ABSTRACT: Redox noninnocent ligands are a promising tool to moderate electron transfer processes within base-metal catalysts. This report introduces bis(imino)acenaphthene (BIAN) cobaltate complexes as hydrogenation catalysts. Sterically hindered trisubstituted alkenes, imines, and quinolines underwent clean hydrogenation under mild conditions (2–10 bar, 20–80 °C) by use of the stable catalyst precursor [(DippBIAN)CoBr₂] and the cocatalyst LiEt₃BH. Mechanistic studies support a homogeneous catalysis pathway involving alkene and hydrido cobaltates as active catalyst species. Furthermore, considerable reaction acceleration by alkali cations and Lewis acids was observed. The dinuclear hydridocobaltate anion with bridging hydride ligands was isolated and fully characterized.

KEYWORDS: hydrogenation, cobalt, hydrides, metalloradicals, reaction mechanism, redox-active ligands

INTRODUCTION

Metal-catalyzed hydrogenations of alkenes constitute one of the key chemical transformations with numerous applications to lab-scale syntheses and industrial manufacturing. The elucidations of the underlying catalytic mechanisms by Eisenberg, Halpern, Tolman, and others were major scientific milestones towards the understanding of catalytic elemental steps and the rational design of more active and selective catalysts.1,2 Very recently, the dominance of hydrogenation catalysts based on the noble metals Rh, Ru, Ir, Pd, and Pt has been challenged by the development of highly active 3d transition metals.3 While the use of more abundant, cheaper, and often less toxic base metals constitutes an important contribution to a more sustainable chemistry, their distinct reactivity and selectivity was often plagued by undesirable destructive side reactions.4 Recently, elaborate ligand design enabled the development of highly active cobalt catalysts by the groups of Beller, Budzelaar, Chirik, Hanson, Elsevier, de Bruin, and others (Figure 1).5–8 In the most recent literature, the implementation of pincer ligands (e.g., NNN; PNP; CNC) proved pivotal to the control of high activity and selectivity.5 Following our previous work on metalates with redox noninnocent arene ligands,9,10 we believed that an efficient 3d metal catalyst for hydrogenation reactions would fulfill the following criteria: (i) facilitation of redox steps at the metal by a redox-active ligand; (ii) modular ligand design that allows for...

convenient synthesis and easy catalyst tuning; (iii) stabilization of reduced forms of the catalyst by the ligand, and (iv) broad scope of hydrogenations of unsaturated C–C and C–X bonds.

Imines have been used as ligands in transition metal catalysis for the hydrogenation of alkenes, particularly in the case of highly activated alkenes (Scheme 1).20 The high efficiency of the developed protocol was demonstrated in the hydrogenation of challenging alkenes (e.g., tetra-substituted), imines, and heteroarenes proceed under mild conditions. Mechanistic insight was gained from the isolation of structurally novel olefin and hydride complexes as potential catalyst intermediates that are distinct from those of the traditional noble metal catalysts (Figure 1, bottom).

## RESULTS AND DISCUSSION

### Optimization and Alkene Hydrogenation

Initially, we probed the ability of (DippBIAN)CoBr₂ to act as a precatalyst for the hydrogenation of the model substrate triphenylethylene under very mild conditions (Dipp = 2,6-diisopropylphenyl). High conversion was observed with lithium superhydride (LiEt₃BH) as a cocatalyst at 2 bar H₂ and room temperature with only 3 mol % (DippBIAN)CoBr₂ (Table 1, procedure A). The presence of olefins during the reduction proved beneficial for the high catalyst activity, possibly due to transient olefin coordination and stabilization of the low-valent catalyst.6d,17,18 The significantly lower activity of NaEt₃BH suggests a considerable alkali-cation effect (entry 5; Supporting Information). The high efficiency of the developed protocol was demonstrated in the hydrogenation of challenging tri- and tetra-substituted alkenes such as myrcene, α-pinene, and α,β,β-trimethylstyrene under mild conditions (Scheme 2). Under standard conditions, the hydrogenation of α-methylstyrene exhibited a turnover frequency (TOF) of 780 h⁻¹ (Supporting Information). To the best of our knowledge, this protocol involves one of the most active homogeneous Co catalysts for alkene hydrogenations. Reduction-sensitive functional groups in the alkenes required a different protocol involving addition of the hydride cocatalyst prior to the alkene (protocol B, see Table 1, entry 2, and Scheme 2, right). This alternative protocol B was tolerant to chloride, bromide, ether, and ester functions. In the absence of H₂, 1-octene rapidly isomerized to a mixture of octene regioisomers and stereoisomers. With phenyl-acetylene, slow cycloisomerization to triphenylbenzene was observed in low yield (see the Supporting Information).

### Methodology Extension: Hydrogenation of Imines

The homogeneous Co-catalyzed hydrogenation of imines8b,10 and quinolines8c,10 is still in its infancy, despite being an atom-economic route to bioactive amines.22 Very good conversions were observed with the same cobalt catalyst in hydrogenations of selected electron-deficient and electron-rich imines and quinolines (10 bar H₂, 60 °C, Scheme 2). Ester functions were tolerated. Similarly mild conditions were recently reported with related homogeneous Co catalysts.3b,d10

#### Mechanism

The advent of 3d transition metal catalysts has gone hand in hand with the utilization of ligands that profoundly influence the electronic properties at the metal ions and enable redox reactivity patterns that are distinct from those of noble metals catalysts. The reaction mechanisms of catalytic alkene hydrogenations with second and third row transition metals (Rh, Ru, Ir, Pd, Pt) are very well understood. For the classical Rh-catalyzed hydrogenation, alkene and hydride complexes have been determined as key catalyst intermediates and the elemental reaction steps to involve two electron redox events at the metal.1,2,7,8 There is much less insight into the hydrogenation mechanisms of first row transition metals; the nature of the key catalyst intermediates are still largely unexplored. Chirik and co-workers reported on a bis(aryl-imidazol-2-ylidine)pyridine cobalt hydride complex and a radical pathway that operates in cobalt-catalyzed alkene hydrogenations.6 In this work, we aimed at a concise mechanistic study of Co-BIAN catalysts in alkene hydrogenations that would address the following questions: Is the BIAN ligand redox-active under the reaction conditions? Are radical pathways operating? To what extent are heterogeneous catalyst species involved? Do alkene and hydride intermediates play a similarly important role as with 4d and 5d metal catalysts?

We commenced our mechanistic studies with a set of key experiments that addressed the operation of radical mechanisms and the topicity of the active catalysts species. Initially,
radical probes were evaluated. α-Cyclopropyl styrene underwent dual alkene hydrogenation and hydrogenative ring-opening to give 2-phenylpentane in excellent yields following protocol A or B, respectively (Scheme 3A). This might be indicative of a mechanism involving hydrogen atom transfer (HAT).24 Furthermore, this is in full accord with our observations that nonstyrenic olefins (i.e., alkenes without aryl substituents that could stabilize potential radical intermediates in benzyl positions) constitute more difficult substrates under the standard conditions. Hydrogen atom transfer from the solvent is rather unlikely as no deuterium incorporation could be determined from reactions in THF-d8 (Scheme 3B). The high activity of the catalyst was further demonstrated by the hydrogenation of a C–C σ-bond in cyclopropylbenzene (Scheme 3C).

The clear distinction between homogeneous and heterogeneous catalyst species is intricate,23 yet our observations are consistent with a homogeneous mechanism. Reaction progress analyses documented an immediate onset of catalytic activity and steady conversion, which indicates a zero order for the substrate in the rate law (Scheme 4, red curve). Thus, the rate-determining step presumably does not include olefin coordination. A plot of the initial rates versus catalyst procedure B: catalyst reduction in the absence of substrate.

Scheme 2. Hydrogenation of Imines and Quinolines

Scheme 3. Key Mechanistic Experiments

Scheme 4. Catalyst Poisoning Studies with P(OMe)3, Hg, and dct
concentrations showed a first order rate in cobalt (SI). The absence of any sigmoidal curvature argues clearly against initial precatalyst nucleation and particle formation.6 However, an induction period might be not visible due to the experimental setup (procedure B, substrate conversion determined by gas-uptake; H2 consumption was recorded after precatalyst formation and substrate addition; SI). Kinetic poisoning studies are a competent tool to ascertain the topicity of the operating catalyst species.25 The attempted amalgamation of the catalyst with 300 equiv. Hg had only a minimal effect on the reaction rate. Upon addition of subcatalytic amounts of trimethylphosphite (P(OMe)3, 0.3 mol %), partial catalyst inhibition was recorded. Complete inhibition was achieved at a catalyst/poison ratio of 1:1 which is consistent with a homotopic catalyst (Scheme 4, green curve). The selective homotopic catalyst poison dibenzo[a,e]cyclooctatetraene25 (dct, 10 equiv per Co) resulted in catalyst inhibition which was slightly diminished by the concomitant hydrogenation of dct as a competing substrate (Scheme 4, violet curve, 31% conversion of dct; SI). The lower efficacy of dct as poison is presumably a consequence of the lower stability of 3d olefin complexes vs their heavier congeners.18

Complexes and Catalyst Intermediates. Based on the initial mechanistic experiments, we postulate a homotopic mechanism by molecular cobalt catalysts. The distinct electronic properties of 3d transition metals vs their heavier congeners might also entail the participation of catalyst structures that are different from the Rh(I) catalysts of hydrogenation reactions. While the operation of alkenes and hydride pathways has been intensively studied in rhodium-catalyzed hydrogenations, the knowledge of related catalyst intermediates with cobalt is still rather in its infancy. In an effort to identify potential catalyst species, we investigated reactions of [(DippBIAN)CoBr2] with 3 equiv LiEt3BH in THF solution (Scheme 5). LIFDI-MS (liquid injection field desorption mass spectrometry) analyses of the crude catalyst mixture displayed the formation of the low-valent dimer [(DippBIAN)Co]2, which is structurally related to a complex with two direct cobalt-arene bonding interactions prepared by Yang and co-workers using a different diimine.26 We surmised that the low-valent monomeric unit [(DippBIAN)Co] might exhibit catalytic activity and thus employed several arenes/olefins as labile coordination placeholders during the reductive dehalogenation of DippBIANCoBr2. Reduction of DippBIAN-CoBr2 in THF with 3 equiv LiBEt3H and excess amounts of 1,5-cyclooctadiene (cod) led to the formation of [Li(thf)3]([DippBIAN]Co(cod)) (1) which was isolated after recrystallization in 17% yield.27,16c This complex is the corresponding Li salt to our previously described potassium homotopic catalyst poison dibenzo[a,e]cyclooctatetraene25 which was isolated after recrystallization in 17% yield.27,16c This complex is the corresponding Li salt to our previously described potassium cobalate (2) and shows similar 1H and 13C spectra.27c Based on literature precedents, the oxidation level of BIAN in 1 can be assigned as 2− from the crystallographic bond distances (C−C: 1.389(4) Å; C−N: 1.383(3) Å; Figure 2).28,29 In comparison, DippBIANCoBr2 consists of a neutral BIAN (C−C: 1.513(7) and 1.521(6) Å); C−N: 1.277(7)–1.286(8) Å).16d,28,29

The analogous reduction of DippBIAN-CoBr2 with 3 equiv LiEt3BH in benzene furnished the neutral complex [(DippBIAN)Co(n:η2-C5H4Br2)] (3) as dark red single crystals in 64% yield. (3 is also formed from the same reaction in a mixture of 1,5-cod and benzene).30 Single crystal structure analysis suggests a radical anion state of the BIAN ligand (C−C 1.433(2) Å; C−N 1.3246(19) Å and 1.3224(19) Å, Figure 2), which was further investigated by EPR.28,29 The X-band spectrum of 3 in toluene glass at 20 K (Figure 3) shows a rhombic symmetry and was simulated in accordance with an unpaired electron coupled to a spin 7/2 nucleus. We attribute this signal to a cobalt-centered radical (SI). Inclusion of the Euler angles [−2.0, +90.0, 0] proved to be necessary to align the g and Aco tensors and provided a more satisfactory simulation of the measured spectrum. Some linear and quadratic A-strain parameters have been included to simulate
the final line shape (SI). Some remaining slight deviations in the line shapes between simulation and experiment can be attributed to nonperfect glass formation. The provided simulation allowed for accurate determination of the $g$ and $A_{Co}$ tensors (MHz): $g = 2.013, 2.145, 2.134$ and $A_{Co} = 185.0, +406.0, 198.4$, respectively. These results are in agreement with an effective magnetic moment $\mu_{eff}$ of 1.9 $\mu_B$ (Evans method, C$_4D_8$), which is only slightly higher than the spin-only value for an $S = 1/2$ system ($\mu_{eff} = 1.7 \mu_B$).

Further analysis of 3 included elemental analysis, LIFDI-MS ($m/z = 637.2781$), cyclic voltammetry (CV, one reversible reduction, $E = -2.3 \text{ V vs Fe/Fe}^+$), and UV–vis (C$_6H$_6, $\lambda_{max} = 481 \text{ nm}, \epsilon_{max} = 14300 \text{ mol}^{-1} \text{ cm}^{-1} \text{ L}$). The combined data point to a highly unusual electronic structure of complex 3 which is described as a [[(BIAN)Co]$_2$] complex that contains a very rare high-spin Co(I) center. The BIAN radical anion is (strongly) antiferromagnetically coupled to BIAN. Accordingly, the observed bond lengths of the BIAN ligands in 3 are slightly shorter than in 4a (Figure 1; C–N 1.333(3)–1.349(3) Å; C–C 1.412(3)–1.419(3) Å, yet are in good agreement with the monoanionic BIAN in the complex [[(OppyBian)Fe] (C–N 1.3367(15) and 1.3393(15) Å; C–C 1.4234(18) Å) which contains a high-spin Fe$^{2+}$ that is antiferromagnetically coupled to BIAN. Accordingly, the observed bond lengths of the BIAN ligands in 4a suggest a radical anion state of BIAN which is supported by theoretical studies (vide infra).28,29,37

The sum formula of 4a was further verified by negative-ion mode ESI mass spectrometry (Figure 4, $m/z = 1121.4$). The compound proved highly sensitive as unsealed THF solutions decomposed in an argon-filled glovebox within several hours to a red-brown paramagnetic mixture presumably by formation of H$_2$. Direct evidence of such decomposition came from the gas-phase fragmentation of the mass-selected anionic component of 4a in ESI-MS. Apart from dissociation into its monomeric subunit [[(OppyBian)Co]$_2$], the dinuclear cobaltate readily underwent dehydrogenation (Figures S25 and S26). Remarkably, multiple dehydrogenation steps were operative ($\geq$7). Most likely, the released H atoms originated from the bridging hydrides and from the isopropyl groups of the OppyBian. The $^1$H NMR spectrum of 4a displayed a characteristic, broad singlet resonance for the three bridging hydrides at $-75.2$ ppm (see the Supporting Information for 2D NMR analyses). This remarkable high-field shift may indicate an open-shell structure which was further investigated by temperature-dependent $^1$H NMR studies.38 The chemical shift of this resonance is temperature-dependent and shows a strong upfield shift upon
decreasing temperature (Figure 5). A similar behavior is observed for the remaining $^1$H NMR resonances. The observed non-Curie behavior indeed points to an antiferromagnetic coupling of the cobalt centers with the diamagnetic ground state at low temperatures. Signal fitting provided a ratio of the coexisting configurations. Hence, the paramagnetic configurations are 27% of the singlet at 293 K (Figure 5 and SI). The ratio decreased to 0.3% at 193 K ($\Delta E_{\text{triplet}-\text{singlet}} = 21.4$ kJ/mol). An effective magnetic moment $\mu_{\text{eff}} = 2.1 \mu_B$ per dimer was determined in solution at 293 K (Evans method, THF-$d_8$).

The solid-state magnetic behavior of the crystalline sample of 4b was investigated in the 2–250 K range by SQUID magnetometry (Figure 6). The $\chi_M T$ product was 1.76 cm$^3$ mol$^{-1}$ K (or 3.75 $\mu_B$) at 250 K and decreased to almost zero by lowering the temperature, indicating overall antiferromagnetic coupling and a diamagnetic ground state of 4b. The best fit was achieved using a model of four antiferromagnetically coupled centers: two BIAN radical anions with $S = 1/2$ and two $S = 3/2$ cobalt(II) ions. The best fit parameters were the following: $g(\text{BIAN}) = 2.0$ (fixed), $g(\text{Co(II)}) = 2.08$, $J(\text{BIAN-Co}) = -427$ cm$^{-1}$ and $J(\text{Co-Co}) = -17$ cm$^{-1}$.

Additional analyses of the cobaltate 4a include elemental analysis (EA), UV–vis spectroscopy ($C_{6}H_{6}$, $I_{\text{max}} = 474$ nm, $\epsilon_{\text{max}} = 1200$ mol$^{-1}$ cm$^{-1}$ L), and cyclic voltammetry (THF/[$n$Bu$_3$N]$\cdot$PF$_6$; one reversible reduction was observed $E = -2.4$ V vs Fc/Fc$^+$. The combined data are strongly indicative of a highly unusual electronic structure of the trihydridodicobaltate anion of 4a,b, which is best described as $\left\{\left[\text{DippBIAN}^-\right]_3\text{Co}^{\text{III}}\right\}^-$.

Hydrogenation Activities of Complexes 1–4 and Mechanistic Proposal. We evaluated the catalytic activities of the isolated cobalt complexes 1–4 and various precatalyst mixtures in a hydrogenation model reaction (Table 2). The cobaltate complex $\left[\text{Li(thf)}_3\text{DippBIAN}\right]\left[\text{Co(cod)}\right]$ (1) was...
indicate Lewis acid-assisted catalysis. The borane could facilitate the cleavage of H₂ as demonstrated by Peters and co-workers with a borylcobalt complex.40a The catalytic inactivity of the corresponding potassium derivative [K(thf)₂{(DippBIAN)Co(cod)}] showed moderate hydrogenation activity which was significantly enhanced by further reduction with 0.5 equiv of LiEt₃BH (entries 12 and 14). It may be speculated that the hydridocobaltate anion present in 4a,b (or related derivatives) acts as a catalyst reservoir for mononuclear hydrides as indicated by in situ NMR studies (SI). A catalytic mechanism via multinuclear metal complexes can likely be ruled out (first order in [Co], poisoning studies, SI).41 Based on the collected synthetic, spectroscopic, and theoretical data, we propose a homotopic reaction mechanism that involves cobaltate complexes as active catalyst species. Rate acceleration by Lewis acids and an alkali-cation effect were observed.

The observed alkali cation effect was also evident in the more effective stoichiometric hydrogenation of 1 vs 2 (Scheme 6, A). Preliminary explorations of the reactivity of relevant hydrides were performed with 4b as model compound: Protolysis occurred with the strong Bronsted acid HCl in dioxane to give H₂ evolution (2.3 ± 0.1 equiv H₂). In the presence of benzaldehyde, 4b reacted to give 28% benzyl alcohol and 27% pinacol coupling product (Scheme 6B). This may indicate the competing operation of hydride transfer and single-electron transfer processes from 4b. In the absence of dihydrogen, incomplete isomerization of (Z)-stilbene to (E)-stilbene was observed (51%, Scheme 6C). 4a represents a conceivable intermediate in our recently published (BIAN)Co-catalyzed amine-borane dehydrogenation reaction as it affords the same reaction products (borazine, cyclotriminoborane, cycloaminoborane, H₂B₃N₃H₁₁, polyborazine, and polyaminoborane; SI).16e

### CONCLUSION

In summary, this report has established reduced cobalt complexes as competent catalysts in a user-friendly hydrogenation protocol for challenging alkenes under mild conditions. The obtained reactivity suggests bidentate BINAs as interesting alternatives to well-established pincer-type motifs possessing comparably high activities in cobalt-catalyzed alkene and imine hydrogenations. Mechanistic studies revealed considerable alkali-cation and Lewis-acid effects. Synthetic, kinetic, and spectroscopic experiments indicate a mechanism involving homotopic cobaltate catalysts. Catalytically relevant cobalt complexes were isolated that document the redox noninnocence of the BIAN ligand. Especially, the isolation of trihydridocobaltates 4a,b represents a tangible advance over the current state-of-the-art of transition metal hydrides. Their molecular structures show the first reported anionic cobalt complex with bridging hydride ligands. In contrast to the vast majority of reported transition metal hydrides bearing

(20) α-Methyleneene was hydrogenated under standard conditions in the presence of various functional additives (1 equiv, protocol B, 3 h, 20 °C, THF (2 mL)): No decrease in hydrogenation activity was observed with added PhNH2, whereas reduced activity was observed with 4-Tol–CH2–OH and Ph(CO)2Ph, respectively. No conversion was obtained in the presence of PhCH2, PhC(O)2H, and PhNO2, respectively (SI).

(28) Based on molecular structure optimizations of the anion of 4a,b with the BP86 functional and Alhrich’s def2-TZVP basis set, the closed-shell singlet (css) represents the lowest energy state, with the triplet (t) being the next highest in energy (ΔE(t − css) = 30.8 kJ/mol), followed by the quintet state (q) (ΔE(q − css) = 50.2 kJ/mol).

(29) For average bond distances of BIAN from the literature, see ref 16c: BIAN 2− C–N 1.28, C–C 1.49; BIAN 3− C–N 1.34, C–C 1.44; BIAN 2− C–N 1.39, C–C 1.40.
