Repairing Nanoparticle Surface Defects

Emanuele Marino*, Thomas E. Kodger*, Ryan W. Crisp, Dolf Timmerman, Katherine E. MacArthur, Marc Heggen, and Peter Schall*

Abstract: Solar devices based on semiconductor nanoparticles require the use of conductive ligands; however, replacing the native, insulating ligands with conductive metal chalcogenide complexes introduces structural defects within the crystalline nanostructure that act as traps for charge carriers. We utilized atomically thin semiconductor nanoplatelets as a convenient platform for studying, both microscopically and spectroscopically, the development of defects during ligand exchange with the conductive ligands Na\(\text{SnS}_4\) and \((\text{NH}_4)_2\text{Sn}_2\text{S}_6\). These defects can be repaired via mild chemical or thermal routes, through the addition of L-type ligands or wet annealing, respectively. This results in a higher-quality, conductive, colloidal-stable nanomaterial that may be used as the active film in optoelectronic devices.

Colloidal semiconductor nanocrystals (NCs) represent a versatile class of materials with unique optoelectronic properties that are fundamentally defined by their nanometric confinement. The use of NCs in optoelectronic devices ranges from optical displays\(^\text{[5]}\) and transistors\(^\text{[6]}\) to solar cells.\(^\text{[7]}\) Specifically, photovoltaic devices fabricated from NCs are amenable to inexpensive room-temperature solution processing, with the promise of yielding large-scale thin films.\(^\text{[8]}\) Power conversion in a solar cell requires, in sequence, light absorption, charge carrier separation, charge transport, and extraction at the contacts. Whereas light absorption can be optimized by the choice of material, for example, by tuning the NC composition, size, and shape, charge carrier separation and transport within the macroscopic film are limited by the NC surface properties, requiring the presence of conductive pathways between individual nanocrystals. Metal chalcogenide complexes have been used as conductive surface ligands that improved charge transport in devices;\(^\text{[9]}\) however, replacing the native insulating ligands requires an often detrimental ligand exchange (LE) process, which greatly reduces the photoluminescence quantum yield (PLOY) by orders of magnitude and decreases the long-term colloidal stability from years to days.\(^\text{[10]}\) Insight into the LE process through investigation of a model system would thus be greatly beneficial.

Atomically thin semiconductor nanoplatelets (NPs)\(^\text{[11]}\) exhibit superior uniformity in their confining dimension, which is reflected by the coincidence of their ensemble and single-particle PL spectra.\(^\text{[12]}\) This key feature results in exceedingly sharp excitonic absorption peaks and band-edge emission with no Stokes shift, which was recently exploited for stimulated emission studies.\(^\text{[7]}\) Herein, we utilized NPs as a model system for studying the development of structural defects during LE. Defects in NPs become particularly apparent both topologically and in their PL spectra whereas equivalent changes in quantum dots may be concealed in their intrinsic polydispersity, and thus NPs offer a unique opportunity for investigating LE-induced damage. Surprisingly, we found that defects caused by LE are healed through mild treatments, which led to recovery of the native structural integrity and most of the initial PLQY of the NPs.

We synthesized CdSe NPs with monodisperse lateral dimensions of \(94 ± 9 \text{ nm} \times 15.5 ± 1.5 \text{ nm}\); the sharp absorption transition at \(514 \text{ nm}\) is indicative of a thickness of 4.5 atomic monolayers, corresponding to 1.2 nm (Figure 1a,b; see also the Supporting Information, S1).\(^\text{[8]}\) The top and bottom facets, (001) facets of zinc blende CdSe\(^\text{[30]}\) are Cd-terminated and passivated by oleate ligands (OA, one-electron donor or X-type).\(^\text{[9]}\) These ligands provide the NPs with colloidal stability in non-polar solvents by steric stabilization but induce stacking of the NPs upon drying (Figures 1a, S1, and S8). Replacing the insulating oleate ligands with conductive metal chalcogenide complexes is a necessary step to achieve sufficient electronic transport in thin films.\(^\text{[5,10]}\) To this end, we used a two-phase system in which a solution of thiasolate ligands (Na\(\text{SnS}_4\) or \((\text{NH}_4)_2\text{Sn}_2\text{S}_6\)) in a polar solvent, such as an aqueous solution of \(\text{NH}_3\text{OH}\), was placed in contact with a dispersion of NPs in hexane (see the Supporting Information for details). Stirring the mixture allowed for LE to proceed until the NPs had fully migrated to the polar phase. After ligand exchange, the NPs were still well dispersed as shown by dynamic light scattering (DLS) measurements, which revealed only minor changes in the hydrodynamic radius between pristine and LE NPs (Figure S8). Remarkably,
While the aqueous $\text{NH}_4\text{OH}$ solution of cadmium selenide (CdSe) nanocrystals (NCs), as the ligand, we observed the dramatic decrease in photoluminescence quantum yield (PLQY) (ca. 0.02%) with respect to the original pristine NCs with oleate ligands (10%). We also studied LE-induced damage in the absence of promoter ligands that may trigger L-promoted Z-type ligand displacement, by altering the composition of the polar phase from pure water ($\varepsilon \approx 80$) to N-methylformamide (NMF, $\varepsilon \approx 182$). Interestingly, the PLQY dramatically decreased to approximately 0.01%. Thus, a judicious choice of the polar component during LE can reduce structural damage, the effects on the spectroscopic properties remain deleterious. We therefore studied the healing of NCs after LE in the presence of NH$_4$OH. Unexpectedly, upon addition of DMP to an already damaged dispersion of NCs with Na$_2$SnS$_4$ as the ligand, we observed the recovery of the structural integrity and the healing of holes, with no measurable changes in the NP lateral dimensions (Figures 2a, S4, S5, and S7). Additionally, the PLQY underwent a tenfold increase, indicative of the recovery of crystalline integrity of the NCs together with an improved surface passivation, and the absorption spectrum was slightly blue-shifted as a result of the effective decrease in the local NP thickness through the removal of rough areas (Figure 2b).

As an alternative to chemical treatments, we also explored temperature treatments without DMP as the healing process should depend on the thermal energy supplied. We investigated this by performing a wet annealing (WA) treatment, starting from a dispersion of damaged NCs in water and increasing the temperature of the solution to 100°C. Immediately thereafter, the dispersion slightly changed in color; we continued to follow the structural and spectroscopic changes by taking aliquots every few minutes (Figure 2c). After 5 min of WA, the absorption and PL peaks underwent a red shift of about 10 nm, suggesting structural modification of the NCs; remarkably, the PLQY recovered by a factor of 230 compared to the values measured after LE, reaching 4.5%. As the WA proceeded, the absorption and PL peaks were red-shifted by an additional ca. 5 nm after 10 min; the excitonic peaks of the absorption lost definition, the scattering was enhanced, and the PL spectrum broadened. Direct visualization of the NCs after WA by STEM revealed surface reconstruction, yielding whole NCs (Figure 2d).

DC conductivity studies showed that the conductance of a non-annealed thin film of LE NCs is up to three orders of magnitude higher than that of pristine NCs, yielding an electron mobility value of approximately $0.5 \times 10^{-3} \text{ cm}^2 \text{V}^{-1} \text{s}^{-1}$ (Figures 1c and S10). To the best of our knowledge, this is the first report of conductivity for NCs passivated with thiostannate complexes. Concomitant with the strong increase in conductance, however, a dramatic degradation of structural integrity was observed for the ligand-exchanged NCs, seen as punctures in the atomic crystal lattice (Figures 1d and S2–S4); at the same time, the PLQY greatly decreased (Figure 1b). The direct observation of the development and propagation of surface defects is enabled by the exceptionally thin NCs as the removal of just a few atoms from the (001) facets strains the lattice, inducing perforations.[9a] While the aqueous solution of NH$_4$OH, itself an L-type (two-electron donor) promoter ligand, enables the LE with thiostannate ligands to proceed rapidly,[9b] it also supports degradation, likely following a process known as L-promoted Z-type ligand displacement. Calibrated HAADF STEM images showed that at least 50% of the material was removed from the damaged areas (Figure S4d, e). These results highlight the mobility of surface atoms in such II–VI NCs.

We found this structural and PLQY degradation to be quite general. The displacement potency of a ligand depends on multiple attributes, such as electronic effects, chelation, and steric properties.[9a] We varied the latter by replacing NH$_4$OH with another promoter ligand pyridine, 3-methylpyridine, or 2,6-dimethylpyridine (DMP), which are all L-type ligands, and found that all LE treatments resulted in perforation of the NCs; furthermore, treatment with DMP also resulted in material rearrangement from the NP core onto the surface (Figure S2). This structural damage always correlated with a dramatic decrease in PLQY (ca. 0.02%) with respect to the original pristine NCs with oleate ligands (10%).

An alternative to chemical treatments, we also explored temperature treatments without DMP as the healing process should depend on the thermal energy supplied. We investigated this by performing a wet annealing (WA) treatment, starting from a dispersion of damaged NCs in water and increasing the temperature of the solution to 100°C. Immediately thereafter, the dispersion slightly changed in color; we continued to follow the structural and spectroscopic changes by taking aliquots every few minutes (Figure 2c). After 5 min of WA, the absorption and PL peaks underwent a red shift of about 10 nm, suggesting structural modification of the NCs; remarkably, the PLQY recovered by a factor of 230 compared to the values measured after LE, reaching 4.5%. As the WA proceeded, the absorption and PL peaks were red-shifted by an additional ca. 5 nm after 10 min; the excitonic peaks of the absorption lost definition, the scattering was enhanced, and the PL spectrum broadened. Direct visualization of the NCs after WA by STEM revealed surface reconstruction, yielding whole NCs (Figure 2d). Similarly to the DMP treatment, WA...
leads to NP recovery, confirming the enhancement of the surface mobility under mild conditions. The process eventually triggered growth on side facets, bridging NPs together, as demonstrated by both STEM and DLS (Figures 2d, S6, and S8h). Allowing the WA to continue further resulted in the lateral thinning of the NPs along the [110] direction and in material overgrowth (Figure 2d3). Side facets are more favorable to growth and more resistant towards dissolution than top facets owing to both the formation of one extra Cd-Se bond and a smaller nucleation energy barrier, as shown in recent work. If used in a controlled way, this process can yield surface healing or soldering of NPs. Further nanoscopic details of the NP healing process are revealed by the PL spectra recorded at different stages of recovery (Figure 3a–c). Pristine NPs passivated with OA showed a second broad PL band at longer wavelengths accompanying the sharp emission profile at the band edge (Figure 2a). Side facets are more favorable to growth and more resistant towards dissolution than top facets owing to both the formation of one extra Cd-Se bond and a smaller nucleation energy barrier, as shown in recent work. surface quality (Figure S2). Still, DMP- and WA-healed NPs outperform visually undamaged NMF LE NPs by at least one order of magnitude in terms of the PLQY (Figure 3d). Additionally, such NMF LE NPs can also be repaired by using the reported DMP and WA recovery routes; also in this case, the PLQY increased significantly, consistent with the NH\(_{2}\)-OH LE NPs after recovery (Figures S5 and S6).

The effect of structural recovery on the optoelectronic properties was further investigated by time-resolved microwave conductivity (TRMC) measurements, which probe the conductivity within individual NPs. The mean path length of charge carriers measured by this technique is about 30 nm (see the Supporting Information for details); therefore, TRMC measurements uncover the dynamics of photogenerated carriers on the length scale of a single NP. The values for charge carrier mobility in treated NPs correlate well with the PLQY (Figures 4 and S9), confirming that LE introduces traps that can be healed by a mild treatment of the NPs. Importantly, this shows that independent of the extent to which the NP integrity is disrupted during LE, structural repair through chemical and thermal routes can recover a high-quality nanomaterial. Remarkably, the PLQY of the NPs after WA treatment nears 5%, which is only slightly lower than that of pristine OA-passivated NPs and corresponds to a recovery by a factor of 250 with respect to post-LE NPs. This moderate loss of PL comes at the vital advantage of the LE-induced structural disruption, we were able to drive the healing of NPs both structurally and spectroscopically by chemical (mild L-type ligands) and thermal (WA) routes. This resulted in a higher-quality and colloidal stable nanomaterial that may be self-assembled into novel structures such as superlattices\(^\text{[13]}\) to be used as active films of optoelectronic devices. Future work to microscopically investigate these recovery routes on individual NPs may determine the exact nature of the trapped and recovered states similar to previous works\(^\text{[14]}\).
