Reconstructing the mixed mechanisms of health:
the role of bio- and sociomarkers

Virginia Ghiara, V.Ghiara@kent.ac.uk

It is widely agreed that social factors are related to health outcomes: much research has served to establish correlations between classes of social factors on the one hand and classes of disease on the other hand. However, why and how social factors are an active part in the aetiology of disease development is something that is gaining attention only recently in the health sciences and in the medical humanities. In this paper, we advance the view that, just as biomarkers help trace the causal continuum from exposure to disease development at the biological level, sociomarkers ought to be introduced and studied in order to trace the social continuum from exposure to disease development. We explain how sociomarkers differ from social indicators and how they can be used in combination with biomarkers in order to reconstruct the mixed mechanisms of health and disease, namely mechanisms in which both biological and social factors have an active causal role.

Key words biomarker • sociomarker • aetiology of disease • social indicators • epidemiology

Introduction

In the health sciences, the relationship between socio-economic factors and health has been long studied, especially by epidemiologists and sociologists. That certain diseases and health conditions are strongly associated with certain socio-economic factors is well established and documented. In particular, considerable attention has been paid to how inequalities at the socio-economic level are mirrored by inequalities at health level, and vice-versa (House, 2002; Marmot, 2005; McLean et al, 2014). In recent years, the relationship between the biological and the social dimensions
of health has been addressed from novel perspectives (Vineis et al, 2017a). In the
field of the health sciences, groundbreaking studies such as the EU-funded project
Lifepath (www.lifepathproject.eu) and the research conducted at the Center For
Youth Wellness in San Francisco (https://centerforyouthwellness.org) have cast a new
light on the social aspects involved in the aetiology of disease (Walker and Carrion,
2015; Bucci et al, 2016; Purewal et al, 2016; Vineis et al, 2017d). In addition, new
discussions in the health sciences have emerged in relation to the complex processes
disease formation and prevention (Galea, 2007; Castagné et al, 2016; Davillas et
al, 2017; Kelly-Irving and Delpierre, 2017; Vineis et al, 2017c). In the medical
humanities, instead, novel theoretical studies have offered insights into the interaction
of the social and the biological dimensions of health and its consequences for health
policies (Berkman et al, 2000; Kelly et al, 2014; Kelly and Russo, 2017). We take a
broad perspective on what counts as ‘medical humanities’, encompassing approaches
coming from the social studies, history and philosophy (of science and, specifically,
of medicine), and ethics (Arnott et al, 2001).

In the health sciences, the Lifepath project is particularly worthy of attention
since it is the third of a series of projects that have studied the causal relationships
between health and environmental exposure through biomarkers. Together with
EnviroGenomarkers (www.envirogenomarkers.net) and EXPOsOMICS (www.
exposomicsproject.eu), Lifepath contributes to understanding exposure and disease
development using innovative methodologies and concepts (Vineis and Perera, 2007;
Vineis and Chadeau-Hyam, 2011; Kelly-Irving and Delpierre, 2017; Vineis et al,
2017b). This line of research, given its groundbreaking character, also attracted the
attention both of the medical humanities (Russo and Williamson 2012; Vineis et al,
2017d), and of philosophy of science, (Canali 2016; Illari and Russo 2016).

In particular, Lifepath brings to the fore new philosophical and methodological
questions related to the biological and the social dimensions of health. In fact, current
research projects using biomarkers typically try to elucidate how socio-economic
factors affect disease development at the biological level. Recently, however, the
literature in medical methodology – a strand of research in the medical humanities that
rigorously investigates study design and research techniques, as well as foundational
issues in medical research – has been pressing on other specific conceptual issues
still posing a threat to the advancement of the mechanistic understanding of this
phenomenon. More specifically, the details of a mixed mechanism in which both
socio-economic and biological factors play a causal role needs further specification,
both conceptually and methodologically.

In this paper, we focus on one specific conceptual issue, namely how socio-
economic factors can be more than just ‘indicators’ for broader social or health
conditions. We ask the question whether, in analogy to biomarkers, which help trace
the trajectory from exposure to disease at the biological level, we can identify and
study sociomarkers that would work in a similar way, namely helping to trace the
trajectory from exposure to disease development.

The paper is organised as follows. In the next two sections we introduce the study
of social determinants of health and disease, paying particular attention to how
social factors are measured. We claim that, over the last few years, the biological
component of the mixed mechanisms of health has been explored at a fine-grained
level, whereas the social component is analysed at a rather coarse-grained level through
socio-economic indicators and proxies. Next, we introduce the idea of causation as
Reconstructing the mixed mechanisms of health

information transmission, which constitutes a theoretical basis for using biomarkers in the study of disease mechanisms at the molecular level. Then, by analogy with biomarkers, we introduce sociomarkers as a tool to reconstruct the trajectory from exposure to disease; this, we think, explicates the causal role of social factors in disease mechanisms. We move on to further develop two aspects: the mixed nature of disease mechanism and the need to study these mechanisms at the population and at the individual level. These two characteristics of disease causation lend further support to the need to introduce sociomarkers, next to biomarkers. Finally, in the conclusion we claim that sociomarkers can help to address three challenges characterising the study of mixed mechanisms of disease: (1) the discrepancy between the mechanistic understanding at the biological level and at the social level; (2) the discrepancy between the study at the individual level of the biological components of health and the study at the population level of the social components of health; (3) the need for all these dimensions (individual/population and social/biological) for the purposes of policy interventions.

Social determinants of health

It is widely agreed that certain diseases arise from a set of risks identified at the behavioural and social level, such as people’s smoking, dietary habits and social norms (Commission on the Social Determinants of Health, 2008; Hernández-Quevedo et al, 2010; Davillas and Pudney, 2017). It is also generally accepted that the health of populations is shaped by certain ‘social determinants’ like social ties, poverty and low education (Wilkinson and Marmot, 2003; Braveman and Gottlieb, 2014). Despite this broad core of agreement, however, social and behavioural factors are seldom brought into the aetiological discussion of mechanisms of health and disease. This is partly because social factors are thought to provide a classification of the parts of the population more at risk. Their relevance is associated with categorisation, not explanation. Furthermore, even when it is accepted that social factors play an active role in the development of disease, how to integrate socio-behavioural and biological variables in order to develop all-encompassing models of disease causation remains largely underdeveloped. Still now, biological and social factors are considered distinct factors, whose causal role is different and whose action is far from being integrated. This assumption is evident in the linguistic use of terms such as ‘proximal’ and ‘distal’ causes, where biological factors are proximal and thus directly affecting health and disease, whereas social factors are distal, just wider determinants of health, but not proper causes (Krieger, 2008; Kelly et al, 2014: 309).

And yet, the need of integrated models of disease causation, where biological and social factors are considered equally relevant to the causal understanding of health has been claimed in both camps of the health sciences (Vineis and Kriebel, 2006; Velupillai et al, 2008) and the medical humanities (Russo, 2009; Kelly et al, 2014). This offered a raison d’être for those epidemiological studies putting at the heart of their investigations how social factors might influence health (Galea and Link, 2013). To give an example, Castagné et al (2016) measured inflammation through 28 markers and related them to a number of indicators for the socio-economic position of individuals. Attempts to enhance our understanding of the social component of health, however, have been often downgraded by the increasing gap between the biological and the social research advancements. Indeed, while from the biological
point of view the striking technological improvements have contributed to enhancing the mechanistic understanding of disease at the biological level (Kronfeldner, 2014), at the social level the progress has not been as fast.

This brings us to the present, when the biological component of the mechanisms of health is explored at a fine-grained level, but the social component is still analysed at a rather coarse-grained level. Indeed, social factors at the population level are often explored by using only the traditional socio-economic position indicators.

Traditionally, socio-economic status has been measured by using three social indicators: income, occupation and educational level. Studies based on such indicators have provided useful information, and yet they suffer from substantial limitations. The main problem concerns the kind of knowledge that can be derived from this approach: the analysis of the socio-economic indicators highlights that socio-economic factors are relevant to health, however it does not establish why this is the case, namely how social factors affect health. In other words, while these measurements can show that there are robust correlations between specific socio-economic conditions and health, they are not sufficient to uncover the mechanisms through which such socio-economic conditions affect health (Muntaner, 2013).

The rationale behind this paper is that even the more accurate description of the biological aspect of disease causation is not sufficient to fully understand the phenomena of health and disease and to address questions concerning prevention and interventions. We follow existing discussions in understanding some mechanisms of health as ‘mixed mechanisms’, in which both biological and social factors have an active causal role (Russo, 2009; Kelly et al, 2014). We do not look at those mechanisms operating only at the biological level (such as the development of disease due to random genetic mutations) or merely at the social level (such as the way in which, through the lack of access to healthcare, socio-economic position can cause mortality).

In this paper, and in analogy with biomarkers, we contribute to the characterisation of mixed mechanisms by sketching a new way to approach the social component of health through the identification of sociomarkers at the individual level.

In the literature, the definition of biomarkers is not unanimous (see for instance the Biomarkers Definitions Working Group (2001) and the International Programme on Chemical Safety (2001)). The main aspect of biomarkers is, according to us, that they are measures of something: they are always used as biological clues or measures to reconstruct the continuum from exposure to disease. In parallel, we take sociomarkers to be the corresponding social measures at the individual level that allow us to understand how socio-economic factors ‘get under the skin’ and affect the biological level – we return to this point later in the section Biomarkers. Our approach tackles a fundamental issue associated with the study of the social realm that is not yet entirely resolved: the problem of measuring the social.

**Measuring the social**

The study of the social dimensions of health requires the use of some measures at the social level. How to measure social phenomena, however, is a matter of debate, especially considering that not all concepts that can be measured at the social level are alike.

Some concepts refer to certain qualitative or quantitative characteristics that things have, such as the average age at marriage in a specific country or the average female
Reconstructing the mixed mechanisms of health

pay rate. Other concepts categorise things according to several loosely interconnected features, as in the case of ‘poverty’ or ‘socio-economic position’. When concepts cover specific features, the selection of the methods used to generate accurate and precise measures is more straightforward and the measures are generally direct. There is no need to develop indirect measurement procedures: in order to know how many women live in a neighbourhood, for example, researchers can directly count them.

On the contrary, when a concept is multifaced or constructed in various ways, the choice of the measurement procedures is controversial and is likely to entail the sacrifice of some of its aspects. Socio-economic position, for instance, can refer both to material and social resources and assets, and to individuals’ rank or status in a social hierarchy (Krieger, 2001). The measurement procedure is in general indirect and requires the selection of indicators or indices. In this case, researchers have two options: they can either develop/choose various indicators to measure all the dimensions characterising such a concept, or they can select more precisely only some of the features constituting the concept and measure them, accepting leaving behind the other dimensions characterising the concept. Measurements of concepts such as socio-economic position or poverty are likely to differ greatly, depending on how they are conceptualised.

Note that this distinction between simple and multifaced concepts does not correspond to the distinction between observable and unobservable things. Although certain simple concepts can be directly observed (like a person’s sex), there are cases where observation cannot be performed with precision (as in the case of age). In the case of young individuals applying for the international protection without proper birth documentations, for instance, physicians use measurements obtained through wrist radiographs and clavicle computerised tomography to estimate age (Sauer et al., 2016).

The fact that some concepts are not easily observable has a great impact on the social sciences, as measuring them appears challenging. Researchers tackle this problem with proxies. Unlike indicators, proxies are not supposed to represent concepts. A proxy is a measure that correlates to the unobservable or unmeasurable concept under study sufficiently highly to be used as its predictor (Sapsford, 2006: 145).

Some examples may clarify this point: let us consider the way in which socio-economic status is studied in epidemiological studies. In low- and middle-income countries, given the shortcomings of available measures, the presence or absence of night-time lights visible from space is increasingly used as a proxy for the concept of socio-economic position (Chen and Nordhaus, 2011). Among academic research and within government policy in England and Wales, instead, the Free School Meal Eligibility is very often used as a proxy for socio-economic position (Hobbs et al., 2007). Recently, in addition, scholars in the UK have proposed the use of the council tax band as an alternative proxy (Howe et al., 2012). The number attached to the presence of night-time lights in a specific zone, the Free School Meal Eligibility and the council tax band are not supposed to structurally correspond to the concept of socio-economic position. Rather, given the absence of available measures representing it, researchers use alternative data to obtain information about that concept.

The adequacy of measures and proxies entails, hence, different questions. As for direct and indirect measures based on indicators, researchers have to establish whether the measures correctly represent the phenomena. In other words, they have to examine
the adequacy of the relation between the concept and the numerical measurement. In the case of a proxy, adequacy requires the correlation between the proxy and the phenomenon to be sufficiently high. These distinctions are illustrated in Table 1.

Such an approach to measuring the social has allowed for the accumulation of a large and compelling body of evidence demonstrating that socio-economic factors are correlated to a wide range of health outcomes. The result of a meta-analysis conducted by Galea and colleagues (2011), for instance, showed that the number of US deaths in 2000 correlated to socio-economic factors such as low education, racial segregation and low social support, and that such a correlation was comparable to the number of deaths correlated to cerebrovascular disease and lung cancer. Although this growing weight of evidence reflects strong associations between socio-economic factors and health, the study of socio-economic indicators and proxies does not help to uncover the causal mechanisms behind them. It follows that socio-economic factors are rarely brought into the aetiological discussion of mechanisms of health.

At the biological level, instead, much attention has been paid to eliciting the mechanisms behind correlations at the individual level, trying to understand them at an increasing level of detail. Researchers pin down the biological and chemical basis of disease causation as far as the molecular level, and in these studies biomarkers play an essential role. Some interesting findings have been established in recent years through the study of biomarkers, yet without a mechanistic understanding of the social component of health, social epidemiology runs the risk of veering towards biologic reductionism (Muntaner, 2013).

**Markers**

*Markers and information transmission*

In general, causal claims in social epidemiology involve statements about risks: scientists want to know whether certain socio-economic conditions are good predictors of disease. As considered above, however, researchers do not only aim at claiming that socio-economic factors are correlated to health, they want to establish (1) that such factors are causally linked to health outcomes and (2) how they can cause health outcomes. While the recognition that there is a causal link can be obtained through different methods, typically, the ‘how’ question is answered by considering the causal process linking the putative causal factor to the effect at the biological level.
In similar cases, the continuum is explored by collecting information through **markers**. In the context of the biomedical sciences, they are most often referred to as *biomarkers*. Such markers are clues, signals to detect in order to understand how factors at different molecular levels can be causally linked to different stages of disease development. It is important to note that markers are not just ‘objects out there’. Sometimes, they are described in terms of ‘events’ in the continuum from the cause to the effect (Schulte and Perera, 1993), other times they are considered ‘possible intersecting signals’ representing parts of an active process (Chadeau-Hyam et al, 2011). The key feature of markers is that they are always *marks of specific links, events or processes*. It is impossible to establish what objects count as markers in the abstract: markers are not defined in terms of intrinsic properties or correlations, but in terms of the *function* they have within particular biological processes under investigation. It follows that researchers have to decide whether something is a marker or not by considering the concrete research situations in which markers are studied, rather than on a priori set of identification criteria.

While the idea of a marker – and especially a biomarker – is most common in contemporary biomedical research, it is worth noting that it has already been introduced in the philosophy of causality, since the 1980s. Causal processes can be characterised in several different ways. One of the prominent interpretations is Wesley Salmon’s ‘mark transmission theory’ (Salmon, 1984; Dowe, 1992). According to this account, what makes causal processes different from non-causal or pseudo-processes is the fact that causal processes are the ones transmitting marks. For instance, a moving car can be considered a causal process because, if we mark or dent it, such a mark will be carried along with the car, and it will remain detectable at later stages. On the contrary, if we try to mark the car’s shadow (for instance interrupting the shadow by shining a light), that kind of mark will not travel with the car at later stages, therefore the mark will not be transmitted. Unlike the car example, however, there are many situations in which a process cannot be marked: this is the reason why Salmon formulated his proposal in counterfactual terms: a process is causal if, and only if, it were marked, the mark would be transmitted to later stages of the same process.

Salmon’s approach is intuitively strong but limited: it is specifically tailored to physics, and considers marks as physics quantities, such as energy and momentum. Consequently, it cannot be directly used as a conceptual tool to understand causal links that cannot be spelled out with the language and tools of physics. This limitation has long been recognised in the health sciences, where researchers explicitly recognise the importance of studying the reality at different levels (such as the biological and the social levels), for instance using a longitudinal approach, where marks are observed rather than introduced (Vineis, 1997).

However, an adjustment can be made to tackle this problem: a marker might be something that is already transmitted by a causal process, rather than a ‘physics’ mark that should be introduced. This would appear in line with what is done in epidemiological studies (such as in the aforementioned Lifepath, EXPOsOMICS and EnviroGenomarkers), where researchers follow a longitudinal thread of marks (observing, for instance, that aflatoxin causes the formation of adducts, that in turn induce p53 mutations that are the same found in liver cancer). In the philosophy of causation and philosophy of medicine literature, it has been recently suggested that the link shown by markers is better conceptualised using the notion of ‘information transmission’ (Illari and Russo, 2016; Vineis et al, 2017d).
Thus, markers can be conceptualised as *signals* of transmission of information. It is important to note that the notion of information transmission is located at the level of *epistemology*, not of ontology: information transmission deals with the way in which scientists reconstruct the continuum between factors at different levels (Vineis et al, 2017d). This proposal is not necessarily in contrast with the prominent mechanistic thinking now widespread in philosophy of causality and in the sciences: when looking for markers, indeed, researchers might be guided by mechanistic knowledge. Illari and Russo (2016) described mechanisms as information channels where information flows and markers (i.e. the intersecting signals) can be found.

The generality of the information-transmission idea, and of how markers help (re)trace the link from putative causes to putative effects, allows for the development of a general epistemological framework for thinking about causality across different levels (individual, population) and across different types of factors (biological, social). For this reason, understanding causality as information transmission enables us to provide a mechanistic explanation of disease that includes both biological and social factors.

It remains to explain, however, how, more specifically, markers can help detect links at the biological level, and even at the social level. This is what the following two subsections aim to do. At the biological level, the development of new technologies, as well as the availability of large data sets, led to an increasing use of biological markers. In parallel, we argue it is high time to approach social measures not as ‘indicators’ and ‘proxies’, but as *sociomarkers*.

**Biomarkers**

The striking technological advancements of the last few decades have contributed to enhancing the mechanistic understanding of disease from a biological point of view. The main protagonists of this advancement are the so-called ‘-omics’ technologies and their products, known by the name of biological markers, or *biomarkers*. One of the major contributions of ‘-omics’ technologies is through the identification of relevant markers at the molecular level. Traditionally, epidemiology established correlations between macro-variables: those associated with the environment and those describing diseases. Biomarkers, instead, allow researchers to go much smaller: both the macro-level factors themselves, such as air pollution, and their effects can now be measured at the molecular level.

Biomarkers do not necessarily correspond to specific molecular entities. Often, they are constructed by cross-checking large data sets and using background information about the processes that biomarkers are supposed to signal. They are not studied per se, or to identify those entities causing health effects, but to understand the trajectory of disease development. They can be conceptualised as the ‘missing links’ between factors at the population (macro) level (such as external or environmental exposure) and factors at the individual (micro) level (such as DNA alterations leading to disease). By helping to detect some key stages linking such factors, biomarkers suggest the existence of a continuum between them.

Biomarkers can mark salient points in the continuum from exposure to disease in several ways, consequently they can stand in different relationships with each other, the effect and the cause. Diagrams consisting of variables linked by arrows or lines, also known by the name of Directed Acyclic Graphs (DAGs), can be used to illustrate relationships that are relatively complicated, as in the case of a large causal...
Reconstructing the mixed mechanisms of health

Figure 1

![Diagram of causal relationships between variables]

Note: (a) represents the situation in which the biomarker B is part of the causal process linking the cause X and the effect Y. In (b), the biomarker B and the effect Y are correlated because both are caused by X. In (c), the biomarker B is correlated to the event Z, that is part of the process but cannot be measured. In (d), B is just correlated and is not causally linked to the effect Y. B may be, for instance, a background condition.

system based on interrelationships relevant to health (Joffe et al, 2012). In Figure 1, we illustrate most possible linkages between the biomarker and the phenomenon under study through the use of DAGs, where arrows represent causal relationships and lines simple correlations.

Biomarkers are conceived and used to mark processes that happen at the biological level, reconstructing the link between exposure and disease. They shed light on several aspects of disease mechanisms at the molecular level, and contribute to early diagnosis and better prediction. However, disciplines such as social epidemiology or medical sociology have long established and argued for the important role of social factors for health (Braveman and Gottlieb, 2014). What remains to understand is whether there is any way to shed light on the social mechanisms of health at the individual level. This is what we explore next.

Sociomarkers

Rather than being considered competing approaches, the individual and population level can be reconciled through the study of sociomarkers: it is the analysis of sociomarkers at the individual level that can enhance our understanding of the social components of health at the population level.

Traditionally, social epidemiology establishes correlations between health outcomes and population-level factors such as poverty and socio-economic position. On the contrary, sociomarkers can be used to trace social processes at the individual level, helping to find the missing link between social factors at the population level and health factors at the individual level.

It is important to note that the shift from the notion of social indicators to the concept of sociomarkers does not necessarily require the collection of new measures. Available measures, already used as proxies and indicators, might count as markers. It is not the particular nature of measures but how they are used that determines whether something is a sociomarker. The aim, when using sociomarkers, is to pick up signals to reconstruct the continuum from social factors to disease, in analogy with how biomarkers help pick up signals from exposure to disease at the biological level. In practice, this might require using socio-economic variables measured at the individual level, rather than aggregate level. This does not exclude the use of aggregate variables or of multilevel methods that use both population- and individual-level variables. In some cases, for instance, it could be possible to use population-level sociomarkers that describe the role of structural causes (this would go into the same direction as Galea and Link’s, according to which epidemiology is ‘all social’ (Galea...
and Link, 2013: 844)). It does suggest, however, how else individual-level variables that measure socio-demo-economic characteristics can be used. Individual-level variables, furthermore, might measure both individual behaviours (such as social interaction) and individual-level effects that depend on structural causes active at the population or macro level (such as violent behaviours caused by some structural features of society).

When measures are used as sociomarkers, they are not associated with specific concepts, and are not supposed to have a structural correspondence with them, like indicators. Sociomarkers are always located in relation to the causal continuum. As biomarkers, they might be part of the continuum, or might be simply correlated to the continuum, as shown in Figures 1(b) and 1(c). When sociomarkers exhibit just a difference-making relationship with the continuum, however, they do not act just as proxies. In causal reasoning proxies are used to establish that something (notably, what they stand for) makes a difference (for instance, using the council tax band as a proxy of poverty, we can claim that poverty exerts an effect on health), while sociomarkers help to find out how something causes the effect (for instance, individual values of council tax bands should be linked to specific individual biological outputs). The ‘how’, again in analogy with biomarkers, is provided by the process linking socio-economic characteristics and health outcomes, and sociomarkers help intercept this process at relevant places, just as biomarkers do. In this way sociomarkers do more than just identify social risks — they indicate where to intervene in the whole process.

Recently, scholars have begun to use the label ‘markers’ for socio-economic measures in a rudimentary way. For instance, measures such as birthweight, household income, education, maternal smoking during pregnancy, mother’s body mass index and mother’s age at birth, known to affect later health, were used to explore how the link between socio-economic position and health is mediated by certain social pathways (Barboza Solís et al, 2016; Davillas et al, 2017). It is exactly when such measures are used, we claim, that a precise conceptualisation of sociomarkers is needed.

Let us consider an example: it is known that a low socio-economic status in early life is correlated with poor health and increased mortality in adulthood (Anda et al, 2006). At the social level, a general hypothesis is that socio-economic factors in childhood get under the skin (at the molecular level) through severe chronic stressors to which children are exposed (Miller et al, 2011).

To detect signals of this process at the social level, some researchers have used the so-called Adverse Childhood Experiences (ACEs). This expression describes certain stressful or traumatic events that can be experienced by children while growing up. The original ACEs study was conducted by the Centers for Disease Control and Prevention (CDC) in collaboration with the American integrated managed care consortium Kaiser Permanente (Felitti et al, 1998). In this study, researchers developed a list of ten indicators of child adverse experiences: emotional abuse; physical abuse; emotional neglect; physical neglect; contact sexual abuse; mother treated violently; alcoholic or drug users among the household members; not being raised by both biological parents; household member who was imprisoned; household member who was chronically depressed, suicidal, mentally ill or in a psychiatric hospital.

The original ACEs, as well as the new ACEs added in the literature such as separation from family and serious childhood illness (Hughes et al, 2017), have all the characteristics required to be used as sociomarkers. First, it is possible to use ACEs information as intersecting signals of a continuum. ACEs can indeed be employed to
identify some key stages connecting social factors at the population level, such as the socio-economic position, and biological factors at the individual level (biomarkers). In such a way, ACEs are not just indicators, but sociomarkers that can help to establish how socio-economic determinants exert an impact on health through biological mechanisms. This is possible for two reasons. One the one hand, at the population level, ACEs appear to be more prevalent among children in low-income families: in the US, for instance, data from the National Survey of Children’s Health (NSCH) showed that children in low- and middle-income families are more than twice as likely to experience two or more ACEs (Halfon et al, 2017). This prevalence, hence, supports the idea that socio-economic conditions during childhood could affect health through these adverse experiences. On the other hand, several studies have provided evidence of the associations between ACEs and allostatic load biomarkers, inflammatory biomarkers and cancer biomarkers (Tietjen et al, 2012; Kelly-Irving et al, 2013; Barboza Solís et al, 2015). Such correlations support the idea that ACEs could be the link connecting ‘the social’ and ‘the biological’, as described by Danese and McEwen: ‘adverse childhood experiences are likely to signal high levels of environmental threat and to trigger adaptive responses in the nervous, endocrine, and immune systems in children’ (2012: 31). Second, in contrast to traditional socio-economic indicators, ACEs help to investigate the processes from social events to biological changes at the individual level. Like biomarkers, ACEs are identified by examining real individuals: ACEs can be experienced only by real, individual children. This is particularly relevant if we consider that for each individual adverse childhood experiences can vary in duration, timing and type, and that individual characteristics can lead to very different responses to very similar adversities. In this and similar cases, hence, sociomarkers would help us to capture some aspects of the subjective/reflexive/perceived dimension of the social: the assumption justifying the use of ACEs would be that events such as the incarceration of a parent can be associated with an individual, perceived dimension, that can in turn influence the individual’s health.

Types of markers and levels of causation

Under Biomarkers above, we suggested that, next to biomarkers, we need to study sociomarkers too. Bio- and sociomarkers help with identifying/detecting the process from exposure (biological and social) to health outcomes at two levels: (1) the biological and social level, and (2) the individual and population level. Concerning the first, this is how we can shed light on the mixed mechanisms of health and disease – we address this further immediately below. Concerning the second, earlier, in ‘Measuring the social’ we noticed that measurements of the social still pertain to the population level. However, with the advent of molecular approaches, even epidemiology could reach the individual level. How do these two levels relate to each other? We address this after the next subsection.

Biosocial mechanisms of disease

Our proposal is that socio- and biomarkers should be used in combination. In such a way it would be possible to finally uncover the mixed, biosocial mechanisms whereby ‘the social’ can influence ‘the biological’, returning to a more holistic understanding of the aetiology of disease (Russo, 2009; Kelly et al, 2014).
In the current situation, the biological component of the mechanisms of disease is explored at a fine-grained level (explanations of disease at the molecular level are paradigmatic in this respect), while the social component is analysed at a rather coarse-grained level, or at the level of population using mainly aggregate variables. As a consequence, the mechanisms of disease appear to be spelled out only in biological terms, while the study of the social components allows researchers only to establish that there are robust correlations between specific social factors and some biological outcomes. In line with recent arguments of Kelly et al (2014), and Kelly and Russo (2017) we aim to put the social in the mechanisms explaining disease.

The combination of biomarkers and sociomarkers, we argue, would finally help researchers uncover the mixed mechanisms through which ‘the social’ affects health. To begin with, sociomarkers would fill the gap between biological fine-grained variables, and social coarse-grained variables, enabling researchers to study both the biological and the social components at a fine-grained level. Together, biomarkers and sociomarkers would enable researchers to sample the different levels of reality at different time points, and the passages from specific sociomarkers to certain biomarkers would provide some compelling linkages between these different domains. Given that the continuum traced through these markers could involve both social and biological components, it follows that such markers would allow for the identification of the key stages of a mixed mechanism of disease, from the social components triggering the mechanism, to certain key events involving social or biological components, to the biological factors leading to the health outcome.

Sociomarkers would hence help us recognise, despite their ‘distance from the skin’, the epistemic importance of ‘the social’ for the mixed mechanism of disease; and sociomarkers and biomarkers together would lead us to reconceptualise, from a mechanistic point of view, causality across different types of factors (social and biological). This means that, while bio- and sociomarkers are ontologically distinct, a priori they have equal importance in the explanation and reconstruction of exposure and disease development.

Population and individual causation

With biomarkers, we study processes that happen at the individual level, and molecular epidemiology aims to provide a ‘population-level’ study of them. On the one hand, biomarkers are searched for and validated using individual-level data – biosamples pertain to individuals; on the other hand, the fact that we can rely on very large biobanks or cohorts make it possible to make an epidemiological study out of it. So, if we run a study at the individual level – and even at a finer-grained level (i.e. the molecular level), the ultimate goal is to say something at the population level. This, in the early days of molecular epidemiology created a tension in the field. As Schulte put it, it might sound an oxymoron to do epidemiology with molecular data (1993: 10). We agree with Schulte that this is not the case, but we are forced to rethink the relation between population- and individual-level causal knowledge, and specifically the role of biomarkers in the production of generic knowledge of health and disease. Likewise, a large part of social science interested in health has worked at the population level, while our proposal to use sociomarkers shifts the level of analysis to the individual level. How do we reconcile these different levels of analysis?
To begin with, it is worth clarifying the terminology used. We endorse the categorisation provided by Illari and Russo (2014), and summarised in Table 2, taken from their work.

**Table 2:** A recap of more terms used in the literature, where they apply and their purpose

<table>
<thead>
<tr>
<th>Population/Individual</th>
<th>Meaning</th>
<th>Example</th>
<th>Used by/context</th>
<th>Applies to</th>

<tbody>
<tr>
<td></td>
<td>Refers to a causal claim at either the population level or at the individual level</td>
<td>Smoking causes cancer/Bob’s smoking caused his cancer</td>
<td>Philosophical literature, probabilistic causality</td>
<td>Causal claim</td>
</tr>
</tbody>
</table>

| Type/Token | Refers to a causal relation between instantiated events | Smoking causes cancer/Bob’s smoking caused his cancer | Philosophical literature, probabilistic causality | Causal claim |

| Generic/Single-case | Refers to a causal relation that can be instantiated more than once or to an instantiated relation/Single-case causal relations can also be at the population level | Smoking causes cancer/Bob’s smoking caused his cancer/The financial crisis in 2008 caused recession in Europe | Link philosophical and scientific literature | Causal claim |

| Aggregate/Individual | Summary of characteristics of individuals comprising a group/Measure of individual characteristics, taking values of each of the lower units in the sample | Mean income of state residents/Income of each individual in the group | Scientific literature | Variable |

Source: Illari and Russo (2014: 43)

Biomarkers are identified using biosamples of real, particular patients, but their study in large data sets allows scientists to make inferences about the population, rather than single individuals. The change of the scale of measurement, the size of the sample and the way in which inferences from ‘-omics’ analyses are made allows us to make something of unprecedented novelty: to study individual-level processes in order to understand population-level phenomena.

In analogy to the study of biomarkers, we want to suggest studying sociomarkers. These sociomarkers will differ substantially from the widely used social indicators in that they allow us to trace social process at the individual level. Again, in analogy with biomarkers, we can then develop an ‘epidemiology’ of sociomarkers, and thus gain understanding of the social mechanisms that operate at the individual level, but within a group or population. By construction, the sociomarkers sought will be those likely to interact with the biochemical disease mechanisms. With sociomarkers we will be able to trace the onset and development of disease in its biological and social aspects. The equal epistemic relevance of bio- and sociomarkers will help us to reconstruct the mixed mechanism of health, while taking their ontological differences into account.
Knowledge of the development of sociomarkers, furthermore, can be used for early diagnosis and screening at the individual level, just as it happens for biomarkers.

The introduction of sociomarkers also contributes to avoiding the risk of reductionism in at least two senses. First, health and disease are not reduced to the biological realm; instead, social factors are active causes in disease aetiology. Second, while the study of sociomarkers at the individual level help eliciting the mixed mechanisms, health and disease are not confined to the individual level; instead, individual-level sociomarkers help understand how population-level social risks act.

Conclusion

The interaction between social and biological components of health has been at the heart of several studies in the last few decades. This paper identifies the following challenges, that we try to address constructively. First, the increased understanding of the biological factors involved in the mixed mechanisms of diseases formation has not been accompanied by an appropriate comprehension of the active role played by social factors. It follows that our mechanistic understanding is in general obtained only at the biological level, while the social level is still studied through correlations between population-level variables.

Second, concerning the biological components, our mechanistic understanding can be achieved at the individual level through the use of biomarkers. In contrast, social components are still studied at the population level.

Third, all these dimensions (individual/population and social/biological) are relevant for the purposes of policy interventions. Let us consider obesity: in order to develop an intervention, researchers ought to take into account population- and individual-level social factors, such as food availability, the presence or absence of walkable neighbourhoods, and the individual lifestyle and ideal concerning body size. Similarly, they might consider macro- and microbiological factors, such as the presence of environmental factors and molecular mechanisms underlying obesity.

This paper contributes to addressing these challenges by proposing to use social measures as sociomarkers. To describe what sociomarkers are, a parallel with biomarkers has been proposed. Both social and biological markers can be understood as ‘intersecting signals’ and can be related in different ways to the causal process under study. Furthermore, in both cases markers would help to trace causal processes at the individual level.

The combination of social and biological markers, in conclusion, would reveal how social factors can ‘get under the skin’, and would help researchers to move from causal claims at the population level to causal claims at the individual level.

Conflict of interest

The authors declare no potential conflicts of interest with respect to the research, authorship, and/or publication of this article.

Acknowledgments

We are deeply indebted to Paolo Vineis, Pietro Ghezzi and Oliver Robinson for comments that greatly improved the manuscript.
