ABSTRACT

We report on the discovery of a dramatic change in the energy spectrum of the X-ray pulsar GX 304–1 appearing at low luminosity. Particularly, we found that the cut-off power-law spectrum typical for accreting pulsars, including GX 304–1 at higher luminosities of $L_X \sim 10^{36}–10^{37}$ erg s^{−1}, transformed at lower luminosity of $L_X \sim 10^{34}$ erg s^{−1} to a two-component spectrum peaking around 5 and 40 keV. We suggest that the observed transition corresponds to a change of the dominant mechanism responsible for the deceleration of the accretion flow. We argue that the accretion flow energy at low accretion rates is released in the atmosphere of the neutron star, and the low-energy component in the source spectrum corresponds to the thermal emission of the optically thick, heated atmospheric layers. The most plausible explanations for the high-energy component are either the cyclotron emission reprocessed by the magnetic Compton scattering or the thermal radiation of deep atmospheric layers partly Comptonized in the overheated upper layers. Alternative scenarios are also discussed.

Key words: accretion, accretion discs – scattering – stars: magnetic field – stars: neutron – pulsars: general – X-rays: binaries.

1 INTRODUCTION

Spectral energy distribution of astrophysical objects reflects physical processes responsible for the observed emission. Extreme conditions in the vicinity of highly magnetized neutron stars (NS), X-ray pulsars (XRP), result in a very complex interplay between various physical and geometrical effects happening in the emission regions. As a consequence, no physically motivated spectral model able to describe spectra of various XRPs at different luminosities emerged so far. Moreover, the existing models focus on the description of X-ray spectrum at high luminosities (see e.g. Becker & Wolff 2007; Farinelli et al. 2016) as no high-quality observations at low luminosities were available until recently. From observational point of view, spectra of all bright XRPs are quite similar, and can be roughly described with a cut-off power-law-type continuum. We

note, however, that there is at least one exception: a low-luminosity XRP X Persei.

The spectrum of this persistent Be X-ray binary deviates significantly from the standard picture and exhibits two distinct humps with maxima around 10 and 60 keV. Several interpretations have been suggested to describe the observed spectrum. Di Salvo et al. (1998) proposed the continuum model consisting of two cut-off power-law components. The soft component was attributed to the partially thermalized emission from the NS atmosphere, whereas the hard component was suggested to be associated to the optically thin cyclotron emission in a strong magnetic field. Alternative interpretation was proposed by Doroshenko et al. (2012), who associated the two spectral components with thermal and bulk Comptonization in the vicinity of the NS. Finally, the source spectrum can be described with a single continuum component, for example, in the form of a power law modified by the high-energy cut-off, which is typical for bright XRPs. In this case, however, inclusion of a deep broad absorption feature at ~ 30 keV is required (cyclotron resonant

* E-mail: sergey.tsygankov@utu.fi

scattering feature, CRSF; see e.g. Coburn et al. 2001; Lutovinov, Tsygankov & Chernyakova 2012).

The main difference between X Persei and others XRP observed in broad energy band is that it has a significantly lower luminosity of a few times 10^{34} erg s^{-1} . Unfortunately, X Persei is a persistent source with insignificant variations in the mass accretion rate, so it was not possible to observe this source also at higher luminosities, and verify whether its spectrum at much higher accretion rates is more similar to that of other XRPs. On the other hand, observations of more distant sources at comparably low-luminosity levels were not possible until recently, thus their behaviour at low accretion rates remained largely unexplored.

The situation has changed with the launch of *NuSTAR* observatory (Harrison et al. 2013), which allows detailed investigations of transient systems with Be companions (Be/XRP) known to exhibit giant outbursts covering luminosity range of up to 5 orders of magnitude (see e.g. Reig 2011).

In this work, we present results of the spectral analysis of the X-ray emission from one of the most suitable for such research transient Be/XRP GX 304–1 observed with *NuSTAR* at a luminosity around 10^{34} erg s^{-1} , the lowest ever observed for this source (Rouco Escorial, van den Eijnden & Wijnands 2018). The source exhibits regular Type I outbursts almost every periastron passage (Kühnel et al. 2017), covering broad range of mass accretion rates. It has a relatively long pulse period of ~ 272 s (McClintock et al. 1977) and orbital period of ~ 132.5 d (Priedhorsky & Terrell 1983). The magnetic field of the NS in the system is known from the CRSF energy of ~ 54 keV (Yamamoto et al. 2011). Note that the CRSF energy also exhibits clear positive correlation with the source luminosity (Klochkov et al. 2012). The distance to the source is now known with high accuracy thanks to the *Gaia* results ($d = 2.01 \pm 0.15$ kpc, Treuz et al. 2018).

2 DATA ANALYSIS AND RESULTS

The source was observed with *NuSTAR* on 2018 June 3 (ObsID 90401326002; MJD 58272–58273). The raw data were processed following the standard data reduction procedures described in the *NuSTAR* user guide, and using the standard *NuSTAR* Data Analysis Software (NUSTARDAS) v1.6.0 provided under HEASOFT v6.24 with the CALDB version 20180814. The source and background spectra were extracted from the circular regions with radius of 60 arcsec using the NUPRODUCTS routine. The background was extracted from a source-free region in the corner of the field of view. Total exposure time of the analysed observation is 58 ks.

To expand our spectral analysis to lower energies, we used the data from the XRT telescope (Burrows et al. 2005) on-board the *Neil Gehrels Swift Observatory* (Gehrels et al. 2004) obtained simultaneously with *NuSTAR* (ObsID 00088780001). Observation was performed in Photon Counting mode with total exposure of 2 ks. Spectrum extraction was done using the online tools (Evans et al. 2009)¹ provided by the UK Swift Science Data Centre. To fit the spectra in the XSPEC package, we binned the spectra to have at least 1 count per energy bin and fitted them using W-statistic (Wachter, Leach & Kellogg 1979).² The data from *Swift*/XRT and *NuSTAR* were used in the 0.3–10 and 3–79 keV bands, respectively.

Figure 1. EF_E spectra of GX 304–1 in different states with luminosity varying by more than three orders of magnitude, from 2.2×10^{37} erg s^{-1} and 0.2×10^{37} erg s^{-1} for the two top spectra down to $\sim 10^{34}$ erg s^{-1} for the bottom one. The bright state spectra (grey circles) are taken from Mushtukov et al. (2015b). The black, red, and blue crosses correspond to the *Swift*/XRT and *NuSTAR* FPMA and FPMB data in the low state of GX 304–1, respectively. The solid line represents the best-fitting model consisting of two COMPTT components shown with dashed lines. The corresponding residuals are presented at the lower panel.

Figure 2. The spectra of X Persei as seen by the *INTEGRAL* observatory (green points; Doroshenko et al. 2012) and GX 304–1 along with the best-fitting models consisting of two Comptonization components. Separate model components (COMPTT in XSPEC) are shown with dashed and dashed-dotted lines for GX 304–1 and X Persei, respectively.

The broad-band spectrum of the source as observed by *NuSTAR* and *Swift*/XRT at luminosity around 10^{34} erg s^{-1} is shown in Fig. 1 (lower data points). The spectrum shows two humps around 5 and 40 keV of approximately same fluxes. This is very different from the *INTEGRAL* spectra at higher luminosities of 2.2×10^{37} and 0.2×10^{37} erg s^{-1} (upper two sets of data points in Fig. 1, Mushtukov et al. 2015b), which can be well fitted with the standard XRP power-law model modified by a high-energy cut-off and a cyclotron absorption line at ~ 60 and ~ 50 keV, respectively.

To fit the low-state spectrum, we explored several models representing different combinations of physically motivated and phenomenological components. Particularly, to model the second hump in the spectrum as a separate emission component,

Table 1. Best-fitting results for the GX 304–1 broad-band spectrum obtained with *NuSTAR* + *Swift*/XRT.

Parameter ^a	Low-energy part	High-energy part
COMPTT + COMPTT		
T_0 , keV	0.46 ± 0.07

C-statistic (d.o.f.)	1826.4 (1877)	

Note: ^a Here T_p , τ_p , and T_0 are the plasma temperature, plasma optical depth, and temperature of the seed photons for the COMPTT model. Fluxes are given in the 0.5–100 keV energy range. The hydrogen column density is fixed at the Galactic value in the source direction $N_{\text{H}} = 1.1 \times 10^{22}$ cm⁻².

we used (i) a combination of two Comptonization components (COMPTT + COMPTT model in XSPEC, Titarchuk 1994); and (ii) a combination of Comptonization for the low-energy hump and an emission line with Gaussian profile for the high-energy one (COMPTT + GAU model in XSPEC). Alternatively, the spectrum can be described with a single-component continuum modified by an absorption feature around 15 keV. In particular, we used COMPTT + GABS combination. Another possibility is to consider bulk Comptonization model COMPTB (Farinelli et al. 2008) to describe the whole continuum, however, we note that the effect of bulk motion should be negligible because of the expected small optical depth of the infalling gas at small accretion rates (see Section 3.2). We emphasize that parameters of the used Comptonization models have physical meaning only for low magnetic fields and they should be treated with caution for the high-field XRPCs.

We also included PHABS component to account for interstellar photoelectric absorption with N_{H} fixed at the Galactic value in the source direction of 1.1×10^{22} cm⁻² (Kalberla et al. 2005), because neither strong absorption was ever reported for this source, nor was required by our fit. To account for minor differences in the absolute flux calibration of the FPMA and FMPB instruments onboard *NuSTAR* and *Swift*/XRT telescope, the normalization factors were added to the separate data groups. As a result, the fluxes from FPMA and FMPB instruments match to within 2–3 per cent, whereas the XRT normalization is about 1.3 times lower likely due to the fact that *NuSTAR* and *Swift* observations were not strictly simultaneous. In Fig. 1, the fit with two Comptonization components is shown with the corresponding residuals.

The fit results are presented in Table 1 and can be summarized as follows: (i) the spectrum can be fitted equally well with all sets of models; (ii) in the case of two separate spectral components, the

flux in the high-energy part is about half of the low-energy one; and (iii) in the case of two Comptonization components, the plasma temperature of the high-energy component is about five times the low-energy one.

3 DISCUSSION

The spectrum of GX 304–1 in the low-luminosity state resembles the spectrum of another Be/XRP X Persei obtained at only slightly higher luminosity, $L_X \sim 8 \times 10^{34}$ erg s⁻¹ (see Fig. 2). Both sources exhibit double-hump spectra with components peaking at energies separated by a factor of about 5–10. This similarity suggests that physical processes responsible for the spectrum formation at low mass accretion rates are also similar. In this section, we discuss the possible nature of the emission from GX 304–1 in the low state and the reasons for the observed abrupt changes of the source spectrum.

3.1 Cyclotron line

As already mentioned, a cyclotron line is observed in the spectrum of GX 304–1 at high luminosities (Walter et al. 2015). Moreover, a positive correlation of the line energy with the luminosity has been reported (Klochov et al. 2012). Particularly, the energy was found to decrease from ~ 60 keV at luminosity of $L = 2.2 \times 10^{37}$ erg s⁻¹ to ~ 50 keV at 10 times lower luminosity (Mushtukov et al. 2015b). Therefore, one may argue that observed two-component spectrum of the source is mimicked by an absorption feature at ~ 15 keV between two humps in the source spectrum, which is the cyclotron line shifted from the original ~ 60 keV due to substantially lower mass accretion rate.

The extrapolation of the observed correlation to low fluxes implies, however, significantly higher energy $E_{\text{cyc}} \approx 30$ keV. Moreover, such a large decrease appears to be unrealistic in the context of the two models proposed so far to explain the observed correlation of line energy with flux. In the model by Mushtukov et al. (2015b), the observed correlation is produced by the Doppler effect in the flow, whose velocity is affected by radiation pressure, which is more efficient at higher luminosities. The maximal relative shift here is limited by a factor of two, as the flow velocity changes from the free-fall with $v \approx 0.5c$ to zero. Because the highest observed line energy is ~ 60 keV, the lowest possible energy is ~ 30 keV, which is significantly higher than the observed ~ 15 keV.

The second model associates shifts of the CRSF energy with changes of the height of a collisionless shock above the NS polar cap (Rothschild et al. 2017). For the dipole field, the decrease of line energy from ~ 60 to 15 keV implies an increase of the height of the line-forming region by half an NS radius. The geometric dilution of radiation from a polar cap of size < 100 m is very significant at such height, with only ~ 1 per cent of the cap continuum photons passing through the cross-section of the accretion channel (which is only 3–4 times larger at this height than the cap area). We conclude, therefore, that the description of the observed low-luminosity spectrum of GX 304–1 with a single continuum component with a CRSF at ~ 15 keV is implausible also in this model.

3.2 Nature of the high-energy component

The conclusion above implies that the two humps in X-ray spectrum of the source are likely indeed two separate components. The soft blackbody-like component with a typical temperature of $kT \leq 2$ keV can be explained as radiation from hotspots at the NS surface heated up by the accretion process. However, the origin of the

second component, which can also be fitted by a blackbody with the temperature ≈ 9 keV or a broad Gaussian emission line (see Table 1) is much less clear. Below we discuss several possible physical origins of this spectral component:

(i) *Bulk Comptonization*: as was mentioned in the Introduction, hard spectral component in X Persei was described by the model of bulk Comptonization in the accretion channel (Doroshenko et al. 2012). We note that the effective interaction between electrons and photons is only possible if optical depth of the interaction region is sufficiently large ($\tau \sim 5$ –10). Such optical depth across the accretion flow is only realized at high accretion rates corresponding to the onset of an accretion column (Mushtukov et al. 2015a). In case of GX 304–1, an upper limit on the Thomson optical depth in the interaction region is about $\tau_T \approx 0.01(L_X/10^{34} \text{ erg s}^{-1}) \ll 1$ (see equation 18 in Mushtukov et al. 2015a). We conclude, therefore, that bulk Comptonization is likely inefficient in GX 304–1 and in other pulsars with $L_X \leq 10^{35} \text{ erg s}^{-1}$, i.e. including X Persei. This conclusion is also supported by our spectral fit using the COMPTB model. Particularly, fixing efficiency of bulk over thermal Comptonization (parameter δ) at zero value allows us to get an excellent quality fit with parameters similar to the COMPTT + COMPTT model.

(ii) *Collisionless shock*: the hard component may originate from the collisionless shock above NS surface (Shapiro & Salpeter 1975; Langer & Rappaport 1982), where the kinetic energy of the accreting particles is transferred to their thermal energy with characteristic temperatures for ions and electrons being close to their virial temperatures. In this case, Coulomb interactions might be effective enough to transfer thermal energy of ions to the electrons which are able to cool effectively by cyclotron radiation, resulting in cooling of the post-shock region and settling of the plasma on to the NS surface. The height of the post-shock region determined by the cooling rate is comparable to the NS radius and its spectrum for $\dot{M} = 6 \times 10^{14} \text{ g s}^{-1}$ does qualitatively resemble the spectra observed in X Persei and GX 304–1 in their low-luminosity state (Langer & Rappaport 1982). However, the spectra in this model were computed under assumption of optically thin cyclotron emission, which is not correct, and the physical mechanism for the formation of a hypothesized collisionless shock is not really clear. It is therefore premature to draw any firm conclusions.

(iii) *Cyclotron emission*: thermally broadened cyclotron emission as a source of the hard component in X Persei was discussed by Di Salvo et al. (1998) based on the model by Nelson, Salpeter & Wasserman (1993). Because the line-forming region in this scenario is assumed to be located at the NS surface, the temperature determining the line broadening was expected to be similar to the temperature of the soft component of about 2 keV, which is much smaller than the observed width of the hard component. On the other hand, the upper layers of the NS atmosphere heated by the accretion are not cooled efficiently by their thermal emission and can be overheated to ~ 10 –100 keV depending on the accretion rate and the magnetic field strength (Zane, Turolla & Treves 2000; Deufel, Dullemond & Spruit 2001; Suleimanov, Poutanen & Werner 2018; González-Caniulef et al. 2019). In this case, thermal broadening of the cyclotron emission line, which forms in these hot layers, is high enough to explain the observed width of the hard component. However, there is still a strong discrepancy between the model and observations in GX 304–1: the hard component reaches its maximum at an energy significantly below the cyclotron energy at the NS surface. We argue that this discrepancy can be explained by specifics of radiative transfer in the atmosphere of highly

magnetized NS which is determined by multiple Compton scattering of X-ray photons. The scattering cross-section is resonant at the cyclotron energy (Mushtukov, Nagirner & Poutanen 2016) and photons cannot leave the atmosphere close to this energy. Instead, photons diffuse to lower energies by scatterings and leave the atmosphere in a low-energy wing, where the cross-section is small enough. Thus, the hard component can be explained by cyclotron emission in the atmosphere heated by accretion and reprocessed by magnetic Compton scattering.

(iv) *Thermal Comptonization*: existence of the overheated upper layers of the NS atmosphere can explain the hard energy spectral component by the Comptonization of ordinary mode photons (which experience Compton scattering with a larger cross-section in comparison with extraordinary photons). The examples of Comptonized spectra calculated by Lyubarskii (1988) show two components, which should have significant difference in polarization. This scenario can be verified with upcoming X-ray polarimeters. We note that Comptonization of extraordinary mode photons is also expected to contribute to the broadening of the cyclotron line discussed in previous paragraph, i.e. two mechanisms are highly complementary and likely operate simultaneously. These effects should be taken into account in detailed calculations of emerging spectra and polarization.

4 CONCLUSION

We presented here the analysis of the spectrum of XRP GX 304–1 observed with *NuSTAR* in a very low state with $L_X \sim 10^{34} \text{ erg s}^{-1}$. The spectrum was found to differ dramatically from the previously observed spectra of the source at higher luminosities ($L_X \sim 10^{36}$ – $10^{37} \text{ erg s}^{-1}$). The latter are typical for XRPs and can be described by Comptonization in a hot electron slab with a cyclotron absorption feature at 45–60 keV. On the other hand, at low-luminosity two components with characteristic temperatures of $kT \sim 2$ and ~ 10 keV can be identified. A similar spectrum has been reported previously only for the persistent low-luminosity XRP X Persei. A transition between the two spectral states has, however, never been observed in any XRP.

Given the similarity in low-luminosity spectra of GX 304–1 and X Persei, it is reasonable to assume that the physical processes shaping their spectra are also similar. The bulk Comptonization interpretation invoked previously for X Persei to explain the hard part of the spectrum is, however, problematic for GX 304–1 due to necessarily low optical depth of the accretion flow. We have also demonstrated that the two-component spectrum cannot be mimicked by the flux depression between the two components by the resonant scattering.

We considered two possibilities to explain the observed low-luminosity spectrum of GX 304–1. The first scenario is associated with electron heating by hot ions. In this case, the softer component is associated with thermal emission from the deep layer of temperature ~ 2 keV, while the harder component is associated with cyclotron photons reprocessed further by magnetic Compton scattering in the upper layers of the atmosphere. In the second scenario, the thermal polar cap emission is partly Comptonized in the overheated upper layers of the atmosphere. Both these models are rather qualitative at this stage and have to be verified by numerical modelling and comparison with the available observations of both sources.
