands Cancer Institute, Amsterdam, The Netherlands) and the resulting vector, designated pSUPER-H1.shCCR2, was subsequently sequenced to confirm identity.

Silencing effect of pSUPER-H1.shCCR2

HEK 293 cells, grown at 37°C and 5% CO2 in Dulbecco modified Eagle medium (DMEM) supplemented with 10% fetal calf serum (FCS), 100 μg/mL streptomycin, 100 U/mL penicillin, and 2 mM L-glutamine (all from Cambrex Bio Science, Verviers, Belgium), were transiently cotransfected with a constant amount of pEGFP-N1/CCR2 (0.5 μg) and 0.1 μg, 0.5 μg, and 1.5 μg pSUPER-H1.shCCR2, supplemented to 1.5 μg with pSUPER-H1.Empty vector using Lipofectamine 2000 (Invitrogen). As controls, the effects of an shRNA designed against luciferase (pSUPER-H1.shLuc, CTGACGGGAATACCTCGA) and a nonsense sequence (pSUPER-H1.shInert, AGGCTGTTGACGATCTA) cloned into pSUPER on CCR2 expression levels were determined. After 48 hours, total RNA was extracted from the HEK 293 cells and reverse transcribed as described under “Cloning and expression of murine CCR2-GFP in HEK 293 cells.” Quantitative analysis of CCR2 expression was performed using an ABI PRISM 7700 Taqman apparatus (Applied Biosystems, Foster City, CA) as described previously37 (Table 1). The amplicon encompassed the core sequence (nucleotides 851-991), enabling the analysis of sequence-specific degradation of murine CCR2 mRNA and excluding artifacts due to the presence of shRNA. Human hypoxanthine phosphoribosyltransferase (hHPRT) was used as a standard housekeeping gene and non–reverse transcribed RNA samples were used as controls to determine genomic DNA contamination. Murine CCR2 mRNA expression was calculated relative to that of hHPRT on the basis of ΔCt values.

After transfection with pEGFP-N1/CCR2 and pSUPER-H1.Empty, pSUPER-H1.shLuc, pSUPER-H1.shInert, or different amounts of pSUPER-H1.shCCR2, the cells were harvested, resuspended in phosphate-buffered saline (PBS), and analyzed using fluorescence activated cell sorting (FACS; FACScalibur, BD Biosciences) for GFP expression. For Western blotting, transfected cells were washed gently with PBS, scraped off, and subsequently lysed in sodium dodecyl sulfate (SDS) sample buffer supplemented with a protease inhibitor cocktail (Roche, Mannheim, Germany). Equal amounts of protein were applied to a polyacrylamide gel (12.5%) and transferred to nitrocellulose. Visualization of GFP with a mouse anti-GFP antibody (Sigma, Zwijndrecht, The Netherlands) to verify equal loading of the samples.

Lentivirus vector construction and production

The lentiviral expression vectors pRRl-cPPr-H1.PreSIN (H1.Empty) and pRRl-cPPr-H1.shCCR2-PreSIN (H1.shCCR2) were constructed by removing the cytomegalovirus (CMV) promoter from the expression vector pRRl-cPPr-CMV-PreSIN using ClaI and PstI digestion, followed by insertion of the H1 promoter or the complete H1.shCCR2 construct. Virus was produced as described by using transient calcium phosphate cotransfection of 293T cells with the H1.Empty or H1.shCCR2 vector together with pMDL/RRRE, pRSV-REV, and pVSV-G. Viral supernatants were passed through a 0.45 μm filter and concentrated by ultracentrifugation (41 000 g, 2 hours, 4°C). Viral titers were determined essentially as described by Sastry et al. In short, HEK 293 cells were transduced with serially diluted viral supernatant, and 48 hours after transduction total genomic DNA was isolated from these cells and the number of vector DNA copies was determined using PCR analysis with pRRl-cPPr-H1.PreSIN vector as the calibration standard (forward primer: GTGAGCAGCAGACACATTTG; reverse primer: CCCCAGACTGTGAGTTGCAA).

Animals

All animal work was approved by the regulatory authority of Leiden and performed in compliance with the Dutch government guidelines. C57Bl/6 mice were obtained from Charles River (Maastricht, the Netherlands). Ccr2−/− mice were kindly provided by Dr Maeda (University of North Carolina, Chapel Hill). Mice that underwent bone marrow transplantation were housed in sterile filter-top cages and fed a sterile regular chow diet (RM3; Special Diet Services, Witham, United Kingdom). Drinking water was infused with antibiotics (83 mg/L ciprofloxacin and 67 mg/L polymyxin B sulfate) and 6.5 g/L sugar and was provided ad libitum.

In vitro transduction protocol for bone marrow cells

Bone marrow cell suspensions were isolated from C57Bl/6 mice by flushing the femurs and tibias with PBS. Single-cell suspensions were prepared by passing the cells through a cell strainer and 105 cells/well were plated in a 12-well plate. Viral transductions were performed by incubating the bone marrow cells with different titer of pRRl-cPPr-PGK-GFP-PreSIN in complete DMEM supplemented with 10 μg/mL diethylaminoethyl (DEAE)–dextran at 37°C. After 24 hours, cells were washed with PBS and fixed in 4% paraformaldehyde for FACS analysis to determine GFP expression levels. Viral copy number inserted in the bone marrow cells after 24 hours was determined by isolation of total genomic DNA (from 106 bone marrow cells) and PCR analysis.

Irradiation and bone marrow transplantation

To induce bone marrow aplasia, female C57Bl/6 mice (12 to 14 weeks of age) were exposed to a single dose of 9 Gy (0.19 Gy/min, 200 kV, 4 mA) total body irradiation, using an Andrex Smart 225 Roentgen source (YXLON International, Copenhagen, Denmark) with a 6-mm aluminium filter, one day before transplantation. Bone marrow cell suspensions were isolated from C57Bl/6 mice as described in the previous section. Subsequently, bone marrow cells (1.0 × 107) were transduced with either H1.Empty or H1.shCCR2 lentivirus in the presence of 10 μg/mL DEAE-dextran (multiplicity of infection [MOI] = 15). After 24 hours, the cells were injected into the tail vein of the irradiated recipients (n = 4 per group). As a positive control, irradiated C57Bl/6 mice (n = 5) received 1.0 × 107 bone marrow cells isolated from male Ccr2−/− mice. In a similar set-up, C57Bl/6 mice (n = 2) were injected with bone marrow cells transduced with GFP lentivirus. In these mice, GFP expression levels in blood cells were determined 6 weeks after transplantation by preparing cytopsin of white blood cells (9 g, 5 minutes) after lysis of the erythrocytes. The images were taken with a Leica DM-RE microscope and LeicaQwin software (Leica Imaging Systems).

Macrophage recruitment

Six weeks after bone marrow transplantation, the mice receiving H1.Empty or H1.shCCR2 lentivirus–transduced bone marrow and the mice reconstituted with Ccr2−/− bone marrow were injected intraperitoneally with sterile 3% (wt/vol) Brewer thioglycollate solution (Difco, Detroit, MI). Peritoneal macrophages were isolated 5 days later by lavage of the peritoneal cavity with PBS (10 mL) and counted after lysis of erythrocytes. Also, blood smears were prepared, stained with Wright Giemsa (Sigma), and scored manually. Total RNA was isolated from peritoneal macrophages and gene expression was determined by reverse transcription (RT)–PCR compared with murine HPRT (Table 1). After, bone marrow was isolated from each individual mouse and, after lysis of the bone marrow cells, genotyped and, after lysis of the bone marrow cells, genotyped for the presence of the Ccr2 gene in a single reaction (primers: CCR2 forward, 5′-GATGATGGTGAGCCTTGTCA-3′; CCR2 reverse, 5′-CACACGCAT-GAACAAATGAACCA-3′; and a pgk-neo specific primer, Neo 5′-TTA-AGGCCC-AGCTCAATCCCT-3′). In wild-type mice, a 360 base pair sequence is amplified corresponding with intact Ccr2, whereas in the Ccr2−/− mice a 290 base pair sequence is generated. Also, viral copy number in the bone marrow was determined. In addition, the percentage repopulation of male bone marrow in the female recipients at that time point was determined by means of Taqman PCR analysis on the Sry gene, located on the Y-chromosome. To quantify the percentage of male bone marrow, a calibration curve was used containing increasing amounts of male bone marrow supplemented with female bone marrow to standardize the amount of genomic DNA per well.

Statistical analysis

Data are expressed as mean plus or minus the standard error of the mean (SEM). A 2-tailed Student t test was used to compare individual groups. To determine the significance of the relative mRNA expression levels, statistical analysis was performed on ACt values.

Results

Silencing CCR2 expression by shRNA vectors

To determine the silencing capacity of an shRNA against CCR2 (pSUPER-H1.shCCR2) on murine CCR2 expression, HEK 293 cells were cotransfected with pEGFPN-1/CCR2 fusion vector and increasing amounts of pSUPER-H1.shCCR2. As controls, the effects of an shRNA sequence against luciferase and a nonsense shRNA sequence on CCR2 expression were also determined. CCR2 mRNA levels were already found to be significantly reduced after cotransfection with only 0.1 μg of pSUPER-H1.shCCR2 (Figure 1A, P < 0.001 compared with the shRNA controls at all concentrations) with a maximum reduction of 94% at 1.5 μg pSUPER-H1.shCCR2, whereas the shRNA controls and pSUPER-H1.Empty had no effect. In agreement, expression analysis by fluorescence microscopy revealed an almost complete quenching of GFP-tagged murine CCR2 protein expression in HEK 293 cells cotransfected with pSUPER-H1.shCCR2 compared with that of the pSUPER-H1.Empty cotransfected control (Figure 1B). Subsequent FACS analysis (Figure 2A) confirmed that CCR2/GFP fusion protein expression was dose-dependently blunted after cotransfection with increasing amounts of pSUPER-H1.shCCR2, whereas the shRNA controls (ie, pSUPER-H1.Empty, pSUPER-H1.shLuc, and the nonsense shRNA sequence) were ineffective. Also, the fluorescence intensity of the GFP-positive cells was reduced to the level of untransfected HEK 293–cell controls (on average 380) after cotransfection with pSUPER-H1.shCCR2 (Figure 2B). These FACS data were confirmed by Western blot analysis (Figure 2C).

Intracellular calcium levels were measured in HEK 293 cells expressing CCR2 and the H1.shCCR2 or H1.Empty sequence in response to the murine CCR2 ligand JE. Upon incubation with JE (1 nM), transient calcium influx was observed after 2 minutes, and peaked at 4 minutes, after which intracellular calcium levels...
Photoshop 7.0.

scanning microscope (1000 magnification), and images were digitized with Adobe Photoshop 7.0.

gradually declined to base values. Transfection of these cells with pSUPER-H1.shCCR2 completely abolished the JE-induced calcium influx to levels comparable with that of nonstimulated cells (Figure 2D), indicating that the observed reduction in CCR2 mRNA and protein levels establishes a complete loss of CCR2 function in response to JE.

Transduction of CCR2-transfected HEK 293 cells with H1.shCCR2 lentivirus resulted in a significantly reduced expression of CCR2 relative to hHPRT (5.95 ± 0.67 versus 14.4 ± 3.6 in cells transduced with H1.Empty virus; P = .02).

Transduction of bone marrow cells

In the next stage, the transduction efficiency of lentivirus in bone marrow cells was optimized. FACS analysis of bone marrow cells showed that transduction was not satisfactory at low multiplicities of infection (moi 6.5% ± 0.6% and 9.8% ± 3.3% at moi’s of 1 and 2, respectively). The use of higher titers and DEAE-dextran (10 μg/mL) led to a strong increase in infection efficiency from 3.1% ± 0.5% in control cells via 67.1% ± 6.0% (moi = 5) and 76.2% ± 2.0% (moi = 10) to 86.1% ± 2.3% (moi = 20) 24 hours after infection (Figure 3A). Viral incorporation analysis revealed that bone marrow cells contained on average 2 copies of virus per Hprt gene 24 hours after transduction of the cells with GFP, H1.shCCR2, or H1.Empty control lentivirus (Figure 3B). The high transduction, obtained at moi’s of 10 to 20 in the presence of 10 μg/mL DEAE-dextran, suffices for in vivo transplantation purposes and circumvents the need of a laborious preselection step. Six weeks after injection of GFP lentivirus–transduced bone marrow into irradiated C57Bl/6 mice, cytospin analysis showed that approximately 80% to 90% of all white blood cells were GFP positive (Figure 3C-F).

Transplantation of H1.shCCR2-transduced bone marrow

To generate chimeras with silenced CCR2 expression, bone marrow from C57Bl/6 mice was transduced with either H1.shCCR2 or H1.Empty control lentivirus in the presence of 10 μg/mL DEAE-dextran and intravenously injected into irradiated C57Bl/6 recipient mice, while a third group received Ccr2−/− bone marrow. No differences were observed in either weight gain during the experiment or in mononuclear-cell and neutrophil content of the total white blood cell population at 7 weeks after transplantation (data not shown). At that point, macrophages were recruited to the peritoneal cavity by an intraperitoneal thioglycollate challenge. Assessment of the number of peritoneal macrophages, 5 days after challenge, revealed a significant 70% reduction in macrophage recruitment in mice that had received H1.shCCR2 lentivirus–transduced bone marrow compared with the H1.Empty lentivirus controls (8 × 10^6 ± 4 ± 10^6 cells versus 27 × 10^6 ± 6 × 10^6 cells; P = .03, Figure 4A). Interestingly, macrophage recruitment was comparable to that of mice reconstituted with Ccr2−/− bone marrow (8 × 10^6 ± 1 × 10^6 cells; P = .9 versus the H1.shCCR2 lentivirus group). Macrophage recruitment levels of mice reconstituted with H1.Empty-transduced bone marrow pose...

VOLUME 106, NUMBER 4
matched with those found in control mice that underwent transplantation (female C57Bl6 recipient mice that had received untransduced male C57Bl6 bone marrow, data not shown), which indicates that lentiviral transduction of bone marrow per se does not elicit an inflammatory response.

Analysis of CCR2 expression by peritoneal macrophages revealed a highly significant reduction in CCR2 mRNA levels in mice that received a transplant of H1.shCCR2- versus H1.Empty lentivirus–transduced bone marrow (expression relative to murine HPRT: 0.4 ± 0.1 and 1.3 ± 0.2, respectively; \( P = .002 \)). For comparison, mice that had received Ccr2\(^{-/-}\) bone marrow showed a relative CCR2 expression of 0.09 ± 0.02 (Figure 4B).

As expected, genotyping showed that C57Bl6 mice that received a transplant of H1.Empty- or H1.shCCR2 lentivirus–transduced bone marrow displayed the 360 base pair amplicon, indicative of wild-type Ccr2 (Figure 4C). C57Bl6 mice that had received Ccr2\(^{-/-}\) bone marrow showed the Ccr2\(^{-/-}\) phenotype (290 base pair sequence). Reconstitution with male bone marrow in the female recipient mice was quantitative and persistent for at least 7 weeks in all 3 groups, as judged from PCR analysis of the Sry gene (Figure 4D). PCR analysis of genomic DNA from bone marrow revealed that unpurified bone marrow from mice that received a transplant of H1.shCCR2 contained on average 2 virus integrants per Sry copy in both the H1.shCCR2 (2.30) and the H1.Empty groups (1.98), while as expected in bone marrow from mice that received a transplant of Ccr2\(^{-/-}\) no virus particles were detected. Furthermore, no differences were observed in peritoneal macrophage expression levels of other chemokine receptors, such as CCR3, CCR5, and CXCR3 (Figure 5A-C, \( P = NS \)), or of inflammatory mediators like interferon \( \beta \) (IFN\( \beta \)) and IFN\( \gamma \) (data not shown), indicating that the shRNA against CCR2 was highly specific and did not display significant off-target effects on the expression levels of other relevant genes. Intriguingly, macrophages of mice that received a transplant of Ccr2\(^{-/-}\) showed an almost 50% reduction in relative CCR5 mRNA expression levels (\( P = .04 \)).

**Figure 3.** Efficient transduction of bone marrow cells using GFP lentivirus. (A) Transduction of whole bone marrow with GFP lentivirus led to a titer-dependent increase in percentage of GFP-expressing cells. (B) Virus particle incorporation in bone marrow cells compared with HPRT of untransduced control cells and 24 hours after transduction with GFP-, H1.Empty-, or H1.shCCR2-lentivirus. Error bars in panels A and B represent SEM. (C,D) Fluorescence and light microscopic high-power field, respectively, of a white blood cell cytospin from control mice 6 weeks after transplantation of nontransduced bone marrow (original magnification, \( \times 200 \)). (E,F) Blood cells from mice that underwent transplantation with lentiviral GFP-transduced bone marrow show approximately 90% GFP-positive cells (panel E; original magnification, \( \times 200 \)), indicating that transplantation of lentivirus-transduced bone marrow results in sustained transgene expression by blood cells. Images were captured with a Leica DM-RB microscope equipped with a 20× objective lens and a 10× ocular lens, and Leica QWin software (Leica Imaging Systems) was used.

**Figure 4.** Lentiviral shCCR2 results in reduced macrophage influx due to reduced CCR2 expression. (A) Macrophage recruitment to the peritoneum in mice that underwent transplantation with H1.shCCR2 lentivirus–transduced bone marrow is significantly reduced compared with those that received H1.Empty lentivirus–transduced bone marrow. Recruitment levels were found to be similar to control mice that underwent transplantation with Ccr2\(^{-/-}\) bone marrow (\( *P < .05 \), \( **P < .01 \)). (B) CCR2 mRNA expression level in peritoneal macrophages of mice that underwent transplantation with H1.shCCR2-transduced bone marrow was reduced 7 weeks after transplantation (\( ***P < .001 \), \( ****P < .0001 \) compared with H1.Empty; \( P < .01 \) compared with H1.shCCR2). (C) Ccr2 genotyping of transplanted C57Bl6 mice, revealing a 360-base pair amplicon of wild-type Ccr2 in mice that underwent transplantation with H1.Empty- or H1.shCCR2 lentivirus–transduced bone marrow and the 290–base pair amplicon was observed in mice that underwent transplantation with Ccr2\(^{-/-}\) bone marrow. (D) Percent male bone marrow in bone marrow cell lysates from recipient mice, determined by PCR analysis on the Sry gene, located on the Y-chromosome. Error bars in panels A, B, and C represent SEM.

**Discussion**

Transplantation of transgenic or knockout bone marrow to wild-type recipients is a widely used technique to determine the role of a particular leukocyte gene in several inflammatory disorders, such as arthritis\(^1\) and atherosclerosis.\(^2,4\) Unfortunately, the time-consuming generation of transgenic or knockout mice and the subsequent backcrossing to an appropriate disease background for analysis of gene function considerably delays progression in gene function research. In this study, we demonstrate the high potential of a novel lentiviral gene silencing approach on bone marrow cells for the in situ generation of leukocyte knockdowns of the aimed target gene. Targeted gene silencing by means of shRNA has, since its discovery, proven to be a powerful tool in the analysis of gene function in vitro as well as in vivo as it can result in prolonged selective inhibition of target gene expression even in eukaryotic cells.\(^2,21-23\) To deliver shRNA and warrant prolonged shRNA expression, we made use of third-generation self-inactivating lentiviruses,\(^12,13\) which have been demonstrated to efficiently infect and integrate their genome into a range of mitotic and nonmitotic cells.\(^14,15,32\) Although rather efficient retroviral transduction of stem
cells of up to 64% has been reported.6–11 This required extensive manipulation of bone marrow stem cells to increase their mitotic capacity, possibly compromising the hematopoietic potential.40 Efficient lentiviral infection requires only a short in vitro incubation period and preventing undesired differentiation of the hematopoietic stem cells.

In this study, the transduction of bone marrow cells with GFP lentivirus was almost quantitative (80%–90%) when using titers of 10 moi to 20 moi. Transduction levels in our study exceeded reported transduction efficiencies for human bone marrow–derived CD34+ stem cells41–43 and even were sufficiently high to perform bone marrow transplantation without prior selection of infected cells. Generally, 2 or more consecutive transduction steps were required to achieve similarly high levels, although Banerjee et al, for example, communicated on efficient gene transfer in a single-step protocol.44 Our protocol is a compromise of a limited culture period of bone marrow cells in growth factor–free medium (24 hours) on the one hand, preventing undesired differentiation or maturation of the bone marrow cells, and lowest possible virus titer on the other. Furthermore, a single transduction protocol will also minimize the risk of multiple, potentially harmful viral integrants per cell due to, among others, insertion mutagenesis.45 However, it should be noted that in the case of shRNAs, multiple integrations per host cell may even be beneficial, as multiple integrations will be accompanied by higher transcript expression, leading to more efficient silencing of the target gene. In our study, the initial infection levels of the bone marrow cells by the H1.Empty and the H1.shCCR2 lentivirus were shown to be similar to that of GFP lentivirus–transduced cells.

As a model gene to illustrate the potential of lentiviral gene silencing in vivo, we have chosen the CC-chemokine receptor 2 (CCR2). CCR2 is critically involved in monocyte recruitment to sites of inflammation in response to an inflammatory stimulus during atherosclerosis, renal fibrosis,47 or pulmonary inflammation.48 An shRNA sequence, targeting nucleotides 867 to 885 of the murine Ccr2 gene, reduced CCR2 mRNA levels by 94% and protein levels in HEK 293 cells to an almost similar extent. Furthermore, the shCCR2 construct completely prevented CCR2 signal transduction in response to its natural ligand JE, as revealed by intracellular calcium release measurements.

Interestingly, transplantation of bone marrow cells transduced with a lentivirus carrying the shCCR2 construct strongly attenuated thioglycolate-elicted, CCR2-dependent migration of macrophages into the peritoneal cavity. The amount of recruited peritoneal macrophages in mice that underwent transplantation with H1.shCCR2 lentivirus–transduced bone marrow was comparable to that of mice that received Ccr2−/− bone marrow transplants. Macrophage recruitment levels of the H1.Empty and H1.shCCR2 lentivirus group were essentially similar to those of mice that received Ccr2−/− bone marrow transplantation, and lowest possible virus titer on the one hand, preventing undesired differentiation of the hematopoietic stem cells.

In conclusion, here we show effective delivery of lentiviral shRNA to bone marrow cells and subsequent transplantation into irradiated recipient mice as a strategy to generate hematopoietic knockdowns with silenced CCR2 expression. shRNA-mediated silencing of gene expression persisted for at least 7 weeks after transplantation and led to a complete loss of CCR2 function without any noticeable side effects. Speed and efficiency render this strategy very valuable for addressing the role of other hematopoietic, and in particular leukocyte, genes in inflammatory disorders.
