Tackling the Multiscale Challenge of Climate Modelling

by Daan Crommelin (CWI; Korteweg-de Vries Institute for Mathematics, University of Amsterdam), Wouter Edeling (CWI) and Fredrik Jansson (CWI)

The atmosphere and oceans are key components of the climate system, each involving a wide range of space and time scales. Resolving all relevant scales in numerical simulations with atmosphere/ocean models is computationally not feasible. At CWI, we are tackling this longstanding multiscale challenge by developing new algorithms, including data-based and stochastic methods, to represent small, unresolved scales.

Simulating the climate system on a computer presents a formidable challenge. A major difficulty is the multiscale nature of the key components of the climate system - the atmosphere and oceans. They possess physical and dynamic processes that occur across a range of spatial and temporal scales. Some aspects of the global atmospheric circulation operate at the planetary scale, in the order of $10^4$ km, yet it is also significantly affected by atmospheric convection and cloud formation, processes taking place at scales of order 10-100 m. Similarly disparate scales play a role in oceanic circulation.

Resolving all these scales at once in numerical simulation is computationally unfeasible. Therefore, global models employ simplified representations, or “parameterizations” of the effect that the unresolved processes have on the resolved-scale processes. Formulating such parameterizations is difficult, and the limitations of common, existing methods of doing so are well-known. The uncertainties and errors of parameterizations are a major source of uncertainty in climate change.
parameterization studies have reduced cloud formation explicitly. To reduce atmospheric convection and resolution of 50 m so that they can resolve subgrid scales in a simple ocean model that generated the data. In [2], we explored several methods to parameterize unresolved scales with stochastic models trained from data. The methods were tested on a multiscale test model (the Kac-Zwanzig heat bath model) that has its origins outside the climate domain yet forms a suitable test bed. One approach, making use of data resampling (or bootstrapping) for parameterization, was shown to be particularly effective.

Building on the results from [2], we use the resampling approach for parameterizing subgrid scales in a simple ocean model in [3], with positive results. The data-driven parameterization approach can be viewed as a methodology for surrogate modelling, as the parameterization is meant to replace (i.e., serve as a surrogate of) the expensive high-resolution base of the data. Stochastic (as opposed to deterministic) methods for surrogate modelling have not been explored much to date; our resampling approach is such a stochastic surrogate modelling method. We are currently making this approach part of the software toolkit VECArtk, under development in the EU H2020 project VECMA (Verified Exascale Computing for Multiscale Applications). Furthermore, we are strengthening our methods by using machine learning methods to build stochastic surrogates with wider capacity.

This research was supported by the Netherlands eScience Center, by the Dutch Research Council (NWO) through the Vidi project “Stochastic models for unresolved scales in geo-
Both biotic and abiotic space holders is benthic populations at different spatial scales. Detecting temporal variations in reliable measurements and monitoring undersea photogrammetry represent this bottleneck.

Underwater photogrammetry requires the use of ECMWF’s computing and archive facilities.

A State of the Art Technology in Large Scale Underwater Monitoring
by Gaia Pavoni, Massimiliano Corsini and Paolo Cignoni (ISTI-CNR)

In recent decades, benthic populations have been subjected to recurrent episodes of mass mortality. These events have been blamed in part on declining water quality and elevated water temperatures (see Figure 1) correlated to global climate change. Ecosystems are enhanced by the presence of species with three-dimensional growth. The study of the growth, resilience, and recovery capability of those species provides valuable information on the conservation status of entire habitats. We discuss here a state-of-the art solution to speed up the monitoring of benthic population through the automatic or assisted analysis of underwater visual data.

Ecological monitoring provides essential information to analyse and understand the current condition and persisting trends of marine habitats, to quantify the impacts of bounded and extensive events, and to assess the resilience of animal and plant species.

The underwater world is a hostile working environment for humans, with researchers’ activities being limited in time and space. Large-scale exploration requires underwater vehicles. The use of autonomous data-driven robotics for acquiring underwater image data is making large-scale underwater imaging increasingly popular. Nevertheless, video and image sequences are a trustworthy source of knowledge doomed to remain partially unexploited. A recent study [1] reported that just 1-2% of the millions of underwater images acquired each year on coral reefs by the National Oceanic and Atmosphere Administration (NOAA) are later analysed by experts. Automated solutions could help overcome this bottleneck.

Underwater photogrammetry represents a useful technology for obtaining reliable measurements and monitoring benthic populations at different spatial scales. Detecting temporal variations in both biotic and abiotic space holders is a challenging task, demanding a high degree of accuracy and fine-scale resolution. The detailed optical spatial-temporal analysis involves the acquisition of a massive stream of data. Evaluating changes in the benthos at a scale reflective of the growth and dissolution rates of its constituents requires a pixel-wise classification. This task, called semantic segmentation, is highly labor-intensive when conducted manually. Current manual workflows generate highly accurate and precise segmentation for fine-scale colony mapping but they demand about one hour per square metre.

The automatic extraction of information can contribute enormously to environmental monitoring efforts and, more generally, to our understanding of climate change. This operation can be performed automatically by using Convolutional Neural Networks (CNNs). Nevertheless, the automatic semantic segmentation of benthic communities remains a challenging task owing to the complexity and high intra-specific morphological variability of benthic organisms, as well as by the numerous artefacts related to the underwater image formation process.

In our work, we propose to carry out the classification and the outlining of species from seabed ortho-mosaics. From a machine learning perspective, ortho-mosaics display a reduced variance of distinctive class features, simplifying the task of automatic classification.

While fully automated semantic segmentation can significantly reduce the amount of processing time, current state-of-the-art solutions still lack the accuracy provided by human experts. Besides, the automation of such specific processes requires specific tools to prepare the data and provide control over the results. So, we propose a human-in-the-loop approach in which a skilled operator and supervised learning neural networks cooperate through a user-friendly interface to achieve the required degree of accuracy. This can be seen as an interactive segmentation cycle for the automatic analysis of benthic communities: intelligent tools assist users in the labelling of large-scale training datasets. Exploiting these data, CNNs are trained to classify coral species, and predictions inferred in new areas. In the evaluation of predictions, the human operator intervenes again to correct both ML-based and human annotation errors. This maximises accuracy when it comes to extracting demo-
