Regioselective Hydroformylation of Internal and Terminal Alkenes via Remote Supramolecular Control

Pim R. Linnebank, Stephan Falcão Ferreira, Alexander M. Kluwer, and Joost N. H. Reek

Abstract: Regioselective catalytic transformations using supramolecular directing groups are increasingly popular as it allows for control over challenging reactions that may otherwise be impossible. In most examples the reactive group and the directing group are close to each other and/or the linker between the directing group is very rigid. Achieving control over the regioselectivity using a remote directing group with a flexible linker is significantly more challenging due to the large conformational freedom of such substrates. Herein, we report the redesign of a supramolecular Rh–bisphosphite hydroformylation catalyst containing a neutral carboxylate receptor (DIM pocket) with a larger distance between the phosphite metal binding moieties and the DIM pocket. For the first time regioselective conversion of internal and terminal alkenes containing a remote carboxylate directing group is demonstrated. For carboxylate substrates that possess an internal double bond at the Δ-9 position regioselectivity is observed. As such, the catalyst was used to hydroformylate natural monounsaturated fatty acids (MUFAs) in a regioselective fashion, forming of an excess of the 10-formyl product (10-formyl/9-formyl product ratio of 2.51), which is the first report of a regioselective hydroformylation reaction of such substrates.

Supramolecular approaches in transition metal catalysts offer unique tools to achieve selectivity in transformations that are otherwise difficult to control. Unrivalled selectivity by supramolecular strategies has been demonstrated for a wide array of organic and organometallic transformations. A frequently applied strategy involves the use of a functional group on a substrate that serves as a directing group to control the substrate coordination at the metal center, allowing for differentiation of reactive sites that are otherwise indistinguishable for transition metal catalysts. This strategy, coined substrate preorganization, has been broadly demonstrated for substrates in which the directing group is relatively close to the reactive group. It remains an open question if such a strategy can be extended to substrates in which the functional group is remote from the directing group, which may be especially challenging for long flexible alkyl chain type substrates due to the large conformational freedom of such compounds.

Recently, Costas et al. reported a system in which protonated aliphatic amines were oxidized by a manganese catalyst functionalized with crown ether recognition sites, leading to selective oxidation of the C–H carbons to yield a mixture of position 8 and 9 oxidation products using substrate preorganization. Toste et al. reported a transition metal catalyst encapsulated in a self-assembled cage that can be used for site selective hydrogenation of polyenes. Moreover, the selectivity in hydroformylation reactions can also be controlled by substrate preorganization via carboxylate directing groups. The guanidinium functionalized monodentate phoshine ligands introduced by Breit et al. convert terminal and internal alkenes to the outermost aldehyde with high regioselectivity, provided that the carboxylic acid and alkene are in close distance. Our group reported the regioselective hydroformylation of unsaturated carboxylates using bisphosphine and bisphosphate ligands, which contained a neutral anion receptor based on 7,7'-diamido-2,2'-dilinodimethane (DIM pocket). This class of ligands was coined DIMPhos. The rhodium–DIMPhos catalyst based on L1 (Figure 1 a) hydroformylates internal alkenes such as 4-hexenoate with high regioselectivity (78:1 selectivity) but for longer substrates the regioselectivity is much lower and application of L1 in the hydroformylation of natural fatty acids with a double bond on the 9-position gives no regioselectivity (vide infra). Currently there are no hydroformylation catalysts that convert natural monounsaturated fatty acids (MUFAs) in a regioselective fashion, whereas such technologies may allow broader applicability of the biofeedstock.

In this paper we report the redesign of DIMPhos ligand L1 to L2 in which the distance between the active metal and the binding site matches that of typical natural fatty acids (Figure 1 a), and demonstrate that the concept of substrate orientation to control the regioselectivity in hydroformylation also works when the directing group is remote from the double bond.

The distance between rhodium and the 7,7'-diamido-2,2'-dilinodimethane anion receptor for L1 (the DIM pocket, 6.8 Å,
Figure 1. a) Redesign of a rhodium-monophenyl (L1) to a rhodium-biphenyl (L2) DIMPhos complex to match the distance between the acid directing group and alkene functionality in typical fatty acids. b) Modelling (DFT) of 9-decanoate as a fatty acid model bound ditopically to [Rh(L1)(H)(CO)] (left) and [Rh(L2)(H)(CO)] (right). For clarity, the 9-decanoate substrate is shown in green.

Figure 1a) is significantly shorter than the carboxylate-alkene distance of fatty acids (12.4 Å) and this mismatch was proposed to be the reason for the low selectivity observed for long substrates (vide infra). Indeed, DFT calculations (BLYP,DZP,D3BJ) show that 9-decanoate, used as a model for natural fatty acids, needs to fold significantly to bind ditopically to [Rh(L1)(H)(CO)] (see Figure 1b). It was hypothesized that an extended ligand binds substrates with large carboxylate-alkene distances in less folded manners and as a result leads to a higher control over the regioselectivity. To achieve this goal, we designed a ligand that has a biphenyl linker (Figure 1a, L2) between the DIM pocket and the phosphite donor atoms, instead of the phenyl linker that is present in the original DIMPhos ligand (L1). DFT calculations of 9-decanoate ditopically bound to [Rh(L2)(H)(CO)] (Figure 1b) indeed shows less folding compared to binding to [Rh(L1)(H)(CO)]. This is also reflected in the lower folding energy of 9-decanoate bound to a [Rh(L2)(H)(CO)] (9.4 kcal mol\(^{-1}\)) for [Rh(9-decanoate):L2(CO)H] vs. 15.4 kcal mol\(^{-1}\) for [Rh(9-decanoate):L1(CO)H] (see Table S6 in the Supporting Information). Also binding enthalpies of aliphatic deprotonated ω-unsaturated carboxylic acids with various lengths (3-butoenoate to 10-undecenoate) to [Rh(L2)(H)(CO)] were calculated using DFT (see Figure S74). These studies show that 8-nonenolate fits best and has the highest binding enthalpy. In addition, 9-decanoate, which is a better model for natural fatty acids, also binds well to [Rh(L2)(H)(CO)]. Encouraged by these results, we synthesized the L2 ligand using a similar synthetic strategy as previously reported for L1 (see Supporting Information).

To investigate if ligand L2 formed a stable metal complex with rhodium it was mixed with [Rh(acac)(CO)]\(_2\), which is the precursor complex of the hydroformylation catalyst, in a 1:1 ratio in CD\(_2\)Cl\(_2\). H NMR studies show a well-defined complex formed after mixing (see Figure S2) and DOSY spectroscopy reveals the formation of a single species with a hydrodynamic radius of 7.9 Å in line with the size of a mononuclear complex (see Figure S3). Upon addition of 1.5 equivalents of tetrabutylammonium acetate, the N-H protons are downfield shifted, which shows the carboxylate group binds to the DIM pocket of the [Rh(acac)(L2)] in a similar fashion as reported for complex [Rh(acac)(L1)] (Figure S4). Pressurization with 5 bar of syngas (H\(_2\):CO (1:1)) to the solution of the [Rh(acac)(L2)] complex provides the corresponding pentacoordinate [Rh(L2)-(CO)\(_2\)] species as evidenced by the rhodium hydrido signal (δ = −10.5 ppm). Next to the well-defined signal, also a broad rhodium–hydrido signal (δ = −10.7 ppm) appears in the NMR spectrum, which becomes larger over time (see Figure S4). DOSY spectroscopy of the [Rh(L2)(CO)\(_2\)](H) complex under 5 bar CO/H\(_2\) (1:1) in CD\(_2\)Cl\(_2\) gave a larger average hydrodynamic radius (12.1 Å) than for the [Rh(acac)(L2)] complex suggesting that the broad signal is due to formation of dinuclear and/or oligomeric species under these conditions (see Figure S10). However, under identical conditions but in the presence of 4 equivalents guest that binds in the DIM pocket (tetrabutylammonium acetate) the average hydrodynamic radius (8.4 Å) (see Figure S11) is close to that of the [Rh(acac)-(L2)] species, indicating that carboxylate binding in the DIM pocket preorganizes the two phosphorous moieties for the formation of mononuclear species.

A series of (deprotonated) ω-unsaturated carboxylic acids with varying length between the alkene reactive group and the carboxylate directing group was hydroformylated using [Rh(L2)] as a catalyst (Figure 2). As substrates we reacted 4-pentenoic acid (n = 2) up to 10-undecenoic acid (n = 8) both in the presence and the absence of base.

In the presence of base, the carboxylate functional group of the substrate binds in the DIM pocket and thus substrates long enough to span the DIM pocket–rhodium distance are expected to react with improved regioselectivity. In absence of base, the protonated carboxylic acids do not bind in the DIM pocket and as a result the directing group, the carboxylic acid, cannot be used for substrate preorganization with the [Rh(L2)] catalyst and should react with lower regioselectivity. Because of this, the protonated substrates were used as control experiments. All substrates studied gave full conversion to the aldehyde and the linear/branched (l/b) ratios of the aldehyde products were determined by H\(^1\)NMR spectroscopy (Figure 2). The catalytic results show that the long anionic substrates (with n > 4, 7-octenoate and longer) display much higher l/b ratios than the protonated analogues. The distance between the carboxylate and alkene function in these substrates is at least 9.7 Å, and this shows this catalyst is able to control the regioselectivity via substrate preorganization on remote dis-
The linear aldehyde product is also observed under these conditions, which arises from an isomerization/hydroformylation sequence, which is not uncommon for bisphosphite-based catalysts.[47] When we applied the rhodium catalyst based on L1, the catalyst that can also pre-organize but is optimized for smaller substrates, only slightly better selectivities are obtained than with the PPh3-based catalysts. The same trend was observed in the hydroformylation of 9-undecenoic acid; only the [Rh(L2)] catalyst provides the product with high regioselectivity, yielding a 10-formyl/9-formyl ratio of 6.9. Importantly, the redesigned [Rh(L2)] catalyst clearly outcompetes [Rh(L1)] with respect to regioselectivity and conversion for the longer substrates, as a result of more favorable ditopic binding.

Having established our redesigned [Rh(L2)] catalyst is able to control the regioselectivity of remote internal alkynes on position Δ8 and Δ9 through preorganization, we extended our system to naturally occurring monounsaturated fatty acids (oleic acid, palmitoleic acid and myristoleic acid, Table 2). When myristoleic acid is hydroformylated using the PPh3-based rhodium catalyst, equal amounts of the 10-formyl and the 9-formyl products are formed, in line with previous reports.[39–41] Furthermore, when the same reaction was carried out with the [Rh(L1)] catalyst, also equal amounts of the two regioisomers are obtained. In contrast, the [Rh(L2)] catalyst provides a 10-formyl/9-formyl ratio of 1.61 and shows this catalyst can con...
In the experiments performed at syngas pressures of 20 bar instead of 50 bar (entries 9 and 10), but otherwise identical conditions, led to an improved regioselectivity of 2.10 and 2.31. Somewhat counterintuitively, the conversion was also higher in the experiment, reflecting the complicated kinetics of the system. Such complicated kinetics were previously reported for \( \text{Rh(L1)} \), in which the catalytically active species is in equilibrium with dormant state complexes in which carboxylate groups of the substrate and product are directly coordinated to rhodium. Increasing the rhodium:ligand ratio from 1:1.1 to 1:2 (entries 5 and 6) further improved the regioselectivity to yield a 10-formyl/9-formyl ratio of 2.43 under mild conditions (entry 6). Changing the solvent from DCM to THF or DMF (entries 7 and 8) led to lower activity and selectivity, especially for these longer substrates.\(^{23,48,49}\) In the experiment where the catalyst concentration was reduced by a factor 10 (entry 4) the regioselectivity further increased (10-formyl/9-formyl ratio to 2.31). Somewhat counterintuitively, the conversion was also higher in the experiment, reflecting the complicated kinetics of the system. Such complicated kinetics were previously reported for \( \text{Rh(L1)} \), in which the catalytically active species is in equilibrium with dormant state complexes in which carboxylate groups of the substrate and product are directly coordinated to rhodium. Increasing the rhodium:ligand ratio from 1:1.1 to 1:2 (entries 5 and 6) further improved the regioselectivity to yield a 10-formyl/9-formyl ratio of 2.43 under mild conditions (entry 6). Changing the solvent from DCM to THF or DMF (entries 7 and 8) led to lower activity and selectivity, especially for these longer substrates.\(^{23,48,49}\)
plained by lower levels of isomerization of the alkene, commonly observed for hydroformylation reactions carried out at higher CO concentration.[3,11]

In conclusion, supramolecular substrate orientation is a powerful tool to control selectivity in transition metal catalysis, which has been mainly demonstrated for substrates in which the supramolecular functional group is close to the reactive group. In this paper, we demonstrate that supramolecular substrate orientation can also work when this group is remote from the reactive group, thereby increasing the scope of the approach. In order to show this a previously reported hydroformylation catalyst with an integrated anion receptor, DIMPPhos ([Rh(L1)]), was redesigned to accommodate larger substrates. This hydroformylation catalyst ([Rh(L2)]) converts substrates with high regioselectivity when the carboxylic directing group is remote from the alkene group, including monounsaturated fatty acids (MUFAs) and their model substrates. The [Rh(L2)] catalyst provides the hydroformylation product with a 10-formyl/9-formyl ratio of 2.51 for myristoleic acid, which represents the first selective catalyst for this biobased compound. These results show that catalysts that operate via supramolecular substrate preorganization can be redesigned to provide selective catalysts for substrates of different sizes, and as such we are able to make a catalyst that can convert fatty acids in a regioselective fashion. This paves the way for the design of other challenging conversions for which no catalysts exist yet.

The effective concentration for substrate bound in the DIM pocket was roughly estimated: The maximum radius between the rhodium center and the double bond of natural fatty acids is approximately 11 Å which is $1.1 \times 10^{-8}$ dm$^3$. This translates to $4/3 \pi (1.1 \times 10^{-8}$ dm$^3)^2 = 5.5 \times 10^{-26}$ dm$^3$. Of this spherical volume it was estimated the alkene could occupy 50%. This translates to an effective concentration of $\approx 0.6$ M. Since the substrate concentration is 0.2 M for most experiments, non-bound substrates will likely compete and allow for a non-selective background reaction. This nicely explains why the regioselectivity increases upon lowering of the concentration as this background reaction is repressed.
