ABSTRACT

Complementary hydrogen-bonding interactions between a barbituric acid-substituted fullerene derivative (1) and corresponding receptor (2) bearing thiénylenevinylene units are used to assemble a 1:1 supramolecular complex (K = 5500 M⁻¹). Due to the close proximity of the redox-active moieties within the assembly, strong ground-state electron-donor–acceptor interactions are observed. Photoinduced electron transfer from electron-rich thiénylenevinylene subunits to the fullerene is very fast (kₑᵗ ≈ 5.5 × 10¹² s⁻¹), as determined by fs-time-resolved transient absorption spectroscopy.

The incorporation of fullerenes into conjugated polymer systems affords composite all-organic devices possessing improved photovoltaic properties.¹ To investigate the ground- and excited-state interactions between C₆₀ and conjugated polymers, numerous covalent and supramolecular model systems have been studied in great detail.² Although C₆₀ has been well-known to participate in the formation of electron-donor–acceptor (EDA) complexes with electron donors, including porphyrins,³ aromatic hydrocarbons,⁴ and aromatic amines,⁵ no clear evidence for such interactions has been observed in covalent oligothiophene systems reported to date. Intermolecular ground-state EDA complexes involving C₆₀ are generally weak, with association constants in the range 10¹⁻¹⁰² M⁻¹.⁶,⁷ Studies of covalent C₆₀-porphyrin assemblies

indicate that the distance and relative orientation of the partners are crucial in determining the strength of the observed CT band (log $e$ = 1 to 3), and strong interactions are found for assemblies in which the porphyrin and fullerene moieties are forced into a face-to-face geometry.\textsuperscript{a–c} The recent availability of a C$_{60}$-barbituric acid derivative\textsuperscript{6} greatly facilitates the construction of similar C$_{60}$-conjugated oligomer dyads using supramolecular interactions. In this approach, the hydrogen-bonding molecular recognition motif in 1 (Figure 1) is used to bind this fullerene-bearing moiety within the cavity of a barbituric acid receptor bearing complementary hydrogen-bond donor/acceptor sites. This arrangement (Figure 1) of the anticipated complex formed with six hydrogen bonds between 2 and the fullerene-based electron–acceptor species 1 shows the intimate contact that is possible between the electron donor and the electron acceptor units. Other conformations in which the 2TV units are not proximal to the fullerene are less stable, requiring either rotation of the amide N–CO bonds or perturbation of the binding site.

The energy-minimized structure (PM3 Hamiltonian, see Scheme 1) of the anticipated complex formed with six hydrogen bonds between 2 and the fullerene-based electron–acceptor species 1 shows the intimate contact that is possible between the electron donor and the electron acceptor units. Other conformations in which the 2TV units are not proximal to the fullerene are less stable, requiring either rotation of the amide N–CO bonds or perturbation of the binding site.

Scheme 1. Synthesis of 2$^a$

The energy-minimized structure (PM3 Hamiltonian, see Figure 1) of the anticipated complex formed with six hydrogen bonds between 2 and the fullerene-based electron–acceptor species 1 shows the intimate contact that is possible between the electron donor and the electron acceptor units. Other conformations in which the 2TV units are not proximal to the fullerene are less stable, requiring either rotation of the amide N–CO bonds or perturbation of the binding site.

Mixing equimolar quantities of building blocks 1 and 2 in aprotic solvents such as tolutene or o-dichlorobenzene (oDCB) results in the solubilization of the otherwise poorly soluble fullerene component. The electronic absorption spectra of 1-2 mixtures ([1]/[2] = 1) at various concentrations in oDCB are shown in Figure 2. In addition to the electronic absorption bands in the visible region, characteristic of the fullerene base, a broad absorption band at 300–320 nm is observed in the complex 1-2 in oDCB. This band is attributed to the charge-transfer (CT) transition associated with the fullerene–porphyrin system. The presence of this band in the electronic absorption spectrum of the complex 1-2 in oDCB suggests that the CT transition in the complex is enhanced upon binding to the barbituric acid receptor.

transitions of the individual species, an additional band devoid of fine structure can be observed at 390 nm. This absorption feature, which gives direct evidence for complexation, is not observed in control experiments using 2 and pristine C₆₀ or 5,5-diethylbarbituric acid or 1 and a barbituric acid receptor without the 2TV units. With the exception of the resonances of the N–H protons taking part in hydrogen bonding, which undergo a significant downfield shift, the ¹H NMR spectrum of 1·2 mixtures is similar to that of 2, indicating that no covalent transformation of the components has taken place. The new absorption band is therefore attributed to ground-state EDA interaction between the electron-rich 2TV and electron-poor fullerene moieties, which has not been previously observed in analogous covalent assemblies. The strength of this interaction can be rationalized by the face-to-face approach between the 2TV and fullerene moieties, combined with favorable thermodynamic factors due to hydrogen-bonding. Increasing solvent polarity (toluene, oDCB, benzonitrile) enhances the strength of this interaction can be deduced by subtracting the energy of the band’s absorption maximum.

Monitoring the disappearance of the CT band upon dilution gives direct access to the binding constant for the formation of the 1·2 complex (log Kₘ = 3.74 ± 0.10 M⁻¹ in oDCB assuming 1:1 binding stoichiometry; see ESI for details), which is comparable to association constants observed for assuming 1:1 binding stoichiometry; see ESI for details), absorption spectra of the individual components 1 and 2. The result is a strongly allowed transition typical of EDA complexes (λₓ = 390 nm; εₓ ≈ 32 500 M⁻¹ cm⁻¹ in oDCB).

Like C₆₀, 1 is weakly fluorescent (Φₐ = 9 × 10⁻⁴, τ = 1.2 ns in oDCB). Steady-state fluorescence emission spectra show that the emission of 1 or 2 in 1·2 mixtures is strongly quenched (no emission from the CT state was detected). This decrease in luminescence and lack of sensitized C₆₀ fluorescence upon excitation of the 2TV units in 2 is in agreement with fast photoinduced electron transfer (PET) from 2TV to the excited C₆₀ unit in 1·2, as previously observed in covalent dyad and triad systems containing C₆₀ as an electron acceptor. Addition of methanol (30% v/v) to solutions of 1·2 proved to be effective in restoring the fluorescence of 1, presumably by disrupting the hydrogen-bond network in 1·2. The quenching of the fluorescence of 1 must be accompanied by a reduction of the excited state lifetime. However, time-resolved emission studies indicate that the quenching process is significantly faster than the resolution of our instrument (20 ps fwhm).

Preliminary experiments using ultrafast transient absorption spectroscopy (180 fs fwhm pulse, λₑₓ = 310 nm) confirmed the occurrence of fast PET in the supramolecular assembly. Whereas the transient absorption spectra of 2 in oDCB are characterized by a single band centered at 650 nm, in mixtures of 1 and 2 ([I] = [2] = 4 × 10⁻⁴ M in oDCB), an additional absorption band is seen at 560 nm (Figure 3). The latter is attributed to the absorption of the 2TV⁺⁺ formed by electron transfer to the nearby fullerene in 1·2 assemblies by comparison with the transient spectrum obtained from ns-laser flash photolysis of 2 in the presence of tetracyanoethylene (1:1 CH₃CN/oDCB, λₑₓ = 355 nm).

Figure 3. Transient absorption spectra of 1·2 and 2 (curves A and B, respectively, 3 ps after flash, in oDCB). The absorption of the free 2⁺⁺ (curve C) was obtained by conventional ns-laser flash photolysis of 2 in the presence of tetracyanoethylene (1:1 CH₃CN/oDCB, λₑₓ = 355 nm).

(9) The high-energy position of the band (2.75 eV, as deduced from the onset of the absorption) suggests that it involves orbitals other than the LUMO of 1 and the HOMO of 2.

(10) Photoinduced electron transfer in 1·2 is calculated to be strongly exothermic: ΔGₓ = −0.8 eV, assuming Eₑₓ(2) = 0.89 V and Eₑₓ(1) = −0.7 V vs SCE and Eₓ = 2.75 eV; see ref 2a.
observation of an absorption band in the NIR region at ca.
1050 nm, attributed to 1− bound to 2++. Kinetic analysis at
570 nm provides a forward electron-transfer rate of 5.5 ×
10^{12} \text{ s}^{-1}. The recovery of the ground state (by back electron
transfer) occurs with a rate constant \( k_{\text{b}} = 4.5 \times 10^9 \text{ s}^{-1}. \) No evidence for energy transfer to the lower-lying \( S_1 \) or \( T_1 \)
states of 1 could be detected.

In conclusion, supramolecular 1:1 hydrogen-bonded as-
semblies were constructed using a fullerene–barbituric acid
component and a suitable receptor dyad possessing \( nTV \)
arms. The structure, whose engineered orientation between
the oligothienylenevinylene electron donor and fullerene
electron acceptor is characterized by a large binding constant
and the observation of an intense EDA absorption feature
between the 2TV and \( C_{60} \) moieties, demonstrates the utility
of supramolecular systems in understanding the molecular-
scale interactions between redox-active components.
