Abstract

We propose a grounded dialogue state encoder which addresses a foundational issue on how to integrate visual grounding with dialogue system components. As a test-bed, we focus on the GuessWhat?! game, a two-player game where the goal is to identify an object in a complex visual scene by asking a sequence of yes/no questions. Our visually-grounded encoder leverages synergies between guessing and asking questions, as it is trained jointly using multi-task learning. We further enrich our model via a cooperative learning regime. We show that the introduction of both the joint architecture and cooperative learning lead to accuracy improvements over the baseline system. We compare our approach to an alternative system which extends the baseline with reinforcement learning. Our in-depth analysis shows that the linguistic skills of the two models differ dramatically, despite approaching comparable performance levels. This points at the importance of analyzing the linguistic output of competing systems beyond numeric comparison solely based on task success.†

1 Introduction

Over the last few decades, substantial progress has been made in developing dialogue systems that address the abilities that need to be put to work during conversations: Understanding and generating natural language, planning actions, and tracking the information exchanged by the dialogue participants. The latter is particularly critical since, for communication to be effective, participants need to represent the state of the dialogue and the common ground established through the conversation (Stalnaker, 1978; Lewis, 1979; Clark, 1996).

In addition to the challenges above, dialogue is often situated in a perceptual environment. In this study, we develop a dialogue agent that builds a representation of the context and the dialogue state by integrating information from both the visual and linguistic modalities. We take the GuessWhat?! game (de Vries et al., 2017) as our test-bed, a two-player game where a Questioner faces the task of identifying a target object in a visual scene by asking a series of yes/no questions to an Oracle. We model the agent in the Questioner’s role.

To model the Questioner, previous work relies on two independent models to learn to ask questions and to guess the target object, each equipped with its own encoder (de Vries et al., 2017; Strub et al., 2017; Zhu et al., 2017; Lee et al., 2017; Shekhar et al., 2018; Zhang et al., 2018). We propose an end-to-end architecture with a single visually-grounded dialogue state encoder (cf. Figure 1). Our system is trained jointly in a supervised learning setup, extended with a cooperative learning (CL) regime: By letting the model play the game with self-generated dialogues, the components of the Questioner agent learn to better perform the overall Questioner’s task in a cooperative manner. Das et al. (2017b) have explored the use of CL to train two visual dialogue agents that receive joint rewards when they play a game successfully. To our knowledge, ours is the first ap-
proach where cooperative learning is applied to the internal components of a grounded conversational agent.

Our cooperative learning regime can be seen as an interesting alternative to reinforcement learning (RL)—which was first applied to GuessWhat?! by Strub et al. (2017)—because it is entirely differentiable and computationally less expensive to train than RL. Little is known on how this learning approach compares to RL not only regarding task success, but also in terms of the quality of the linguistic output, a gap we seek to fill in this paper. In particular, our contributions are:

- The introduction of a single visually-grounded dialogue state encoder jointly trained with the guesser and question generator modules to address a foundational question of how to integrate visual grounding with dialogue system components; this yields up to 9% improvement on task success.
- The effectiveness of cooperative learning, which yields an additional increase of 8.7% accuracy, while being easier to train than RL.
- A first in-depth study to compare cooperative learning to a state-of-the-art RL system. Our study shows that the linguistic skills of the models differ dramatically, despite approaching comparable task success levels. This underlines the importance of linguistic analysis to complement solely numeric evaluation.

2 Related Work

Task-oriented dialogue systems The conventional architecture of task-oriented dialogue systems includes a pipeline of components, and the task of tracking the dialogue state is typically modelled as a partially-observable Markov decision process (Williams et al., 2013; Young et al., 2013; Kim et al., 2014) that operates on a symbolic dialogue state consisting of predefined variables. The use of symbolic representations to characterise the state of the dialogue has some advantages (e.g., ease of interfacing with knowledge bases), but it has also some key disadvantages: the variables to be tracked have to be defined in advance and the system needs to be trained on data annotated with explicit state configurations.

Given these limitations, there has been a shift towards neural end-to-end systems that learn their own representations. Early works focus on non-goal-oriented chatbots (Vinyals and Le, 2015; Soroudi et al., 2015; Serban et al., 2016; Li et al., 2016a,b). Bordes et al. (2017) propose a memory network to adapt an end-to-end system to task-oriented dialogue. Recent works combine conventional symbolic with neural approaches (Williams et al., 2017; Zhao and Eskenazi, 2016; Rastogi et al., 2018), but all focus on language-only dialogue. We propose a visually grounded task-oriented end-to-end dialogue system which, while maintaining the crucial aspect of the interaction of the various modules at play in a conversational agent, grounds them through vision.

Visual dialogue agents In recent years, researchers in computer vision have proposed tasks that combine visual processing with dialogue interaction. Pertinent datasets created by Das et al. (2017a) and de Vries et al. (2017) include VisDial and GuessWhat?!, respectively, where two participants ask and answer questions about an image. While impressive progress has been made in combining vision and language, current models make simplifications regarding the integration of these two modalities and their exploitation for task-related actions. For example, the models proposed for VisDial by Das et al. (2017a) concern an image guessing game where one agent does not see the target image (thus, no multimodal understanding) and is required to ‘imagine’ it by asking questions. The other agent does see the image, but only responds to questions without the need to perform additional actions.

In GuessWhat?!, the Questioner agent sees an image and asks questions to identify a target object in it. The Questioner’s role hence involves a complex interaction of vision, language, and guessing actions. Most research to date has investigated approaches consisting of different models trained independently (de Vries et al., 2017; Strub et al., 2017; Zhu et al., 2017; Lee et al., 2017; Shekhar et al., 2018; Zhang et al., 2018). We propose the first multimodal dialogue agent for the GuessWhat?! task where all components of the Questioner agent are integrated into a joint architecture that has at its core a visually-grounded dialogue state encoder (cf. Figure 1).

Reinforcement learning for visual dialogue agents was introduced by Das et al. (2017b) for
VisDial and by Strub et al. (2017) for Guess-What?! Our joint architecture allows us to explore a simpler solution based on cooperative learning between the agent’s internal modules (see Section 5 for details).

3 Task and Data

The Guess-What?! game (de Vries et al., 2017) is a simplified instance of a referential communication task where two players collaborate to identify a referent—a setting used extensively in human-human collaborative dialogue (Clark and Wilkes-Gibbs, 1986; Yule, 1997; Zarrieß et al., 2016).

The Guess-What?! dataset was collected via Amazon Mechanical Turk by de Vries et al. (2017). The task involves two human participants who see a real-world image, taken from the MS-COCO dataset (Lin et al., 2014). One of the participants (the Oracle) is assigned a target object in the image and the other participant (the Questioner) has to guess it by asking Yes/No questions to the Oracle. There are no time constraints to play the game. Once the Questioner is ready to make a guess, the list of candidate objects is provided and the game is considered successful if the Questioner picks the target object. The dataset consists of around 155k English dialogues about approximately 66k different images. Dialogues contain on average 5.2 questions-answer pairs.

4 Models

We focus on developing an agent who plays the role of the Questioner in Guess-What?!.

4.1 Baseline Model

As a baseline model (BL), we consider our own implementation of the best performing system put forward by de Vries et al. (2017). It consists of two independent models: a Question Generator (QGen) and a Guesser. For the sake of simplicity, QGen asks a fixed number of questions before the Guesser predicts the target object. Like the Guesser, the Oracle does not have access to the raw image features. It receives as input the current question asked by the Questioner, encoded by a dedicated LSTM. These three embeddings are concatenated and fed to an MLP that gives an answer (Yes or No).

4.2 Visually-Grounded Dialogue State Encoder

In line with the baseline model, our Questioner agent includes two sub-modules, a QGen and a Guesser. As in the baseline, the Guesser guesses after a fixed number of questions, which is a parameter tuned on the validation set. Our agent architecture differs from the baseline model by de Vries et al.: Rather than operating independently, the language generation and guessing modules are connected through a common ground state encoder (GSE) which combines linguistic and visual information as a prior for the two modules. Given this representation, we will
Figure 2: Question Generation and Guesser modules.

As illustrated in Figure 1, the encoder receives as input representations of the visual and linguistic context. The visual representation consists of the second to last layer of ResNet152 trained on ImageNet. The linguistic representation is obtained by an LSTM (LSTM_e) which processes each question-answer pair in the dialogue. At each question-answer QA, the last hidden state of LSTM_e is concatenated with the image features I, passed through a linear layer and a tanh activation to result in the final layer h_t:

\[ h_t = \tanh (W \cdot [\text{LSTM}_e(qa_{1:t-1}); I]) \]  

where \([; \cdot ; \cdot]\) represents concatenation, \(I \in \mathbb{R}^{2048 \times 1}\), \(\text{LSTM}_e \in \mathbb{R}^{1024 \times 1}\) and \(W \in \mathbb{R}^{512 \times 3072}\) (identical to prior work except for tuning the ResNet-specific parameters). We refer to this final layer as the dialogue state, which is given as input to both QGen and Guesser.

As illustrated in Figure 2, our QGen and Guesser modules are like the corresponding modules by de Vries et al. (2017), except for the crucial fact that they receive as input the same grounded dialogue state representation. QGen employs an LSTM (LSTM_q) to generate the token sequence for each question conditioned on \(h_t\), which is used to initialise the hidden state of LSTM_q. As input at every time step, QGen receives a dense embedding of the previously generated token \(w_{t-1}\) and the image features I:

\[ p(w_t) = p(w_t | w_1, \ldots, w_{t-1}, h_t, I) \]  

We optimise QGen by minimising the Negative Log Likelihood (NLL) of the human dialogues and use the Adam optimiser (Kingma and Ba, 2015):

\[ \mathcal{L}_Q = \sum_i -\log p(w_i) \]  

Thus, in our architecture the LSTM_q of QGen in combination with the LSTM_e of the Encoder form a sequence-to-sequence model (Sutskever et al., 2014), conditioned on the visual and linguistic context — in contrast to the baseline model, where question generation is performed by a single LSTM on its own.

The Guesser consists of an MLP which is evaluated for each candidate object in the image. It takes the dense embedding of the category and the spatial information of the object to establish a representation \(r_j \in \mathbb{R}^{512 \times 1}\) for each object. A score is calculated for each object by performing the dot product between the dialogue state \(h_t\) and the object representation. Finally, a softmax over the scores results in a probability distribution over the candidate objects:

\[ p(o_j) = \frac{e^{h_t^T r_j}}{\sum_j e^{h_t^T r_j}} \]  

We pick the object with the highest probability and the game is successful if \(o_{\text{guess}} = o_{\text{target}}\), where \(o_{\text{guess}} = \arg \max_j p(o_j)\). As with QGen, we optimise the Guesser by minimising the NLL and again make use of Adam:

\[ \mathcal{L}_G = -\log p(o_{\text{target}}) \]  

The resulting architecture is fully differentiable. In addition, the GDSE agent faces a multi-task optimisation problem: While the QGen optimises \(\mathcal{L}_Q\) and the Guesser optimises \(\mathcal{L}_G\), the parameters of the Encoder (\(W, \text{LSTM}_e\)) are optimised via both \(\mathcal{L}_Q\) and \(\mathcal{L}_G\). Hence, both tasks faced by the Questioner agent contribute to the optimisation of the dialogue state \(h_t\), and thus to a more effective encoding of the input context.

5 Learning Approach

We first introduce the supervised learning approach used to train both BL and GDSE, then our cooperative learning regime, and finally the reinforcement learning approach we compare to.

5.1 Supervised Learning

In the baseline model, the QGen and the Guesser modules are trained autonomously with supervised learning (SL): QGen is trained to replicate
human questions and, independently, the Guesser is trained to predict the target object. Our new architecture with a common dialogue state encoder allows us to formulate these two tasks as a multi-task problem, with two different losses (Eq. 3 and 5 in Section 4.2). These two tasks are not equally difficult: While the Guesser has to learn the probability distribution of the set of possible objects in the image, QGen needs to fit the distribution of natural language words. Thus, QGen has a harder task to optimize and requires more parameters and training iterations. We address this issue by making the learning schedule task-dependent. We call this setup modulo-n training, where n indicates after how many epochs of QGen training the Guesser is updated together with QGen.

Using the validation set, we experimented with n from 5 to 15 and found that updating the Guesser every 7 epochs worked best. With this optimal configuration, we then train GDSE for 100 epochs (batch size of 1024, Adam, learning rate of 0.0001) and select the Questioner module best performing on the validation set (henceforth, GDSE-SL or simply SL).

5.2 Cooperative Learning
Once the model has been trained with SL, new training data can be generated by letting the agent play new games. Given an image from the training set used in the SL phase, we generate a new training instance by randomly sampling a target object from all objects in the image. We then let our Questioner agent and the Oracle play the game with that object as target, and further train the common encoder using the generated dialogues by backpropagating the error with gradient descent through the Guesser. After training the Guesser and the encoder with generated dialogues, QGen needs to ‘readapt’ to the newly arranged encoder parameters. To achieve this, we re-train QGen on the human data with SL, but using the new encoder states. Also here, the error is backpropagated with gradient descent through the common encoder.

Regarding modulo-n, in this case QGen is updated at every n^{th} epoch, while the Guesser is updated at all other epochs; we experimented with n from 3-7 and set it to the optimal value of 5. The GDSE previously trained with SL is further trained with this cooperative learning regime for 100 epochs (batch size of 256, Adam, learning rate of 0.0001), and we select the Questioner module performing best on the validation set (henceforth, GDSE-CL or simply CL).

5.3 Reinforcement Learning
Strub et al. (2017) proposed the first extension of BL (de Vries et al., 2017) with deep reinforcement learning (RL). They present an architecture for end-to-end training using an RL policy. First, the Oracle, Guesser, and QGen models are trained independently using supervised learning. Then, QGen is further trained using a policy gradient. We use the publicly available code and pre-trained model based on Sampling (Strub et al., 2017), which resulted in the closest performance to what was reported by the authors.4 This is the RL model we use throughout the rest of the paper.

5.4 Experimental Details
We use the same train (70%), validation (15%), and test (15%) splits as de Vries et al. (2017). The test set contains new images not seen during training. We use two experimental setups for the number of questions to be asked by the question generator, motivated by prior work: 5 questions (5Q) following de Vries et al. (2017), and 8 questions (8Q) as in Strub et al. (2017). As noted in Section 3, on average, there are 5.2 questions per dialogue in the GuessWhat?! data set.

For evaluation, we report task success in terms of accuracy (Strub et al., 2017). To neutralize the effect of random sampling in training CL, we trained the model 3 times. RL is tested 3 times with sampling. We report means and standard deviation (for some tables these are provided in the supplementary material; see footnote 2).

6 Results
Table 1 reports the results for all models. There are several take-aways.

Grounded joint architecture First of all, our visually-grounded dialogue state encoder is effective. GDSE-SL outperforms the baseline by de Vries et al. (2017) significantly in both setups (absolute accuracy improvements of 6.6%)

4Their result of 53.3% accuracy published in Strub et al. (2017) is obsolete, as stated on their GitHub page (https://github.com/GuessWhatGame/guesswhat) where they report 56.5% for sampling and 58.4% for greedy search. By running their code, we could only replicate their results with sampling, obtaining 56%, while greedy and beam search resulted in similar or worse performance. Our analysis showed that greedy and beam search have the additional disadvantage of learning a smaller vocabulary.
Table 1: Test set accuracy for each model (for setups with 5 and 8 questions). GDSE-SL is our grounded supervised learning system, GDSE-CL the cooperative learning setup, and RL the results we obtain with the reinforcement learning system by Strub et al. (2017).

</tbody>
</table>

Cooperative learning and RL. The introduction of the cooperative learning approach results in a clear improvement over GDSE-SL: +8.7% (8Q: from 49.7 to 58.4) and +5.9% (with 5Q). Despite its simplicity, our GDSE-CL model achieves a task success rate which is comparable to RL: In the 8Q setup, GDSE-CL reaches an average accuracy of 58.4 versus 56.3 for RL, giving CL a slight edge in this setup (+2.1%), while in the 5Q setup RL is slightly better (+2.5%). Overall, the accuracy of the CL and RL models is close. The interesting question is how the linguistic skills and strategy of these two models differ, to which we turn in the next section.

We compared to Strub et al. (2017), but RL has also been put forward by Zhang et al. (2018), who report 60.7% accuracy (5Q). This result is close to our highest GDSE-CL result (60.8 ±0.51, when optimized for 10Q). Their RL system integrates several partial reward functions to increase coherence, which is an interesting aspect. Yet their code is not publicly available. We leave the comparison to Zhang et al. (2018) and adding RL to GDSE to future work.

7 Analysis

In this section, we present a range of analyses that aim to shed light on the performance of the models. They are carried out on the test set data using the 8Q setting, which yields better results than the 5Q setting for the GDSE models and RL. Given that there is only a small difference in accuracy for the baseline with 5Q and 8Q, for comparability we analyse dialogues with 8Q also for BL.

7.1 Quantitative Analysis of Linguistic Output

We analyse the language produced by the Questioner agent with respect to three factors: (1) lexical diversity, measured as type/token ratio over all games, (2) question diversity, measured as the percentage of unique questions over all games, and (3) the number of games with questions repeated verbatim. We compute these factors on the test set for the models and for the human data (H).

As shown in Table 2, the linguistic output of SL & CL is closer to the language used by humans: Our agent is able to produce a much richer and less repetitive output than both BL and RL. In particular, it learns to use a more diverse vocabulary, generates more unique questions, and repeats questions within the same dialogue at a much lower rate than the baseline and RL: 93.5% of the games played by BL contain at least one verbatim question repetition, for RL this happens in 96.47% of the cases, whereas for SL and CL this is for only 55.8% and 52.19% of the games, respectively.

7.2 Dialogue Strategy

To further understand the variety of questions asked by the agents, we classify questions into different types. We distinguish between questions that aim at getting the category of the target object (ENTITY questions, e.g., ‘is it a vehicle?’) and questions about properties of the queried objects (ATTRIBUTE questions, e.g., ‘is it square?’ or ‘are...
they standing?'). Within ATTRIBUTE questions, we make a distinction between color, shape, size, texture, location, and action questions. Within ENTITY questions, we distinguish questions whose focus is an object category or a super-category (see the supplementary material for example questions). The classification is done by manually extracting keywords for each question type from the human dialogues, and then applying an automatic heuristic that assigns a class to a question given the presence of the relevant keywords.\(^7\) This procedure allows us to classify 91.41% of the questions asked by humans. The coverage is higher for the questions asked by the models: 98.88% (BL), 94.72% (SL), 94.11% (CL) and 99.51 % (RL).\(^8\)

The statistics are shown in Table 3. We use Kullback-Leibler (KL) divergence to measure how the output of each model differs from the human distribution of fine-grained question types. The baseline’s output has the highest degree of divergence: For instance, the BL model does never ask the output of each model differs from the human distribution of fine-grained question types. The expected, both humans and models almost always start with an ENTITY question (around 97% for BL, SL and CL, 98.7% for RL, and 78.48% for humans), in particular a SUPER-CATEGORY (around 70% for BL, SL and CL, 84% for RL, and 52.32% for humans). In some cases, humans start by asking questions directly about an attribute that may easily distinguish an object from others, while this is very uncommon for models. Figure 3 shows an example: The human dialogue begins with an ATTRIBUTE question (‘does it have cereal on it?’), which in this case is not very effective and leads to a change in strategy at turn 4. The CL model starts by asking an ATTRIBUTE question (‘is it a donut?’) while the RL model begins with a more generic SUPER-CATEGORY question (‘is it food?’).

We check how the answer to a given question type affects the type of the follow-up question. In principle, we expect to find that question types that are answered positively will be followed by more specific questions. This is indeed what we observe in the human dialogues, as shown in Table 3. For example, when a SUPER-CATEGORY question is answered positively, humans follow up with an OBJECT or ATTRIBUTE question 89.56% of the time. This trend is mirrored by all models. Overall, the models also learn the strategy to move from an OBJECT to an ATTRIBUTE question when an OBJECT question receives a Yes answer. The BL, SL, and CL models do this to a lesser extent than humans, while the RL model systematically

\(^7\) A question may be tagged with several attribute classes if keywords of different types are present. E.g., ‘Is it the white one on the left?’ is classified as both COLOR and LOCATION.

\(^8\) In the supplementary material we provide details on the question classification procedure: the lists of keywords by class, the procedure used to obtain these lists, as well as the pseudo-code of the heuristics used to classify the questions.

Figure 3: Game example where GDSE-CL succeeds and RL fails at guessing the target object (framed).
transitions to attributes (in 99.46% of cases), using mostly LOCATION questions as pointed out above. For example (Figure 3), after receiving an affirmative answer to the OBJECT question ‘is it a donut?’ both CL and RL shift to a LOCATION question. Once location is established, CL moves on to other attributes while RL keeps asking the same LOCATION question, which leads to failure. Further illustrative examples are given in the supplementary material.

7.3 Analysis of the CL Learning Process

In order to better understand the effect of the cooperative learning regime, we trace the evolution of linguistic factors identified above over the CL epochs. As illustrated in Figure 4 (a) and (b), through the epochs the CL model learns to use a richer vocabulary and more diverse questions, moving away from the levels achieved by BL and RL, overlapping SL and moving toward humans.

The CL model progressively produces fewer repeated questions within a dialogue, improving over SL in the last few epochs, cf. Figure 4 (c). Finally, (d) illustrates the effect of modulo-$n$ training: As the model is trained on generated dialogues, its linguistic output drifts away from the human distribution of question types; every 5th epoch QGen is trained via supervision, which brings the model’s behaviour closer back to human linguistic style and helps decrease the drift.

8 Conclusion

We present a new visually-grounded joint Questioner agent for goal-oriented dialogue. First, we show that our architecture archives 6–9% accuracy improvements over the GuessWhat?! baseline system (de Vries et al., 2017). This way, we address a foundational limitation of previous approaches that model guessing and questioning separately.

Second, our joint architecture allows us to propose a two-phase cooperative learning approach (CL), which further improves accuracy. It results in our overall best model and reaches state-of-the-art results (cf. Section 6). We compare CL to the system proposed by Strub et al. (2017) which extends the baseline with reinforcement learning (RL). We find that the two approaches (CL and RL) achieve overall relatively similar task success rates. However, evaluating on task success is only one side of the coin. Finally and most importantly, we propose to pursue an in-depth analysis of the quality of the dialogues by visual conversational agents, which is an aspect often neglected in the literature. We analyze the linguistic output of the two models across three factors (lexical diversity, question diversity, and repetitions) and find them to differ substantially. The CL model uses a richer vocabulary and inventory of questions, and produces fewer repeated questions than RL. In contrast, RL highly relies on asking location questions, which might be explained by a higher reliance on spatial and object-type information explicitly given to the Guesser and Oracle models. Limiting rewards to task success or other rewards not connected to the language proficiency does not stimulate the model to learn rich linguistic skills, since a reduced vocabulary and simple linguistic structures may be an efficient strategy to succeed at the game.
Overall, the presence of repeated questions remains an important weakness of all models, resulting in unnatural dialogues. This shows that there is still a considerable gap to human-like conversational agents. Looking beyond task success can provide a good basis for extensions of current architectures, e.g., Shekhar et al. (2018) add a decision-making component that decides when to stop asking questions which results in less repetitive and more human-like dialogues. Our joint architecture could easily be extended with such a component.

Acknowledgements

The work carried out by the Amsterdam team was partially funded by the Netherlands Organisation for Scientific Research (NWO) under VIDI grant nr. 276-89-008, Asymmetry in Conversation. We thank the University of Trento for generously funding a research visit by Barbara Plank to CIMeC that led to part of the work presented in this paper. In addition, we kindly acknowledge the support of NVIDIA Corporation with the donation to the University of Trento of the GPUs used in our research.
