Abstract: We perform extensive simulations of light scattering by a granulated sphere in the size and refractive index range of human granulated leucocytes using the discrete dipole approximation. We calculate total and depolarized side scattering signals as a function of the size and refractive indices of cell and granules, and the granule volume fraction. Using typical parameters derived from the literature data on granulocyte morphology, we show that differences between experimentally measured signals of two granulocyte subtypes can be explained solely by the difference in their granule sizes. Moreover, the calculated depolarization ratio quantitatively agrees with experimental results. We also use the Rayleigh-Debye-Gans approximation and its second order extension to derive analytical expressions for side scattering signals. These expressions qualitatively describe the scaling of signals with varying model parameters obtained by rigorous simulations, and even lead to quantitative agreement in some cases. Finally, we show and discuss the dependence of extinction efficiency and asymmetry parameter on size and volume fraction of granules.

1. Introduction

Simulation of light scattering by homogeneous particles with simple shapes, such as spheroids, is relatively easy [1]. Unfortunately, most natural particles are inhomogeneous and have a complex shape. A broad class of such particles can be characterized by a matrix with multiple inclusions (granules). A number of approximations exist to simulate light scattering by these particles which fall in one of two connected realms: effective medium theories (EMTs) [2-4] or radiative transfer theories [5]. The latter is especially relevant when an infinite medium is considered or granule positions randomly fluctuate with significant amplitude during the observation time.

However, in many cases none of these approximations is accurate enough and rigorous light scattering theories are required. The superposition T-matrix method allows simulation of light scattering by clusters of spheres [6,7], which is a particular case of a granulated particle when the matrix is vacuum. Recently Mishchenko et al. [8] studied clusters of spheres with respect to radiative transfer theories. Apart from that, only general methods like the finite difference time domain method (FDTD) [9] or the discrete dipole approximation (DDA) [10] are capable of simulating light scattering by arbitrarily shaped granulated particles. Most researchers who studied granulated particles are concerned with astrophysical or atmospheric applications [3,4,8,11], while our main application – light scattering by biological cells – is a much less studied field.

Biological cells, when suspended in liquid, have an important advantage with respect to the light scattering simulation. Their relative refractive index is close to unity. This accelerates the rigorous methods and improves the accuracy of the EMTs and other approximate theories. FDTD simulation of light scattering by biological cells was performed in a number of manuscripts by Dunn and coworkers (summarized in [12]). To the best of our knowledge, these are the only studies that include cell organelles and granules in rigorous light scattering modeling. The main conclusion is that side scattering by biological cells are mainly determined by small granules, which agrees with the general notion of flow cytometry [13]. However, only the dependence on the volume fraction and not on the size of the granules was studied.

Study of light scattering by granulated biological cells is motivated by several empirical techniques that use the dependence of light scattering signals measured by flow cytometer on the characteristics of the granules [14-17]. All these techniques are successfully used in practice but lack a rigorous theoretical foundation. For instance, production of the inclusion bodies consisting of protein synthesized by E. coli cells was found to correlate with forward scattering [16,17], which can be qualitatively explained by the increase of total amount of matter that scatters light inside the cells. Probably, the most fascinating application of light scattering to characterize granulated cells is the results of de Grooth, Terstappen and coworkers [14,18,19], who showed that neutrophils and eosinophils can be discriminated by their depolarized side scattering intensity $I_\perp$. This result was extended to other species by Suzuki and Eguchi [15]. The values for light scattering signals are given in arbitrary units by de Grooth et al. [14] and, hence, can be compared to other studies only qualitatively. However, the ratios of the signals, which are also provided, can be compared quantitatively to predictions of any models, thus providing a stringent test of the latter.

Granulocytes are the most numerous type of leukocytes, consisting of three subtypes: neutrophils, eosinophils, and basophils. Their abundance relative to all leukocytes in normal condition is in the ranges 46–73%, 0–4.4%, and 0.2–1.2% respectively [20]. The major role of neutrophils is to protect the host against infectious agents. To accomplish this task, the neutrophil must first sense infection, migrate to the site of the infecting organism, and then destroy the infectious agents [21]. Although rare in healthy individuals, the eosinophil is prominent in peripheral blood and tissue in association with various disease conditions including allergy, inflammatory responses against metazoan helminthic parasites, and certain skin and malignant conditions [22].
In this manuscript we aim at two goals: to get general insight into light scattering by index-matching granulated particles much larger than the wavelength and to rigorously explain why eosinophils and neutrophils have different $I_\perp$. For that we construct a simple model of granulocytes in Section 2, starting from literature data on its morphology. In Section 3 we specify the total and depolarized side scattering signals measured by flow cytometers. We derive analytical expressions for these signals using the Rayleigh-Debye-Gans (RDG) approximation and its second-order extension in Sections 4 and 5 respectively. We show the results of extensive DDA simulations in Section 6, comparing them with predictions of approximate theories and known experimental results. We conclude the manuscript in Section 7 and discuss perspectives for characterizing granulated particles, specifically granulocytes, with light scattering.

2. Simple granulocyte model and DDA simulations

Both neutrophils and eosinophils have a size of 10–15 $\mu$m as measured in blood smears [21]. However Ting-Beall et al. [23] reported that a normal suspended neutrophil has a volume of $299 \pm 64 \mu m^3$, which corresponds to a diameter $8.3 \pm 0.6 \mu m$ (intervals correspond to two standard deviations). A similar value for the diameter of mature neutrophils ($8.3 \pm 1.2 \mu m$) was obtained by Brederoo et al. [24] using electron microscopy. For eosinophils a value of $8 \mu m$ has been reported [22]. The nucleus is separated into definite lobes with a very narrow filament or strand connecting the lobes. Usually, two or three lobes are observed [22,25,26].

Neutrophils contain two major types of granules: azurophilic and specific granules, although more minor classes can be specified [24,27,28]. Azurophilic granules are larger and more dense than the specific ones, and the ratio of their numbers is 1/2–1/3 [29]. A typical size of azurophilic granules is 500 nm, whereas specific granules are either spherical with a size of 200 nm (Livesey, et al., [27] reported the range 100–250 nm) or rod shaped (130×1000 nm) [30]. On average a cell cross section contains 200–300 granules [30], with a total volume of 30 $\mu m^3$ [29]. Eosinophils contain three major classes of granules: crystalloid, primary, and small granules. Crystalloid granules measure 0.5–0.8 $\mu m$ in diameter [22] (Puppels et al. [26] reported another range: 0.9–1.3 $\mu m$) and contain crystalline electron-dense cores surrounded by an electron-lucent matrix. There are approximately 200 crystalloid granules in each cell [22,26]. Primary granules measure 0.1–0.5 $\mu m$ in diameter and are less abundant than crystalloid granules. Small granules are even smaller than primary ones [22].

We use a granulated sphere as a model for granulocytes (see Fig. 1). The sphere contains no nucleus and all the granules are identical and randomly placed inside the cell. Thus, we compromise between realistic shapes (cf. [12]) and a general fundamental approach (cf. [8]). We are able to study the dependence of light scattering of each of the particle parameters independently, and at the same time to quantitatively describe at least the depolarization ratios of neutrophils and eosinophils (see Section 6).

Fig. 1. The granulated sphere model. All granules are identical and randomly positioned.
In the following we describe the default parameters of the model. The diameter of the cell $D_c = 8 \mu m$ and volume fraction of granules $\phi = 0.1$ correspond to the above data on morphology of both neutrophils and eosinophils. Dunn collected information on refractive indices of the cell cytoplasm and constituents from several sources [12]. However, the ranges are broad, which makes it hard to select a particular value. We set the cytoplasm refractive index, relative to the medium (for which we consider buffered saline $m_b = 1.337$), to $m_g = 1.015$, which corresponds to the values obtained by fitting experimental light scattering patterns of lymphocytes by a multi-layered sphere model [31,32]. For the granules we set the relative refractive index to the upper limit as if granules consist entirely of proteins, $m_g = 1.2$. This choice exaggerates all light scattering effects of granules; however, as we will show, all conclusions also are valid for smaller $m_g$. We completely neglect absorption in this study, and set the wavelength to that of a $0.66 \mu m$ semiconductor laser, which is $0.4936 \mu m$ in the medium. The main variable is the granule diameter $d_g$, which is varied from $0.075$ to $2 \mu m$.

The lower limit is determined by the size of the dipole in DDA, which was set to $0.041$ mean value simulation depends on random granule placement, therefore we repeat it 10 times and show all simulations, corresponding to $12$ dipoles per wavelength in the outer medium. Each DDA $D$ default values are intensity collected by the photodetector $I_{SS}$ and convergence threshold (relative residual norm less than $10^{-8}$), polarizability (lattice dispersion relation), iterative method (quasi minimal residual method), computation), allowing simulating light scattering by scatterers much larger than a $v.0.76$, which is capable of running on a cluster of computers (parallelizing a single DDA node has dual Intel Xeon $3.4$ GHz processor with $4$ GB RAM), but it is about $1.5$ hours on $16$ Dutch compute cluster LISA [36]. Typical simulation time is half an hour on $8$ nodes (each node), excluding the limitations of the current code).

We also varied some of the parameters from their default values. To limit the number of DDA simulations and keep the time of this study feasible we varied each parameter with others fixed. For each set of parameters a whole range of $d_g$ was calculated. We tried four additional values of $\phi$: $0.02$, $0.05$, $0.2$, and $0.3$, two values of $D_c$: $4$ and $14 \mu m$, two of $m_g$: $1.1$ and $1.15$, and one of $m_c = 1$, i.e. no cytoplasm at all (actually we used $m_c = 1.000001$ because of the limitations of the current code).

As a numerical implementation of the DDA we have used the ADDA computer code v.0.76, which is capable of running on a cluster of computers (parallelizing a single DDA computation), allowing simulating light scattering by scatterers much larger than a wavelength [34,35]. In this manuscript we use the default ADDA settings for dipole polarizability (lattice dispersion relation), iterative method (quasi minimal residual method), and convergence threshold (relative residual norm less than $10^{-5}$) and employ the built-in granule generator. For each particle we calculated $Q_{ extras}$, $\langle \cos \theta \rangle$, and the whole Mueller matrix for the whole scattering angle with steps of $0.5^\circ$ and $5^\circ$ in polar $\theta$ and azimuthal $\phi$ angles respectively. Moreover, we refined the grid to $0.5^\circ$ step in $\phi$ near the side scattering direction to accurately compute the signals described in Section 3. All simulations were run on the Dutch compute cluster LISA [36]. Typical simulation time is half an hour on $8$ nodes (each node has dual Intel Xeon $3.4$ GHz processor with $4$ GB RAM), but it is about $1.5$ hours on $16$ nodes for $D_c = 14 \mu m$.

3. Orthogonal light scattering
We simulate the side scattering signals exactly as described by de Grooth et al. [14]. The incident light propagates along the $z$-axis and is polarized along the $x$-axis, and the particle is located in the origin. The exact side scattering direction is along the $y$-axis. A lens focused on the particles projects the scattered light on the photodetector; both the lens and the photodetector are centered around and orthogonal to the $y$-axis. A rectangular diaphragm placed before the lens limits the collection scattering angles to $\theta = 90^\circ \pm \Delta \theta$ and $\varphi = 90^\circ \pm \Delta \varphi$. The default values are $\Delta \varphi = 25^\circ$. The measured signals are the total side scattering intensity collected by the photodetector $I_{SS}$ and the total depolarized intensity $I_{d}$, when a polarizer with polarization axis along the $z$-axis is placed before the photodetector. The depolarization ratio is defined as $D_{SS} = I_d / I_{SS}$.
In the original paper [14] an expression of $I_{SS}$ and $I_\perp$ in terms of the amplitude scattering matrix ($S_i$) is derived, however it has a typographical error in one sign. Therefore, we present the corrected derivation in the following and also derive an expression in terms of the Mueller scattering matrix ($S_{ij}$). We denote the radius vector of a point on the lens as $r$, and scattering direction $\mathbf{n} = r/r$, which corresponds to scattering angles $\theta$ and $\phi$. We introduce unity vectors $\mathbf{e}_\perp$ and $\mathbf{e}_\parallel$ orthogonal and parallel to the scattering plane respectively, which are the local basis for scattered wave in point $r$, i.e. $\{ \mathbf{e}_\perp, \mathbf{e}_\parallel, \mathbf{n} \}$ is a right-handed orthogonal basis (according to Bohren and Huffman [33]). These vectors are connected to the basis vectors of a spherical coordinate system by $\mathbf{e}_\parallel = e_\theta$, $\mathbf{e}_\perp = -e_\phi$. We assume that incident light has unity amplitude. Then two components of the scattered electric field in point $r$ (before the lens) is given by:

$$
E_x^{\text{sc}}(r) = (S_x \cos \varphi + S_3 \sin \varphi) \frac{e^{i k r}}{i k r}, \quad E_y^{\text{sc}}(r) = (S_x \cos \varphi + S_3 \sin \varphi) \frac{e^{i k r}}{-i k r}.
$$

The lens rotates the propagation vector of the scattered wave from $\mathbf{n}$ to $\mathbf{e}_y$ together with the electric field vector. We introduce the following auxiliary unity vectors:

$$
\left\{ \mathbf{e}_1, \mathbf{e}_2, \mathbf{n} \right\} = R_\eta(\mathbf{n}),
$$

where $R_\eta(\mathbf{e})$ denotes the rotation by angle $\eta$ around the vector $\mathbf{e}$, which changes the components of the electric field accordingly. The lens transformation does not change the component of the electric field along $\mathbf{e}_1$ and directly maps the component along $\mathbf{e}_2$ to the component along $\mathbf{e}_3$. Therefore the components $E_x^{\text{det}}$ and $E_y^{\text{det}}$ can be obtained from $E_x^{\text{sc}}$ and $E_y^{\text{sc}}$ by rotation of the reference frame by the angle $\eta = \eta_1 + \eta_2$:

$$
E_x^{\text{det}} = E_x^{\text{sc}} \cos \eta + E_y^{\text{sc}} \sin \eta, \quad E_y^{\text{det}} = -E_x^{\text{sc}} \sin \eta + E_y^{\text{sc}} \cos \eta.
$$

It is easy to show from geometrical considerations that

$$
\tan \eta_1 = e_\perp \cdot e_\parallel = \sec \varphi \cot \theta, \quad \tan \eta_2 = n_\parallel \cdot n_\perp = \sec \varphi \cot \theta,
$$

$$
\cos \eta = \frac{\cos \theta \cos \varphi}{1 + \sin \theta \sin \varphi}, \quad \sin \eta = \frac{\sin \theta + \sin \varphi}{1 + \sin \theta \sin \varphi}.
$$

The corresponding angle-resolved total and depolarized intensities, which are sensed by the detector, are

$$
J_{SS} = |E_x^{\text{det}}|^2 + |E_y^{\text{det}}|^2, \quad J_\perp = |E_x^{\text{det}}|^2.
$$

Using Eqs. (1), (4), and (7) and the definition of the Mueller scattering matrix in terms of the amplitude scattering matrix [33] one can obtain:

$$
J_{SS} (\theta, \varphi) = \frac{1}{k^2 r^2} [S_{11} + S_{12} \cos(2\phi) + S_{13} \sin(2\phi)],
$$

$$
J_\perp (\theta, \varphi) = \frac{1}{2 k^2 r^2} \left[ S_{11} - S_{22} \cos(2\eta) + S_{33} \sin(2\eta) \right]
$$

$$
+ \left[ S_{12} \cos(2\eta) + S_{13} \sin(2\eta) \right] \cos(2\phi) + \left[ S_{11} - S_{33} \cos(2\eta) + S_{22} \sin(2\eta) \right] \sin(2\phi).
$$

The same result can be obtained using the Mueller matrix formalism.

The final signals, measured by the detector, are proportional to the intensities integrated over the scattering aperture:

$$
I_{SS, \perp} = k \int_{\text{apert}} d\varphi d\theta r^2 \sin \theta J_{SS, \perp} (\theta, \varphi).
$$
We choose the proportionality coefficient $\kappa = k^2/(4\Delta\theta \Delta\phi)$, so that $I_{SS}$ and $I_\perp$ are linear combinations of the Mueller matrix elements averaged over the scattering aperture. Moreover, in the limit of infinitesimal small aperture, the expressions are especially simple:

$$\Delta\theta, \Delta\phi \to 0 \Rightarrow I_{SS} \to S_{11} - S_{12}, \quad I_\perp \to S_{11} + S_{21} - S_{12} - S_{22},$$

(11)

where all Mueller matrix elements are considered at exact side scattering direction. The particular value of $\kappa$ is not relevant since we will always consider either qualitative behavior of plots including $I_{SS}$ and $I_\perp$ or relative values.

Next, we summarize the experimental conclusions of de Grooth, et al. [14], that we will explain by rigorous DDA simulations in Section 6. The scatter plot of the sample containing eosinophils and neutrophils in $I_\perp$ versus $I_{SS}$ coordinates shows clear discrimination of two subtypes. The $I_{SS}$ signals are almost the same, while $I_\perp$ are larger for eosinophils. Moreover, there is significant correlation between $I_\perp$ and $I_{SS}$ for both neutrophils and eosinophils. Discrimination between two subtypes is the most pronounced using $D_{SS}$, with mean values of 0.044 and 0.013 for eosinophils and neutrophils respectively (averaged over a single sample). They also showed that $D_{SS}$ is almost constant when $\Delta\phi$ is decreased at fixed $\Delta\theta$ for both granulocyte subtypes. Thus, the depolarization signals of granulocytes are inherent in contrast to the aperture depolarization, e.g. of a sphere, which is caused by a finite value of the detector aperture around the exact side scattering direction and decreases to zero with decreasing $\Delta\phi$.

4. The Rayleigh-Debye-Gans approximation

Consider our model of a granulated sphere (see Section 2). The position of the granule centers relative to the origin, which is placed in the cell center, is given by vectors $\mathbf{r}_i$, where $i$ is from 1 to $N$, and $N$ is total number of granules. $V_c$, $x_c$ and $V_g$, $x_g$ are the volume and the size parameter of the cell and one granule respectively, and the volume fraction of granules is given by $f = NV_g/V_c = N(x_g/x_c)^3$. We assume that granules are randomly positioned inside the cell, and they are not allowed to overlap. Furthermore, to simplify our derivations we assume that $x_g \ll x_c$. It is important to note that $x_g$ can be both small and large compared to unity. We formulate the random granule position as: $\mathbf{r}_i$ is uniformly random inside the sphere with size parameter $x_c - x_g$. Thus we neglect the boundary effects due to the non-overlapping of granules, which are significant only for large $f$ in the layer of width of order of $d_g$ from the cell boundary. It is important to note that the pair distribution function of granules, which will be discussed below, is much more sensitive to the non-overlapping condition than the probability distribution function of a single granule position. The incident wave propagates along the $z$-axis and the scattering direction $\mathbf{n}$ is described by angles $\theta$ and $\phi$. We consider the scattering problem of a particle in vacuum, i.e. we divide all relevant quantities by the refractive index of the host medium.

To understand the dependence of side-scattering intensity on the granule size we consider the RDG approximation [33]. We consider the limit of small refractive indices, i.e. $|m - 1| \ll 1$ for both cell cytoplasm and granules. Actually, RDG is strictly valid only when $|m - 1| \ll 1$, which, strictly speaking, is not true for our particles. We will see, however, that it is capable of describing some features that are obtained by accurate DDA simulations.

Our goal is to derive simple analytical expression rather than to keep all derivations as accurate as possible. We can derive the final RDG result numerically with any required accuracy for any particular granule configuration and then perform numerical averaging over all possible configurations. This is a laborious task, albeit much faster than the DDA simulations. However, such brute-force numerical simulations of RDG-based theory are anyway not accurate enough. Therefore, we prefer to additionally sacrifice some accuracy to derive analytical expressions, which give added value compared to rigorous DDA simulations. This value consists in physical insight into the light scattering problem, e.g. scaling laws, and the opportunity for an approximate solution of the inverse light scattering problem. Although
we discuss all employed assumptions and approximations, the accuracy of the final expressions can only be determined by comparison with the DDA simulations. According to the RDG theory, only the diagonal elements of the amplitude scattering matrix are nonzero \([33]\):

\[
S_i(n) = -\frac{ik^3}{2\pi} \sum_{n=0}^{N} (m_i - 1)V_i(h(V_i, n), S_i(n) = S_i(n)\cos \theta, \tag{12}
\]

where the particle is divided into \(N + 1\) domains: \(i = 0\) corresponds to the cytoplasm and the rest to \(N\) granules. \(m_i\) and \(V_i\) are refractive index and volume of each domain. \(h(V_n, n)\) is a form factor given by

\[
h(V_n, n) = \frac{1}{V} \int d^3r \exp(i\mathbf{r} \cdot \mathbf{q}), \tag{13}
\]

where we have introduced \(\mathbf{q} = k(\mathbf{e}_i - \mathbf{n}).\) The form factor for a sphere, which center is in the origin, can be obtained analytically \([33]\):

\[
h_s(x, \theta) = g_s(u) = \frac{3}{u} (\sin u - u \cos u), u = qr = 2x \sin \frac{\theta}{2}, \tag{14}
\]

where \(r\) and \(x\) are the radius and the size parameter of a sphere, and there is no dependency on the azimuthal angle. The asymptotic behavior of Eq. (14) is:

\[
g_s(u) = \begin{cases} 
1 + O(u^3), & u < 1; \\
3u^{-2} \cos u + O(u^{-3}), & u > 1.
\end{cases} \tag{15}
\]

Using the linearity of Eq. (12) in the factor \(m - 1,\) we consider separately the spherical cytoplasm with factor \(m_c - 1\) and superimposed granules with factor \(m_g - m_c.\) Then, Eq. (12) can be rewritten as

\[
S_i(n) = -\frac{ik^3}{2\pi} \left[(m_i - 1)V_i h_s(x_i, \theta) + (m_g - m_c)V_i h_s(x_g, \theta) \xi(N) \right], \tag{16}
\]

where \(\xi(N)\) holds all the dependency on granule positions:

\[
\xi(N) = \sum_{i=1}^{N} \exp(i\mathbf{r}_i \cdot \mathbf{q}). \tag{17}
\]

Averaging of \(\xi(N)\) over all possible granule positions is performed independently for each element of the sum leading to the same integral as the one in Eq. (13), therefore

\[
\langle \xi(N) \rangle = Nh_s(x_c - x_g, \theta). \tag{18}
\]

The second moment of the absolute value of \(\xi(N)\) is given by:

\[
\langle |\xi(N)|^2 \rangle = \sum_{i,j=1}^{N-1} \langle \exp(i(\mathbf{r}_i - \mathbf{r}_j) \cdot \mathbf{q}) \rangle = N + N(N - 1) \langle \exp(i(\mathbf{r}_i - \mathbf{r}_j) \cdot \mathbf{q}) \rangle_{i,j}. \tag{19}
\]

Now we consider a particular case by assuming that \(\mathbf{r}_i\) and \(\mathbf{r}_j\) are independent. In other words, we neglect the effect of the non-overlapping condition on the statistical properties of granule positions. This is only valid for sufficiently small volume fractions \((f \ll 1)\). Then

\[
\langle |\xi(N)|^2 \rangle = N + N(N - 1) h_s^2(x_c - x_g, \theta), \tag{20}
\]

Using Eqs. (18) and (20) one can obtain

\[
\langle |S_i(\theta)|^2 \rangle = \left(\frac{2}{3} x_c^3\right)^2 \left[(m_i - 1)h_s(x_i, \theta) + f(m_g - m_c)h_s(x_g, \theta)h_s(x_c - x_g, \theta)\right]^2
\]

\[
+ f(m_g - m_c)h_s(x_g, \theta)\left[1 - h_s^2(x_c - x_g, \theta)\right]/N. \tag{21}
\]

Equation (21) is obtained under the assumptions \(x_g \ll x_c\) and \(f \ll 1\) (and the RDG approximation itself). In particular, if the limit \(x_g \to 0\) and \(N \to \infty\) is taken, keeping \(f\) constant, then
\[
\left\langle |S_j(\theta)|^2 \right\rangle = \left| \frac{2}{3} x_c^2 (m_c - 1) h(x_c, \theta) \right|^2, \quad m_e = f m_g + (1 - f) m_c,
\]  

which is exactly an RDG result for a homogeneous sphere with effective refractive index \( m_e \). The expression for \( m_e \) can be considered as a simplified Maxwell-Garnett EMT in the limit of both \( m_g \) and \( m_c \) being close to unity. If we consider typical parameters of our problem: \( m_c = 1.015, \quad m_g = 1.2, \quad \lambda = 0.4936 \text{\,\mu m}, \quad D_c = 8 \text{\,\mu m} \), then even for the smallest \( x_g \) and \( f \) that we simulated (\( x_g = 0.48 \iff d_g = 75 \text{\,nm}, \quad f = 0.02 \)) the first term in Eq. (21) (the one that is independent of \( N \)) is about an order of magnitude smaller than the second. Therefore, we may completely neglect the cytoplasm except for its total volume and the effect it has on the refractive index of the granules. By that we introduce an assumption \( x_c \gg 1 \), and use it for a new evaluation of Eqs. (18) and (19) discarding the condition \( f \ll 1 \). Granules are uniformly distributed inside a large volume with volume fraction \( f \), without overlapping. Taking the limit of infinitely large volume (\( N \rightarrow \infty, f = \text{const} \)) and finite \( \theta \) (\( \theta \sim 1 \)), that is equivalent to a model of a hard spheres liquid, for which it is known [37,38]

\[
\langle \xi(N) \rangle = 0, \quad \langle |\xi(N)|^2 \rangle = N S_f(q);
\]

\( S_f \) is a structure factor, for which an explicit albeit cumbersome expression is known [37]:

\[
\frac{1}{S_f(q)} = 1 + 24 f \left[ a_f \left( \frac{2}{v^2} - 1 \right) \cos v + 2 \sin v - \frac{2}{v} \right] + 2 f a_f \left[ \frac{24}{v^3} + 4 \left( 1 - \frac{6}{v^2} \right) \sin v - \left( \frac{12}{v^2} + \frac{24}{v^3} \right) \cos v \right],
\]

\[
v = q d_g = 4 x_g \sin(\theta/4), \quad a_f = \frac{(1 + 2 f)^2}{(1 - f)^4}, \quad b_f = -\frac{3 f (2 + f)^2}{2 (1 - f)^4}.
\]

Employing the assumptions discussed above together with Eqs. (16), (23) one may obtain

\[
\left\langle |S_j(\theta)|^2 \right\rangle = \frac{2}{3} x_c^2 f (m_g - m_c) h(x_c, \theta) |S_f(q)|^2 / N.
\]

Derivation of Eq. (26) under the assumption \( x_c \gg 1 \) is similar to that performed in §3.3 of [39]. The final quantity of interest is the total side scattering intensity [cf. Eqs. (8) and (10)]:

\[
I_{ss} = \frac{1}{4 \Delta \theta \Delta \phi} \int_{\pi/2 - \Delta \theta}^{\pi/2 + \Delta \theta} \int_{\pi/2 - \Delta \phi}^{\pi/2 + \Delta \phi} d\phi d\theta (S_{11} + S_{12} \cos 2\phi + S_{11} \sin 2\phi)
\]

\[
= \frac{1}{2 \Delta \theta \Delta \phi} \int_{\pi/2 - \Delta \theta}^{\pi/2 + \Delta \theta} \int_{\pi/2 - \Delta \phi}^{\pi/2 + \Delta \phi} d\phi d\theta |S_f(n)|^2 \left[ (1 + \cos^2 \theta) + (\cos^2 \theta - 1) \cos 2\phi \right],
\]

where Eq. (12) was used. Since averaging and integration can be interchanged,

\[
\left\langle I_{ss} \right\rangle = \frac{1}{4 \Delta \theta} \int_{\pi/2 - \Delta \theta}^{\pi/2 + \Delta \theta} d\phi \left( 1 + \cos^2 \theta \right) (1 + \cos^2 \theta) \sin 2\phi \left| S_f(\theta) \right|^2.
\]

Using Eq. (26), this integral can be computed numerically for any set of parameters. It is interesting to analyze the scaling of RDG results. For that we rewrite Eq. (28) as

\[
\left\langle I_{ss} \right\rangle = \frac{4}{9} x_c f |m_g - m_c|^2 h_{ss}(x_c, f),
\]

where \( h_{ss}(xf) \) is the following function:
First, we analyze the scaling behavior of \( g_f(v) \). One may show that
\[
g_f(v) = \begin{cases} 
\frac{(1 - v^2)^2}{(1 + 2v^2)^2} + O(v^2), & v < 1; \\
1 + O(v^{-2}), & v > 1,
\end{cases}
\]
and finally:
\[
h_{SS}(x, f) = \begin{cases} 
C_1^{op} \frac{(1 - f)^2}{(1 + 2f)^2} x^3 + O(x^3), & x < 1; \\
C_2^{op} x^{-1} + O(x^{-2}), & x > 1,
\end{cases}
\]
where constants \( C_{1,2}^{op} \) are determined by the aperture angles \( \Delta \theta \) and \( \Delta \varphi \). \( C_2^{op} \) also weakly depends on \( x \), but this is ignored in this discussion.

### 5. The second-order Born approximation

To theoretically approach the depolarized intensity we employ the second order of the RDG or, more precisely, the second-order Born (2-Born) approximation. We use the same definitions as given in Section 4, and the same philosophy of preferring simplicity to the best possible accuracy. The internal field inside the scatterer is a sum of two orders (see e.g. [10]):
\[
E(r) = E^{inc}(r) + E^{(1)}(r), \quad E^{(0)}(r) = E^{inc}(r),
\]
\[
E^{(1)}(r) = \int \frac{d^3 r \mathcal{G}(r,r') \chi(r') E^{(0)}(r') - \frac{4\pi}{3} \chi(r) E^{(0)}(r)}{V_0},
\]
where \( E^{inc}(r) \) and \( E(r) \) are the incident and total electric field, \( \chi(r) = (m^2(r) - 1)/4\pi \) is the susceptibility of the medium, \( V_0 \) is an infinitesimally small spherical exclusion volume around \( r \). \( \mathcal{G}(r,r') \) is the free space dyadic Green’s function, defined as
\[
\mathcal{G}(r,r') = \exp(ikR) \left[ \frac{k^2}{R} \left( I - \frac{\hat{R} R}{R^2} \right) - \frac{1}{R^2} \left( I - \frac{\hat{R} \hat{R}}{R^2} \right) \right],
\]
where \( I \) is the identity dyadic, \( k = \omega c \) is the free space wave vector, \( R = |r - r'| \), \( R = |R| \), and \( \hat{R} \) is a dyadic defined as \( \hat{R}_{\mu\nu} = R_{\mu} R_{\nu} \) (\( \mu \) and \( \nu \) denote Cartesian coordinates).

Most of the scattering quantities can be obtained from the scattering amplitude [33]:
\[
\mathbf{F}(n) = -ik^3 (I - \hat{n} \hat{n}) \int d^3 r' \exp(-ikr' \cdot n) \chi(r') \mathbf{E}(r').
\]
To simplify our derivations we consider the depolarized intensity \( I_\perp^{(0)} \) for zero aperture \( \Delta \theta = \Delta \varphi = 0^\circ \), i.e. we study only the intrinsic part, which is not caused by the finite value of the aperture. Then
\[
I_\perp^{(0)} = |S_1(e_i)|^2,
\]
while \( S_1(e_i) = F_1(e_i) \) for the incident field equal to
\[
E^{inc}(r) = e_i \exp(ikr_i).
\]
It is easy to show that both \( E^{(1)}(r) \) and the last term in Eq. (34) results in zero contribution to
$S_i(e_i)$, from which it follows that

$$S_i(e_i) = -ik^3 \sum_{i,j=1}^N \int d^3r' d^3r \exp(ik(r_i - r_i')) \chi(r') \chi(r) G_{ij}(r,r').$$ \hspace{1cm} (39)$$

Like in the RDG derivations, we divide the scatterer into the whole volume $V_c$ with susceptibility $\chi_c$ and superimposed granules with total volume $V_{grs}$ and susceptibility $\chi_{grs} - \chi_c$. The integral in Eq. (39) is decomposed into four parts: a double integral over $V_c$, a double integral over $V_{grs}$ and two cross-terms (over $V_i$ and $V_{grs}$). The first term is just a second-order Born approximation for a homogenous sphere, which identically equals zero because of symmetry ($S_1$ is always zero for a sphere). The cross-terms are very similar and they both can be thought of as RDG scattering by $V_{grs}$ for an incident field produced by the RDG applied to $V_c$. One can show that the RDG applied to an index-matching homogenous sphere much larger than the wavelength produces an internal field parallel to the incident one, except at a distance of order of wavelength from the boundary. The $x$-component of the internal field does not contribute to the depolarization at exact side scattering direction. Therefore, the relative contribution of the cross-terms in Eq. (39) is at least an order of $m_c - 15.00$ smaller than the remaining granule-granule interaction, and can be neglected. Moreover, interaction of a granule with itself results in identically zero polarization. Hence,

$$S_i(e_i) = -i k^3 \frac{1}{4\pi} (m_c - m_g)^2 \sum_{i,j=1}^N \int d^3r' d^3r \exp(ik(r_i - r_i')) G_{ij}(r,r').$$ \hspace{1cm} (40)$$

Averaging Eq. (37) over all possible sets of granule positions results in

$$\langle I^{(0)} \rangle = \frac{k^6}{16\pi^3} |m_c - m_g|^2 \sum_{i,j=1}^N \int d^3r' d^3r d^3r' \exp(ik(r_i - r_i')) \times$$

$$\times \langle G_{ij}(r,R_{ij} + r') G_{ij}(r',R_{ij} + r') \exp(ik(R_{ij} - R_{ij} + R_{ij} - R_{ij})) \rangle,$$

(41)

where $\ast$ denotes complex conjugate, $R_{ij} = r_i - r_j$, and integration is performed over a granule positioned in the origin. If all four indices: $i, j, i', j'$ are different then $R_{ij}$ and $R_{ij'}$ are independent. We assume that $R_{ij}$ and $R_{ij'}$ ($j \neq j'$) are also independent; by that we neglect the triple correlations. In case arguments of two Green’s tensors in Eq. (41) are independent, they can be averaged independently. The result is then zero because changing sign of the $x$ component of $R_{ij}$ inverts the sign of $G_{ij}(R_{ij})$ while not affecting any of the exponents in Eq. (41). Therefore, we need to consider only the terms with either (1) $i = i'$ and $j = j'$ or (2) $i \neq i'$ and $j = j'$. All the instantiations of (1) are equivalent, and so are the instantiations of (2). Therefore,

$$\langle I^{(0)} \rangle = \frac{k^6}{16\pi^3} |m_c - m_g|^2 N^2 \int \left| H(R_{ij}) \right|^2 \left| 1 + \exp(ik(e_i + e_j) \cdot R_{ij}) \right|^2 d|R_{ij}|,$$

(42)

$$H(R) = \int_{V_{grs}} d^3r' d^3r \exp(ik(r_i - r_i')) G_{ij}(r,R + r').$$

(43)

where $N \gg 1$ is assumed.

To keep the derivations analytical in calculation of $H(R_{ij})$ we assume that $R_{ij} \gg d_g$. However, the following derivation is expected to be approximately correct also for small $R_{ij}$, resulting in the correct scaling laws but with different constants. Employing the assumption of distant granules we obtain

$$H(R) = G_{ij}(R) \int_{V_{grs}} d^3r' d^3r \exp(ik(r_i - r_i' + (r' - r) \cdot n))$$

$$= V_{grs}^2 G_{ij}(R) g_{ij}(x_n - e_i) g_{ij}(x_n - e_j),$$

(44)

where $g_{ij}(u)$ is defined by Eq. (15) and $n = R/R$ is a unit direction vector. Using Eq. (44) and the fact that

#88472 - $15.00 USD Received 10 Oct 2007; revised 12 Nov 2007; accepted 12 Nov 2007; published 29 Nov 2007
(C) 2007 OSA 10 December 2007 / Vol. 15, No. 25 / OPTICS EXPRESS  16571
Eq. (42) can be rewritten as
\[ \langle I_\perp \rangle = \frac{k^4}{16\pi^4} \int dR P(R) h_{\perp}(R) h_{\perp}(x_R, R), \]
where \( P(R) \) is a radial distribution function of relative granule positions, defined so that \( \int dR P(R) = 1 \), and \( h_{\perp} \) is the following result of averaging over the whole solid angle, since all \( \mathbf{n} \) are equiprobable,

\[ h_{\perp}(x, R) = \frac{1}{4\pi} \int d^2 n n^2 \{ 1 + \cos(kR(n_e + n_n)) \} g^2(x) \mathbf{n} \cdot \mathbf{n} g^2(x) \mathbf{n} \cdot \mathbf{n}. \]

The exponent in Eq. (42) was replaced by a cosine function because the imaginary part of \( h_{\perp} \) is zero due to the symmetry properties of the integrand.

It is easy to show that \( P(R) \) for point granules in a sphere of diameter \( D_c \) is given by
\[ P(R) = \frac{6}{D_c^2} R^2 (D_c - R)^2 (2D_c + R), \]
independent of \( f \). Taking into account a finite size of granules, which is assumed much smaller than \( D_c \), modifies \( P(R) \) only for \( R \) close to 0 and \( D_c \). Moreover, we neglect the boundary effects for large \( R \), because the contribution to the integral in Eq. (46) from a small interval near \( D_c \), which has width of order \( d_g \), is relatively small. The correction for small \( R \) can be obtained in the limit of infinitely large \( D_c \), i.e. considering a granulated sphere as an infinite hard sphere liquid \( \left( x_c \gg 1 \text{ and } x_c \gg x_g \right) \). The structure factor given by Eq. (24) is basically a Fourier transform of \( P(R) \), hence \( P(R) \) can be obtained by the inverse Fourier transform

\[ P(R) = \frac{24R^2}{D_c^2} \left( 1 + \frac{d_g^4}{12\pi f} \int dq [S_f(q)/q^2 \sin(qR)] \right). \]

This integral cannot be computed in closed analytical form. Therefore, we expand \( S_f(q) \) in series of \( f \) and leave only terms up to the second order, since higher orders anyway cannot be computed accurately without consideration of triple- and higher scattering orders. After that one may obtain the final result for \( P(R) \):

\[ P(R) = \begin{cases} \frac{24R^2}{D_c^2} \left( 1 + \frac{d_g^4}{24} \right), & d_g \leq R \leq 2d_g; \\ \frac{6}{D_c^2} R^2 (D_c - R)^2 (2D_c + R), & R > 2d_g. \end{cases} \]

Using Eqs. (45), (47), and (50), the integral in Eq. (46) can be computed; however, it is still cumbersome. To simplify, we notice that \( h_{\perp} \) only weakly depends on \( R \), while different parts of \( h_{\perp}(R) \) exhibit very different scaling with respect to \( R \) [cf. Eq. (45)]. The first two terms increase when \( R \to 0 \) [after multiplication by \( P(R) \)], and the integral is determined by a small interval of \( R \), up to several \( d_g \). On the contrary, the third part of \( h_{\perp}(R) \) has a smooth behavior, and it’s integral is determined by the whole range of \( R \). In particular, when evaluating the integral of the third part of \( h_{\perp}(R) \) the cosine term in \( h_{\perp} \) can be neglected, since for \( kR \gg 1 \), which is valid for most of the \( R \) range, the contribution of this term is negligible compared to the unity addend. We denote the resulting \( h_{\perp} \) as \( h_{\perp}(x, \infty) \), and one may show that

\[ h_{\perp}(x, \infty) = \begin{cases} \frac{4}{15} \left( 1 - \frac{4}{5} x^2 + O(x^4) \right), & x < 1; \\ O(x^{-3} \ln x), & x > 1, \end{cases} \]

\[ h_{\perp}(x, R) \leq 2h_{\perp}(x, \infty). \]
Contribution of the third part of $h_{G}(R)$ to the integral in Eq. (46) is
\[
\int dR \, P(R) \frac{k^4}{R^2} h_{\perp}(x_g, R) = \frac{18k^2 x_g h_{\perp}(x_g, \infty)}{D^2}. \tag{53}
\]

Next we calculate the contribution of the first two parts of $h_{G}(R)$. As we will show below, this contribution is significant only for small $x_g$. Therefore, we expand $h_{\perp}(x_g, R)$ in series of $x_g$, similar to Eq. (51), assuming $kR = O(x_g)$:
\[
h_{\perp}(x_g, R) = \frac{2}{15} \left( -\frac{4}{5} x_g^2 - \frac{1}{7} (kR)^2 + O(x_g^3) \right). \tag{54}
\]
Using Eqs. (50), (54) we obtain
\[
\int dR \, P(R) \frac{9+3(kR)^2}{R^6} h_{\perp}(x_g, R)
= \frac{6k^3}{5D^2 x_g^4} \left[ 1 + \frac{f}{4} (1+6\ln 2) + \frac{x_g^2}{35} (52 + f (373 - 522 \ln 2)) + O(x_g^4, f^2) \right]. \tag{55}
\]

It is important to note, that Eq. (55) is not completely accurate, because it is determined by $R \sim d_g$, for which derivation of Eq. (44) is not accurate. Comparing Eq. (55) to Eqs. (53) and (51) one can see that the contribution of the third part of $h_{G}(R)$ is negligible for very small $x_g$ but becomes dominating, compared to other parts, for $x_g$ larger than a few times $x_g^{1/3}$. This conclusion can be derived rigorously for the whole range of $x_g$, using Eq. (52) instead of Eq. (54) for evaluation of the integral in Eq. (55). Physically speaking, for very small granules the depolarized intensity is determined by the short-range interaction of granules that happen to be close to each other. Starting from $x_g \sim x_g^{1/3}$ the main contribution is from the long-range interaction of all granules. Therefore, we may use Eq. (55) for $x_g$ up to some arbitrary chosen constant of order less than unity (we choose it to be unity), and set its contribution to zero for larger $x_g$. Fortunately, this exactly corresponds to the assumptions that were used in obtaining Eq. (55). The final result for depolarization intensity is
\[
\langle I^{(\perp)} \rangle = \frac{4}{135} \left[ m^2 - m^4 \right] f^2 x_g^4 \left[ C_L(x_g, f) + x_g^2 h_{\perp}(x_g, \infty) \right], \tag{56}
\]
\[
C_L(x_g, f) = \begin{cases} 
1 + \frac{f}{4} (1+6\ln 2) + \frac{x_g^2}{35} (52 + f (373 - 522 \ln 2)), & x < 1; \\
0, & x \geq 1. 
\end{cases} \tag{57}
\]
Using Eqs. (29) and (56) one may derive the scaling behavior of depolarization ratio:
\[
D_{SS}(x_g) = f^2 \left[ m^2 - m^4 \right] x_g^2 \left[ C_D + O(f) + O(x_g^{1/4} \ln x_g), x_g \ll 1; \\
x_g^2 O(x_g^{-1} \ln x_g), & x_g \gg 1. \tag{58}
\]
Although our derivations do predict $O(f^2)$ corrections of $D_{SS}$ for small $x_g$, this correction is not accurate because of higher-order scattering effects which are of the same order. The factor $O(x_g^{-1} \ln x_g)$ is almost constant for a range of large $x_g$ that we studied, so we may consider both limiting values of $D_{SS}$ to be independent of $x_g$. Hence, our approximate derivations based on the RDG and the 2-Born predicts the step-wise behavior of $D_{SS}(x_g)$.

The 2-Born also can be used to refine the RDG results for $I_{SS}$. Although this definitely improves the accuracy, it also makes the final result significantly more complex. Derivation for the exact side scattering direction is more cumbersome than that for $I_{\perp}$, because less terms in intermediate equations cancel out. Averaging over the side scattering aperture also does not seem feasible in closed form. Therefore this refinement contradicts our philosophy for approximate theories and we do not pursue it further.
6. Results and discussion

The results of DDA simulations of side scattering by granulated spheres with the default set of parameters and varying granule diameter is shown in Fig. 2. For each \( d_g \) mean values of \( I_{SS} \) and \( I_\perp \) and error bars corresponding to two SDs are shown. Labels near some of the points indicate the values of \( d_g \). One can see that there are two ranges of \( d_g \): from 0.1 to 0.25 \( \mu m \) and from 0.4 to 2 \( \mu m \), which correspond to distinct regions in Fig. 2. The range from 0.25 to 0.4 \( \mu m \) is intermediate, where \( I_{SS} \) and \( I_\perp \) strongly albeit differently depend on \( d_g \). The two regions in Fig. 2 qualitatively correspond to the neutrophils and eosinophils on the plots by de Grooth et al. [14]. Considering the morphological characteristics of neutrophil and eosinophil granules, the difference in depolarized side scattering can be explained solely by the difference in \( d_g \). However, it is important to note, that direct comparison cannot be performed because the model is a significant simplification of the granulocyte morphology. Apart from neglecting a nucleus, it assumes the same size for all granules, while granule population of a real granulocyte is always heterogeneous both in size and refractive index.

The results for several volume fractions are shown in Fig. 3, separately for \( I_{SS} \), \( I_\perp \), and their ratios. One may note that EMT result \( (d_g = 0) \) for \( D_{SS} \) seems to be different from the limiting value of the DDA simulations [Fig. 3(c)]. This is explained by the fact that both \( I_{SS} \) and \( I_\perp \) are mostly determined by the granules even for the smallest \( d_g = 0.075 \mu m \) that we tried. However, for much smaller granules the signals are those of the homogeneous sphere, which has a different depolarization mechanism (see Fig. 5 and Section 5). Therefore, both \( I_{SS} \) and \( I_\perp \) decrease monotonically with \( d_g \), while \( D_{SS} \) “switches” from the limiting value of small granules to that of a homogeneous sphere, which are naturally different.

Apart from this feature, the general behavior of \( I_{SS} \), \( I_\perp \), and \( D_{SS} \) versus \( d_g \) is similar to that predicted by Eqs. (29), (56), and (58): both \( I_{SS} \) and \( I_\perp \) rapidly increase with \( d_g \) for small \( d_g \) and relatively slowly decay for larger \( d_g \). \( D_{SS} \) behaves in a step-like manner, switching from a plateau for small \( d_g \) to another one for larger \( d_g \). We include the literature data on average values of \( D_{SS} \) for neutrophils and eosinophils [14] in Fig. 3(c). One can see that neutrophils approximately correspond to small \( d_g \) limit for \( f = 0.1 \), while eosinophils have the \( D_{SS} \) values between the large and small \( d_g \) limits for the same \( f \). The latter can be explained by the fact that eosinophils have large (> 0.4 \( \mu m \)), small (< 0.25 \( \mu m \)), and intermediate granules, and \( f = 0.1 \) is their typical total volume fraction. It is important to note, that this explanation is
only qualitative, because light scattering signals for a cell with granules of different sizes cannot be obtained by averaging of results for different cells with identical granules. The quantitative comparison between the DDA simulations and experimental results for \( D_{SS} \) is further hindered by the uncertainty of \( m_g \).

To show the dependence of side scattering signals on \( f \) we plot \( I_\perp \) versus \( I_{SS} \) in Fig. 4, normalizing them by \( f^2 \) and \( f \) respectively [cf. Eqs. (29) and (56)]. We omit error bars in Figs. 4–7 for clarity. In all cases they are similar to those depicted in Figs. 2 and 3. The only exception is Fig. 5, for which SD significantly increase with decreasing \( \Delta \phi \) (data not shown). This increase is natural considering the oscillating dependence of all Mueller matrix elements.

Fig. 3. (a). Total and (b) depolarized side scattering intensity and (c) their ratio versus granule diameter for several volume fractions. Other parameters are set to default values (see text). Mean values ± 2×SD are shown. Experimental results for mean values of \( D_{SS} \) of neutrophils and eosinophils are shown in (c) for comparison.

10 December 2007 / Vol. 15, No. 25 / OPTICS EXPRESS 16575
on both $\theta$ and $\phi$. Analyzing Figs. 3 and 4, one can see that the scaling of $I_\perp$ and $I_{SS}$ with $f$ is slower than $f^2$ and $f$ respectively, i.e. the corrections of higher order in $f$ are important. Although our derivations do provide such corrections they are not expected to be accurate and therefore are not further discussed (see Sections 4 and 5). One also can see that the slope of the curves in Fig. 4 is almost independent on $d_g$ for small $d_g$, hence $D_{SS}$ is proportional to $f$ in this regime. This scaling law holds with much better accuracy than that for either $I_\perp$ or $I_{SS}$.

We show the results of varying the aperture in Fig. 5. We keep $\Delta \theta$ fixed and vary $\Delta \phi$ from $0^\circ$ to $25^\circ$. The depolarization ratio does depend on $\Delta \phi$ over the whole range of $d_g$, however this dependence is uniform in the sense, that variation of $\Delta \phi$ do not change the general behavior of $D_{SS}$ versus $d_g$. In other words, the aperture part of the depolarization of the granulated sphere is significant, especially for large $d_g$, however it is always less than the inherent part. There is one natural exception to the above conclusion – the EMT result for $d_g = 0$, which scales approximately as $\Delta \phi^2$ [14].

A plot of $I_\perp$ versus $I_{SS}$ for several $D_c$ is shown in Fig. 6, normalized by $D_c^4$ and $D_c^3$ respectively [cf. Eqs. (29) and (56)]. One may see that plots almost coincide for small $d_g$ and

---

**Fig. 4.** Same as Fig. 2 but for several volume fractions. $I_\perp$ and $I_{SS}$ are normalized by $f^2$ and $f$ respectively to the case $f = 0.1$.

**Fig. 5.** Mean values of depolarization ratio versus granule diameter for several sizes of azimuthal angle aperture. Other parameters, including $\Delta \theta$, are set to default values (see text). An inset shows the magnified region near the origin.
come close to each other for large $d_g$. That means that the simple scaling derived from the approximate theories works satisfactory. Moreover, this scaling law is even more accurate for $D_{SS}$. The results for several $m_g$ and $m_c$, shown in Fig. 7, lead to analogous conclusions: scaling described by approximate theories works well, especially for $D_{SS}$, except for the “resonance” intermediate region of $d_g$. In particular, this scaling can be used to estimate the effect of uncertainty in $m_g$ and $m_c$ on the final simulated results.

All the results above are for several side scattering signals. In Fig. 8 results for other scattering quantities are shown, namely $Q_{ext}$ and $<\cos\theta>$. One can see that these quantities only moderately depend on a particular granule placement, as indicated by relatively small SDs. However, they non-trivially depend on both $d_g$ and $f$. For small $d_g$, $Q_{ext}$ is close to that of a homogeneous sphere with EMT refractive index, which linearly depends on $f$. Since dependence of $Q_{ext}$ of a sphere on $m$ is oscillating, so is the dependence of $Q_{ext}$ of a granulated sphere on $f$ for small $d_g$. For large $d_g$ overall extinction by granules is less dependent on each other, therefore $Q_{ext}$ increases with $f$ for constant $d_g$ (if $f=0$, $Q_{ext}=1.04$). In intermediate region of $d_g$ $Q_{ext}$ smoothly changes from one limiting value to another. The asymmetry parameter can be thought of as another measure of side scattering intensity. And one can see
that $1 - \langle \cos \theta \rangle$ do correlate with $I_{SS}$ when varying both $d_g$ and $f$ [cf. Figs. 3(a) and 8(b)]. However, the dependence of $\langle \cos \theta \rangle$ on $d_g$ has more oscillations (maxima and minima) than that of $I_{SS}$. Although some of the features of Fig. 8 are easy to understand, it does not seem feasible to completely describe this Fig. by any simple approximate theory.

We do not discuss other scattering quantities, e.g. angle-resolved Mueller matrix elements, in this manuscript, because it is hard to choose any of universal interest. Any particular application needs its own combination of Mueller matrix elements and range of scattering angles.

As we have seen above, RDG and 2-Born adequately describe the scaling of the side scattering signals. It is much more enlightening to perform a quantitative comparison of these approximate theories with DDA results. We present an example of such comparison in Fig. 9 for the default parameters of the DDA simulations (see Section 2). RDG results are shown for three volume fractions $f = 0.02, 0.05,$ and $0.1$, while 2-Born only for the default one ($f = 0.1$). One can see that RDG is an accurate approximation for small $f$, especially for small $x_g$. However, it systematically underestimates $I_{SS}$ for larger $f$. This discrepancy is due to multiple scattering effects which are significant for larger $f$ and are completely ignored in the framework of RDG. The RDG also has some more pronounced limitations, for example, the RDG result for $Q_{ext}$ do not depend on $x_g$ but only on $f$, contrary to the DDA simulations [see Fig. 8(a)]. Probably, RDG is more accurate for $\langle \cos \theta \rangle$, but it cannot be accurately calculated in the framework described in Section 4 because of the employed assumption of not small $\theta$.

It is important to note that 2-Born results shown in Fig. 9(b) [Eq. (56)] are obtained for zero scattering aperture, while DDA results are for $\Delta \theta = \Delta \varphi = 25^\circ$. We do not use DDA results for zero aperture because their standard deviations are larger than the values themselves. Since we calculated only 10 different realizations of granule positions for each $x_g$,
the errors of mean value are also large. One can see that the agreement between the 2-Born and the DDA is good, especially up to the first maximum. For larger $x_g$ the 2-Born systematically underestimates the depolarized intensity, which is due to the neglect of higher-order scattering and the fact that even a single large granule is treated inaccurately in the framework of 2-Born.

7. Conclusion

We performed extensive DDA simulations of light scattering by a granulated sphere. We calculated total and depolarized side scattering intensity ($I_{SS}$ and $I_{\perp}$) varying parameters of the model: granule diameter $d_g$, volume fraction $f$, and refractive index $n_g$, cytoplasm diameter and refractive index and size of the side scattering aperture. Parameters used correspond to the literature data on granulocyte morphology. The general appearance of the maps $I_{SS}$ versus $I_{\perp}$ for several $d_g$ is the same for different values of other model parameters: two segments with high correlation between $I_{SS}$ and $I_{\perp}$ for small and large $d_g$ and a connecting region for a narrow range of $d_g$. Both $I_{SS}$ and $I_{\perp}$ increase with $d_g$ for small $d_g$, have a maximum at $d_g$ approximately equal to the wavelength $\lambda$, and slowly decay afterwards. Depolarization ratio $D_{SS}$ behaves in a step-wise manner, having almost constant value for small $d_g$ and a larger constant value for larger $d_g$.

Analytical expressions, obtained in the framework of the Rayleigh-Debye-Gans and second-order Born approximations, describe these results qualitatively well. Moreover, these
expressions quantitatively agree with rigorous DDA simulations for small $d_g$ and $f$. In addition to being extremely fast, these approximate theories give an insight into the light scattering phenomena. In particular, depolarization of granulated sphere is determined by short-range interaction between nearby granules for very small $d_g$, while for $d_g$ of order $\lambda$ and larger it is determined by long-range interactions of all granules. Although, analytical expressions are not accurate enough in many cases, they can be used to construct approximate inversion techniques, which goal is to deduce information about granules from light scattering signals.

We showed that differences between experimentally measured signals of neutrophils and eosinophils [14] can be described solely by the difference in their granule sizes, which agrees with previous phenomenological descriptions of this phenomena. Moreover, calculated $D_{SS}$ quantitatively agrees with experimental results. However, the quantitative comparison is hindered by the uncertainty of $m_g$. Finally, as an example of other scattering quantities we showed and discussed the dependence of extinction efficiency and asymmetry parameter on $f$ and $d_g$. They can also be used to approach the inverse problem.
