The formation of ice is thermodynamically favored in water at temperatures below 0 °C, but the crystallization is kinetically hindered owing to the energy barrier associated with creating the initial ice seed. As a result, pure water droplets can, depending on their size and cooling rate, be supercooled to temperatures as low as −38 °C. Ice crystals can be formed either by homogeneous nucleation at lower temperatures or by heterogeneous nucleation catalyzed by compounds that serve as ice nucleators (IN). The most effective biological IN known are ice-nucleating proteins from bacteria such as *Pseudomonas syringae*. Bacterial INPs can have different sizes but are typically large macromolecules that are anchored to the outer cell membrane of the bacterial cell wall. They are typically present as monomers but have repeatedly been shown to aggregate in the bacterial outer membranes. Large INP aggregates are thought to be responsible for freezing at temperatures around −2 and −4 °C and smaller INP aggregates at temperatures between −7 and −12 °C.

Computer-based homology modeling proposed the bacterial INP structure to be β-helical (Figure 1A) with similarities to hyperactive insect antifreeze proteins (AFPs). More recent models based on molecular dynamic simulations further suggest that a highly conserved threonine-X-threonine motif is used to interact with ice, which again is similar to some AFPs. On the molecular scale, the INPs are believed to work by organizing water into preordered patterns, which increase in size as the temperature decreases until they are large enough to form a stable embryonic crystal, leading to ice growth. However, the role of the INP structure, the interaction of INPs with water, and the underlying working mechanism remain largely unknown. Here, we study the effects of temperature on the structure, hydration shell, and ice-nucleation efficiency of purified proteinaceous IN of *P. syringae*.

We performed purification of fragmented *P. syringae* (Snomax) solutions using falling water ice affinity and rotary ice-shell purification (see the Supporting Information (SI) for details). Both purification methods use the unique property of the INPs to interact with ice and have previously been used to purify AFPs from natural sources. The purification process involved the incorporation of the INPs into the slowly growing ice phase and the exclusion of other biomolecules and impurities. Using this ice-affinity purification, we obtained a mixture of all the INPs present in *P. syringae*, including residual protein-associated lipids. The success of the purification was assessed by determining the ice-nucleation activity of the purified INPs using the high-throughput Twin-plate Ice Nucleation Assay (TINA) (Figure 1 and Figure S2). In the following, we will refer to these purified samples as “purified INPs”.

Figure 1B shows typical statistical freezing curves of aqueous solutions of fragmented *P. syringae* and purified INPs with 0.1 mg/mL, while Figure 1C compares their freezing behaviors inferred from freezing curves recorded for concentrations spanning from 0.1 mg/mL to 1 ng/mL (see also Figure S3).
The curve of *P. syringae* shows two substantial increases in the cumulative number of IN per unit mass, $N_m(T)$ (Figure 1C) around $-3.0$ and $-7.5 \, ^\circ C$ with plateaus between $-4.5$ and $-7.0 \, ^\circ C$ and below $-9.5 \, ^\circ C$. At the plateaus, at temperatures below each increase of $N_m(T)$, fewer IN are active. The two rises in the curve reveal that the ice-nucleation activity stems from two distinct classes of IN with different activation temperatures. We attribute the observed rise at $-3.0 \, ^\circ C$ to large assemblies of INPs (class A IN) and the rise at $-7.5 \, ^\circ C$ to smaller assemblies of INPs (class C IN) in accordance with previous studies. The freezing curve of the purified INPs looks similar to the nonpurified INP solution, with a change in the ratio of the INP number in the two classes at $-3.0$ and $-7.5 \, ^\circ C$ (see also Figure S2). Clearly, the purification process was successful and yielded active INPs. The reduction of class A IN activity for the purified sample indicates that the purification reduced the number of the larger INP aggregates compared to the nonpurified solution. This observation is in line with the hypothesis that the bacterial membranes are involved in the formation of larger functional INP aggregates, and we expect bacterial membrane fragments to have no ice affinity.

Heat-treated INP solutions (see the SI for details on heat treatment) behave fundamentally differently. As apparent from comparing the droplet freezing statistics of the highest dilution concentrations shown in Figure 1B, the rises at $-3.0$ and $-7.5 \, ^\circ C$ are completely absent. Instead, we observe activity only around $-25 \, ^\circ C$, which corresponds to background freezing of pure water in our system. Evidently, the heat treatment of the purified INPs completely inactivates their ice-nucleation abilities.

Using SFG spectroscopy, Pandey et al. reported that fragmented *P. syringae* bacteria (Snomax) show an increased capability to order water in their vicinity when cooled to temperatures close to the melting point of deuterated water. Control experiments using misfolded and denatured INP fragments, lipids, and the protein lysozyme did not show this effect. The alignment of water into an ordered structure was concluded to be a condition that will promote interfacial ice nucleation.

Here, we conducted further SFG experiments with active and heat-inactivated INPs to determine whether there is a direct causal correlation between enhanced SFG water signals at low temperatures and bacterial ice-nucleation activity. In SFG, a broadband infrared pulse resonant with the probed molecular vibrations and a visible pulse are combined at a surface to generate light at the sum frequency of the two incident fields. The SFG process is bulk-forbidden in isotropic media, and only ensembles of molecules with a net orientation, e.g., at an interface, can generate a detectable signal.

Figure 2A shows the temperature-dependent SFG spectra of aqueous solutions of purified INPs. The broad response from the O–D stretching bands of interfacial water molecules appears at frequencies below 2700 cm$^{-1}$ and is affected by their interactions with the INPs adsorbed to the air–liquid interface. In the frequency region of 2800–3000 cm$^{-1}$, the SFG spectra show strong signals that we attribute to C–H stretching vibrations.

The SFG intensity of the O–D bands strongly increases upon lowering the temperature close to the melting temperature (3.82 °C for D$_2$O), indicating an increase in the structural order of the interfacial water molecules. This effect is completely reversible, as evident from the integrals of the water (O–D) bands for two cycles shown in the insets. The observed effect is also significantly larger than the effect observed for pure water (insets in Figure 2 and Figure S4).

In contrast, the signal intensity of the C–H stretching vibrations remains constant upon lowering the temperature.

**Figure 1.** Structure and ice-nucleation activity of the proteinaceous ice nucleators from *P. syringae*. (A) Model structure of the INP from *P. syringae*, possessing a β-helical fold. (B) Statistical freezing curves of aqueous *P. syringae* solutions and their purified INPs, compared to the heat-inactivated INPs and the freezing curve of pure water in our system. Shown is the fraction of frozen 3 μL droplets ($f_{frozen}$) vs temperature for the highest concentrations (0.1 mg/mL) of the utilized dilution series. (C) Freezing spectra of aqueous dilutions (10$^{-3}$ mg/mL to 10$^{-2}$ mg/mL) of *P. syringae* and their purified INPs. Shown are the cumulative numbers of active IN ($N_m$) per unit mass vs temperature. The temperature ranges for class A and class C bacterial IN in water are shaded in blue.
The amide I SFG spectra at room temperature are sensitive to the secondary structure and orientation of proteins. The SFG spectra of the heat-inactivated INPs at the air-liquid interface cause a comparably strong increase in the SFG intensity of the O-H stretching region of \( \sim 3500 \) cm\(^{-1}\) at low temperatures. Although we cannot directly associate the spectral changes following heating above \( \sim 55 \) °C with the complete elimination of the INP contents of the INPs. We propose that the observed irreversible conformational changes cause a loss of the proteins’ native functional structure and are the origin of the complete elimination of the INP’s ice-nucleation activity after heat treatment.

The CD spectrum of the purified INPs (Figure 4A) looks unusual, and its deconvolution using the structural database does not allow a clear distinction into the common secondary structures of \( \alpha \)-helix, \( \beta \)-turn, \( \beta \)-strand, or random coil. The spectral shape, however, shows similarities with those of AFPs derived from \textit{Marinomonas primoryensis} (MpAFP) and \textit{Rhagium inquisitor} (RiAFP) (Figure 4B, 4C) but with slightly shifted peak positions. Both AFPs have \( \beta \)-helical folds, which is in agreement with the current theoretical model of the INP as shown in Figure 1A and the inset of Figure 4A. The negligible changes in CD spectra at low temperatures are further consistent with temperature-dependent measurements of structurally similar \( \beta \)-helical AFPs.

In summary, we purified INPs from \textit{P. syringae} using ice-affinity methods and report experimental evidence that the purified INPs are ice-nucleation active and that they adopt defined solution structures, which show resemblance with \( \beta \)-helical AFP spectra. We further show that enhanced interfacial water ordering at temperatures close to the melting point of ice is found not only for active but also for completely inactivated INPs. While protein-induced enhanced interfacial water ordering likely constitutes an essential part of INPs’
working mechanism, our results reveal that increased water ordering observed with SFG spectroscopy is, by itself, not a sufficient condition for INP activity. Instead, our results highlight that the intact three-dimensional fold is essential for the ice-nucleation activity of INPs. This observation, combined with the similarity of the protein structure of the INPs from *P. syringae* and other ice-binding proteins, suggests that supramolecular interactions and ordering are key to the exceptional ice-nucleation activity of bacterial INPs. We hypothesize that the completely intact native structure of the INP is required for the formation of the functional aggregates that allow the formation of ice nuclei or embryos large enough to enable freezing at \(-2^\circ\text{C}(\sim10^4\text{kDa})\). Specifically, if the observed water ordering effect plays a role in bacterial ice nucleation, we can surmise that some secondary structures of the INPs remain at least partially intact, inducing a similar degree of order. However, the breakdown of higher-order structures (tertiary, quaternary) leads to the loss of the collective alignment of INP units that explains the substantial loss in effectiveness. This hypothesis would predict a freezing behavior of the inactivated INPs comparable to structurally similar antifreeze proteins and will be tested in future studies.
