ABSTRACT

Using the Very Long Baseline Array and the European Very Long Baseline Interferometry Network, we have made a precise measurement of the radio parallax of the black hole X-ray binary MAXI J1820+070, providing a model-independent distance to the source. Our parallax measurement of $(0.348 \pm 0.033)$ mas for MAXI J1820+070 translates to a distance of $(2.96 \pm 0.33)$ kpc. This distance implies that the source reached $(15 \pm 3)$ per cent of the Eddington luminosity at the peak of its outburst. Further, we use this distance to refine previous estimates of the jet inclination angle, jet velocity, and the mass of the black hole in MAXI J1820+070 to be $(63 \pm 3)^{\circ}$, $(0.89 \pm 0.09)c$, and $(9.2 \pm 1.3)M_\odot$, respectively.

Key words: astrometry – parallaxes – stars: black holes – radio continuum: transients – X-rays: binaries – high angular resolution.

1 INTRODUCTION

The distances to astronomical systems are essential quantities that allow us to draw a connection between observed and physical parameters (e.g. flux and luminosity, angular, and physical speeds). In particular, for black hole X-ray binaries (BHXBs) the relation between different accretion phases and Eddington luminosity fractions can then be studied (Maccarone 2003), and the systems can be accurately placed on the X-ray/radio luminosity plane (Gallo, Degenaar & van den Eijnden 2018) to probe jet/accretion coupling. With accurate distances, we can break the degeneracy between the inclination angles of radio jets and their speeds (Fender 2003).
A well-constrained inclination angle can also help in obtaining accurate mass estimates of the black hole (BH) from the mass function of the system (Cantrell et al. 2010). An accurate distance helps in obtaining a well-constrained three-dimensional space velocity and hence the potential kick velocity (PKV) distribution of the system (Atri et al. 2019), providing clues as to the BH formation mechanism (Nelemans, Tauris & van den Heuvel 1999).

Distances to BHXBs are often estimated by studying the optical/infrared spectra of the donor star (Jonker & Nelemans 2004). The proper motion of the receding and approaching jets can also be used to place an upper limit on the distance of the BHXBs (Mirabel & Rodríguez 1994). Lower limits on the distance can be estimated by measuring either the interstellar extinction (Zdziarski et al. 1998, 2004) or the velocities of H I absorption (e.g. Chauhan et al. 2019) towards the source. X-ray dust scattering halo has also been used to constrain the distance to some the BHXBs (e.g. Xiang et al. 2011). However, these methods are all model dependent, involving certain assumptions. The only model-independent method of distance determination is measuring a high-significance trigonometric parallax. However, given their typical distances (several kpc), such high-precision observations can only be carried out using Very Long Baseline Interferometry (VLBI) or by satellites like Gaia (Gaia Collaboration 2018; Gandhi et al. 2019). The Gaia’s capabilities to conduct high-precision astrometry of BHXBs in the Galactic plane can be limited due to high extinction and low optical brightness outside of outburst. Gaia also has a global zero-point offset in its parallax measurements, the magnitude of which is still under debate (Chan & Bovy 2019). Therefore, targeted VLBI astrometry campaigns on outbursting BHXBs remain crucial. Of the ∼60 BHXB candidates (Tetarenko et al. 2016), only V404 Cyg (Miller-Jones et al. 2009), Cyg X–1 (Reid et al. 2011; and low optical brightness outside of outburst.

of BHXBs in the Galactic plane can be limited due to high extinction

2 OBSERVATIONS AND DATA REDUCTION

We monitored MAXI J1820 (see Table 1) with the Very Long Baseline Array (VLBA), using both the Jet Acceleration and Collimation Probe of Transient X-ray Binaries (JACPOT-XRB) programme (e.g. Miller-Jones et al. 2012, 2019, proposal code BM467), and a long-running astrometry programme (e.g. Atri et al. 2019, proposal code BA130), supplemented with a targeted European VLBI Network (EVN) campaign (proposal code EA062). All observations used a combination of J1821+0549 (J1821 hereon) and J1813+065 (J1813 hereon) as the phase reference and astrometric check sources. The calibrator positions were taken from the Radio Fundamental catalogue (rfc2015a1). Our assumed positions (J2000) were RA = 18h21m27.305837, Dec = 05°49’10.65156 for J1821, and RA = 18h13m33.411619, Dec = 06°15’42.03366 for MAXI J1813. We imaged the calibrated data and determined the target position by fitting a point source in the image plane for every epoch.

2.1 VLBA campaigns

In the hard state at the start and end of an outburst, the radio jets are compact and ideal for astrometry. We took four epochs (2018 March, October, November, and December) of observations via the JACPOT-XRB program in which the first three epochs (proposal codes BM467A, BM467O, and BM467R) were observed at 15 GHz. These observations used J1813 (1.93’ away from MAXI J1820) as the phase calibrator (being brighter at 15 GHz), and cycled every ∼2 min between it and the target, observing the check source J1821 (1.39’ away from MAXI J1820) once every eight cycles. We observed geodetic blocks (Reid et al. 2009) for half an hour at the beginning and end of each observation to better model the troposphere. The data were correlated using DiFX (Deller et al. 2011) and standard calibration steps were followed using the Astronomical Image Processing System (AIPS 31DEC17; Greisen 2003). As the source faded in 2018 December, we took the final epoch in the more sensitive 5 GHz band with the observing scheme J1821–J1813–MAXI J1820.

We also observed under the astrometry program BA130 during its 2019 August reflare. We cycled through all these sources at 5 GHz for 1.5 h, and then at 15 GHz for 2.5 h, with geodetic blocks at the start and end of the observation. We followed standard calibration techniques within AIPS (31DEC17). MAXI J1820 was phase referenced separately to J1821 and J1813. Data from the Mauna kea dish were removed for the complete duration of BA130B due to very high dispersive delays that were calculated by the task TECOR.

2.2 Parallax campaign: EVN data

We were also approved to observe with the EVN at 5 GHz during the expected peaks of parallax offset in RA in the months of March and September, and in declination in the months of June and December. The source was observed in 2018 October, 2018 December, and 2019 March, but faded below the detection capability of the EVN before the scheduled 2019 June epoch. J1821 was chosen as the phase reference source due to its close proximity to MAXI J1820 and was observed every 4 min, with J1813 used as a check source. The data were reduced using AIPS (31DEC17). We used the bandpass, a

Table 1. Summary of the observations of MAXI J1820+070. The observing bandwidth was 32 MHz for both the VLBA and the EVN. We give the measured target positions for each epoch. When both J1813 and J1821 were observed as phase calibrators, we give target positions phase referenced to 1821. The error bars denote the statistical errors in the position measurement of the targets.

3 RESULTS AND ANALYSIS

3.1 A Bayesian approach for parallax fitting

To derive the proper motion (\(\mu_\alpha\cos\delta, \mu_\delta\)), parallax (\(\pi\)), and reference position (RA\(_0\), Dec\(_0\)) of MAXI J1820, we fit the position as a function of time (e.g. Loinard et al. 2007), with a reference date equivalent to the mid-point of the observing campaign (MJD 58474). To perform the fit, we adopted a Bayesian approach, using the PYMC3 python package (Salvatier, Wiecki & Fonnesbeck 2016) to implement a Hamilton Markov chain Monte Carlo (MCMC; Neal 2012) technique with a No-U-Turn Sampler (NUTS; Hoffman & Gelman 2011). The Gaia DR2 proper motion and parallax measurements were used as priors in the procedure. We had observations at 5 and 15 GHz and so fit for any potential core shift in the calibration peak emission from 5 to 15 GHz (\(\alpha_s, \delta_s\)) and used a flat prior from \(-1^\circ\) to \(1^\circ\) for both \(\alpha_s\) and \(\delta_s\). We checked for convergence in our MCMC using the Gelman–Rubin diagnostic (Gelman & Rubin 1992). The posterior distributions for all parameters are Gaussian, and the median and the 68 per cent confidence interval of each of the fitted parameters are given in Table 2. All error bars reported hereafter are at 68 per cent confidence, unless otherwise stated. The resulting fits to the sky motion are shown in Fig. 1.

3.2 Distance from parallax

Distances inferred by inverting low-significance parallax measurements suffer from Lutz–Kelker bias and can thus be underestimated (Lutz & Kelker 1973). Thus, the use of appropriate priors is essential to obtain meaningful distances (Bailer-Jones 2015; Astraatmadja &...
Bailer-Jones 2015) using the scaling length parameter $L$ for BHXBs from Gandhi et al. (2019) and find that unlike the Gaia DR2 distance posterior distribution (median of 4.4 ± 2.4 kpc; mode of 3.46 ± 1.06 kpc), our new distance measurement is unaffected by the chosen prior (see Fig. 2). This shows that the high significance of our parallax measurement has led to a model-independent distance to the source.

4 DISCUSSION

With our much improved distance measurement for MAXI J1820, we now consider the physical implications of our result.

4.1 Transition and peak outburst luminosities

The main outburst of MAXI J1820 was observed to have a peak X-ray flux of $(14 ± 1) \times 10^{-8} \text{erg cm}^{-2} \text{s}^{-1}$ in the 1–100 keV band (Shidatsu et al. 2019). A distance of 2.96 ± 0.33 kpc implies that the system only reached 0.15 ± 0.03 $L_{\text{Edd}}$ at the peak of its outburst, where $L_{\text{Edd}}$ is the Eddington luminosity for a 10 $M_\odot$ BH (see Section 4.3). The soft-to-hard state transition luminosity, from a flux of $(2.5 ± 0.4) \times 10^{-8} \text{erg cm}^{-2} \text{s}^{-1}$, implies that the system made this transition at 3 ± 1 per cent $L_{\text{Edd}}$, in agreement with the average luminosity fraction of 1.58 ± 0.93 per cent $L_{\text{Edd}}$ for BHXBs (Vahdat Motlagh, Kalemci & Maccarone 2019; Maccarone 2003). Thus, for MAXI J1820 the state transition luminosity provides a good distance indicator.

4.2 Jet parameters

Assuming intrinsic symmetry, the measured proper motions of corresponding approaching and receding jet ejecta along with a distance can be used to uniquely determine the jet speed and inclination angle between the jet and the line of sight (Mirabel & Rodríguez 1994; Fender et al. 1999), via $\beta \cos i = \frac{\mu_{\text{app}} - \mu_{\text{rec}}}{\mu_{\text{app}} + \mu_{\text{rec}}}$, $\tan i = \frac{\mu_{\text{app}} + \mu_{\text{rec}}}{2 \mu_{\text{app}} - \mu_{\text{rec}}}$, where $\beta$ is the velocity of the jet (normalized to the speed of light $c$), $\mu_{\text{app}}$ and $\mu_{\text{rec}}$ are the proper motions of the approaching and receding components of the jet, respectively, $i$ is the inclination angle of the jet to the line of sight, and $d$ is the distance to the system. Bright et al. (2020) measured the proper motions of corresponding jet ejecta event during the transition phase of MAXI J1820 $\mu_{\text{app}} = 77 ± 1$ mas d$^{-1}$, $\mu_{\text{rec}} = 33 ± 1$ mas d$^{-1}$. We use this with our distance constraint to estimate $\beta = 0.89 ± 0.09$ and $\theta = (63 ± 3)^\circ$.

**Figure 1.** Astrometry of MAXI J1820, as phase referenced to J1821 at 5 GHz. The blue circles and red squares are the positions measured by the VLBA and the EVN, respectively. All marked positions have been corrected for the frame shift due to different calibrators and frequencies. The errors bars denote the statistical and systematic errors added in quadrature. Left-hand panel: Motion in the plane of the sky relative to the fitted reference position, overlaid with the trajectory given by the best-fitting proper motion and parallax (black dashed line). Right-hand panel: Parallax signature of 0.348 (black dashed line) ± 0.033 (grey dashed lines) mas isolated by removing our best-fitting proper motion.

**Figure 2.** Distance posterior distributions of MAXI J1820, for both our new VLBI and the Gaia DR2 parallax measurement. The Gaia DR2 distance posterior has a higher median value for the Milky Way (MW) prior (5.1 ± 2.7 kpc) than for the exponentially decreasing volume density (EDVD) prior (4.4 ± 2.4 kpc), whereas our VLBI distance distribution (2.96 ± 0.33 kpc) is insensitive to the prior chosen.
4.3 Implications for BH mass

Torres et al. (2019) conducted optical spectroscopy on MAXI J1820 and reported a mass function of $f(M) = \frac{M_2}{(M_2 - M_1)^2} = 5.18 \pm 0.15 M_\odot$, where $f(M)$ is the mass function, $i$ is the inclination angle, and $M_1$ and $M_2$ are the masses of the BH and its companion, respectively. Assuming a mass ratio $q = M_2/M_1 = 0.12$, they constrained the inclination angle to be $69^\circ < i < 77^\circ$, and the BH mass to be $7-8 M_\odot$. Using our derived inclination angle of $(63 \pm 3)^\circ$, we re-calculated the BH mass to be $(9.2 \pm 1.3) M_\odot$. Torres et al. (2019) suggested that the value $q = 0.12$ needs confirmation, so we also calculated the mass of the BH for the full suggested range of $q (0.03-0.4)$ to be $(10 \pm 2) M_\odot$. We used this updated inclination angle ($i$) and distance ($D$) to estimate the inner disc radius in the high/soft state, $R_{\text{in}} = 77.9 \pm 1.0 D_{\text{type}} \cos(i)$ km (Shidatsu et al. 2019). Equating this to the innermost stable orbit of the BH, we suggest that the BH in MAXI J1820 is likely slowly spinning (Steiner, McClintock & Narayan 2013).

4.4 PKV

The velocity distribution of BHXBs at Galactic plane crossing has been used to determine the potential kick the system might have received at the birth of the BH (Atri et al. 2019), which is an indicator of the birth mechanism of the BH (Nelemans et al. 1999; Fragos et al. 2009; Janka 2017). A robust PKV distribution requires good constraints on the proper motion, systemic radial velocity, and the distance to the system. We used the parallax and proper motion measurement in this work, combined with the systemic radial velocity of $(-21.6 \pm 2.3) \text{ km s}^{-1}$ (Torres et al. 2019) to determine a PKV distribution with a median of 120 km s$^{-1}$, and 5th and 95th percentiles of 95 and 150 km s$^{-1}$, respectively. This velocity is higher than the typical velocity dispersion of stars in the Galaxy (50 km s$^{-1}$; Mignard 2000) and suggests that the system likely received a strong kick at birth, consistent with formation in a supernova explosion.

5 CONCLUSIONS

We report a precise VLBI parallax measurement of $(0.348 \pm 0.033) \text{mas}$ to the BHXB MAXI J1820. Using this parallax and a Bayesian prior, we inferred a distance of $(2.96 \pm 0.33) \text{kpc}$. We showed that MAXI J1820 reached $(15 \pm 3)$ per cent $L_{\text{Edd}}$ at the peak of its outburst. We constrained the jet inclination angle and velocity to be $(63 \pm 3)^\circ$ and $(0.89 \pm 0.09) c$, respectively. We also report an updated BH mass estimate of $(9.2 \pm 1.3) M_\odot$, and suggest the BH is slowly spinning and likely received a strong natal kick.

ACKNOWLEDGEMENTS

We would like to thank J. S. Bright for allowing us to use their work prior to publication that helped us uniquely solve for the jet parameters in Section 4.2.
