Received 21 September 2018 / Accepted 26 October 2018

**ABSTRACT**

**Context.** With an orbital distance comparable to that of Saturn in the solar system, β Pictoris b is the closest (semi-major axis = 9 au) exoplanet that has been imaged to orbit a star. Thus it offers unique opportunities for detailed studies of its orbital, physical, and atmospheric properties, and of disk-planet interactions. With the exception of the discovery observations in 2003 with NaCo at the Very Large Telescope (VLT), all following astrometric measurements relative to β Pictoris b have been obtained in the southwestern part of the orbit, which severely limits the determination of the planet’s orbital parameters.

**Aims.** We aimed at further constraining β Pictoris b orbital properties using more data, and, in particular, data taken in the northeastern part of the orbit.

**Methods.** We used SPHERE at the VLT to precisely monitor the orbital motion of beta β Pictoris b since first light of the instrument in 2014.

**Results.** We were able to monitor the planet until November 2016, when its angular separation became too small (125 mas, i.e., 1.6 au) and prevented further detection. We redetected β Pictoris b on the northeast side of the disk at a separation of 139 mas and a PA of 30° in September 2018. The planetary orbit is now well constrained. With a semi-major axis (sma) of a = 9.0 ± 0.5 au (1σ), it definitely excludes previously reported possible long orbital periods, and excludes β Pictoris b as the origin of photometric variations that took place in 1981. We also refine the eccentricity and inclination of the planet. From an instrumental point of view, these data demonstrate that it is possible to detect, if they exist, young massive Jupiters that orbit at less than 2 au from a star that is 20 pc away.

**Key words.** planetary systems – stars: individual: HR 2020 – instrumentation: high angular resolution

**1. Introduction**

With its imaged debris disk of dust (see Smith & Terrile 1984, for the discovery image), its falling, evaporating exocomets (Kiefer et al. 2014, and references therein), and an imaged giant planet (Lagrange et al. 2010), the ~20 Myr old β Pictoris is a unique proxy for the study of the early stages of planetary system formation and evolution, when giant planets are formed. Earth-mass planets may still be forming, and most of the protoplanetary gas has disappeared from the disk. Its proximity to Earth (van Leeuwen 2007, distance = 19.454 ± 0.05 pc) and the relatively short (~ two decades) orbital period of β Pictoris b enable detailed studies of its orbit and its physical and atmospheric properties. The system also allows us to study the interaction between planet(s) and disks. β Pictoris b can explain, for example, several (but not all) of the dust disk morphologies, in particular its inner warp, and some outer asymmetries (Lagrange et al. 2010). β Pictoris b could also be the trigger for the infall and evaporation of cometary bodies (exocomets) onto the star, if it has a non-zero eccentricity (Beust & Morbidelli 1996). Last, β Pictoris b was suggested to be responsible for the photometric variations observed in 1981 (Lecavelier Des Etangs et al. 1995) and has tentatively been attributed to a planet transit (Lecavelier Des Etangs et al. 1997).

Careful monitoring of the position of the planet relative to the star (referred to as astrometric measurements) with the Nasmyth Adaptive Optics System (NAOS) Near-Infrared Imager and Spectrograph (CONICA) (NaCo) at the Very Large Telescope (VLT) constrained its orbital properties.
Fig. 1. Images of β Pictoris b with SPHERE IRDIS from December 2014 to September 2018. Each panel displays a FoV of 1″ × 1″. North is up and east is to the left. The intensity scale is adapted at each epoch according to the intensity peak of the planet.

Notes. AM stands for the mean airmass, Apar for the variation in parallactic angle during the coronagraphic sequence, TNcorr for true north correction (TN is the angle between the north position and the detector “North”). Seeing and coherence time (\(\tau_0\)) are mean values throughout the coronagraphic sequence.

(Bonnefoy et al., 2014; Chauvin et al., 2012). By combining data from NaCo and the Gemini Planetary Imager (GPI), Wang et al. (2016) found a similar but slightly different orbit. Assuming that the peculiar photometric event observed in 1981 could be due to the transit of \(\beta\) Pictoris b in front of the star, Lecavelier des Etangs & Vidal-Madjar (2016) identified a second family of orbital solutions: a semi-major axis \(a = 13\) au instead of 9 au, that is, a period of 34 yr instead of about 20 yr, and \(e = 0.3\) instead of less than 0.1. Recently, Snellen & Brown (2018) used Gaia and Hipparcos measurements to constrain the planet period to \(22.2\) yr, and reported a mass of \(11 + 2\,M_{\text{Jup}}\), which is compatible with the constraints derived from radial velocity data alone (Lagrange et al., 2012a) or by the combined analysis of direct imaging and radial velocity data (Bonnefoy et al., 2014).

\(\beta\) Pictoris b was discovered northeast of the star in data obtained in 2003 with NaCo. All available images in addition to this discovery image were obtained in 2009 and later, as the planet orbited southwest of the star, after it passed behind the star (Lagrange et al., 2010). The orbital plane is close to equatorial, and the disk of \(\beta\) Pictoris is seen almost edge-on. This geometrical configuration prevented following the planet in direct imaging when it was projected too close (typically less than 120 mas) to the star. Altogether, only about 50% of the planetary orbit had been monitored thus far, including the 2003 epoch, which suffers from relatively large uncertainties and thus limits the precision on the orbital parameters of the planet. We here present a homogeneous set of planet observations obtained with the Spectro-Polarimetric High-Contrast Exoplanet Research instrument (SPHERE), and in particular, the recent recovery of the planet in September 2018. The observations are described in Sect. 2, and the results are shown and discussed in Sect. 3.

2. Observations

High-contrast coronagraphic SPHERE (Beuzit et al., 2008) observations were obtained between December 2014 and November 2016, and in September 2018, using the IRDIS mode in the context of the SpHere INfrared survey for Exoplanets (SHINE; Chauvin et al., 2017a). In this setup, the IRDIS (Dohlen et al., 2008) and IFS (Claudi et al., 2008) instruments operate simultaneously. The data were obtained under various atmospheric conditions (see Table 1) with the H2 (\(\lambda_c = 1.593\,\mu\text{m}; \Delta \lambda = 0.055\,\mu\text{m}\)) and H3 (\(\lambda_c = 1.667\,\mu\text{m}; \Delta \lambda = 0.056\,\mu\text{m}\)) narrow bands of IRDIS, except in December 2014, when we used the K1 (\(\lambda_c = 2.1025\,\mu\text{m}; \Delta \lambda = 0.102\,\mu\text{m}\)) and K2 (\(\lambda_c = 2.255\,\mu\text{m}; \Delta \lambda = 0.109\,\mu\text{m}\)) narrow bands. The IRDIS images have a field of view (FoV) of \(\sim 10'' \times 11''\), and a pixel size of approximately 12.25 mas. IFS data were also recorded, but they are not analyzed here. We used apodized Lyot coronagraphs that include either a 185 mas diameter focal mask (N_ALC_YJH_S) or, when the planet was closer to the star, a smaller (145 mas) mask (N_ALC_YJ_S), combined to an apodizer as well as a pupil stop (Carbillet et al., 2011). All coronagraphic data were recorded in stabilized pupil mode so as to apply angular differential imaging (ADI) post-processing techniques to remove the stellar halo, as described in Marois et al. (2006). Most coronagraphic data were also recorded while four satellite footprints of the point spread function (PSF) had been created by the deformable mirror of the instrument and were used for fine monitoring of the frame centering and for photometric purposes. The FoV rotation during the coronagraphic observations varied between 16'' and 54'' (see Table 1).

Each observing sequence was obtained with the following pattern: PSF – coronagraphic observations – PSF – sky. The PSF data correspond to non-saturated exposures of the star placed out of the coronagraphic mask and obtained using a neutral density filter. They are used for relative photometric reference and to estimate the image quality at the beginning and end of the observations. The sky data were recorded at the end of the coronagraphic sequence to estimate the background level and hot pixels in the science images. Finally, an astrometric field, either Orion or 47 Tuc, was observed with IRDIS for each run (see Maire et al., 2016). In the case of Orion, the sub-field we used was chosen to be part of the one considered with NaCo since 2008 to allow the best match between the astrometric calibrations of NaCo and SPHERE. The pixel scales and north positions are provided in Table 1.

The data were reduced as described in Chauvin et al. (2017b) and using the SpecCal tool developed for SPHERE (Galicher et al., 2018). \(\beta\) Pictoris b is clearly detected in all images taken between 2014 and 2016, orbiting SW of the star at signal-to-noise ratio (S/N) higher than 9 (Table 2). Figure 1 shows the planet orbit both in observed images with SPHERE and in those obtained with NaCo at 8.2 μm, using both broad and narrow filters.
3. Orbital properties of β Pictoris b

</table>

shows images of the planet at various dates, and Table 2 provides the relative position of the planet with respect to the star. The S/N is relatively poor in the last observation of November 2016, as the projected separation of the planet from the star is less than 125 mas (≈1.5 au only) and the contrast is about 9.5 mag, which leads to larger error bars on its astrometry. To our knowledge, neither β Pictoris b nor any other planet has ever been imaged at such a close projected separation to the star. The 2018 data clearly reveal the planet at 139 mas NE (PA about 30°) from the star.

4. Concluding remarks and perspectives

The sensitivity of SPHERE allowed us to follow β Pictoris b down to 125 mas from the star in projected separation. The latest measurements reveal the planet on the NE side of the star, for the first time since its discovery. It was last detected in November 2016 and was re-detected in September 2018. Based on the observed data, the semi-major axis of the planet is well constrained to 8.90^{+0.25}_{-0.41} au (1σ), its eccentricity to e = 0.01^{+0.029}_{-0.03} and its inclination to i = 89.08^{+0.16}_{-0.19} deg. The data do not support that the planet was responsible for the photometric event in 1981. More data obtained in the NE part of the disk will allow further refining the orbital properties of the planet. Further work will include the combination of these new, crucial astrometric data points with our latest radial velocity measurements and, if possible, a combination with Gaia and Hipparcos data to constrain the dynamical mass of the planet. From an instrumental point of view, these data demonstrate that if they exist, SPHERE can detect young and massive Jupiters as close as 1.6 au from a star located at 20 pc.
